When considering the reported rates of radial nerve damage, one must reflect on the source of the clinical material. Studies that have advocated early exploration often have based their conclusions on a series of patients treated in referral centers where the percentage of complicated problems and failures from other treatment facilities is unusually high. Conversely, studies from major trauma centers, where a consecutive series of patients with humeral shaft fractures complicated by radial nerve palsy are studied, find that most regain radial nerve function and agree that nonoperative management is the treatment of choice.[17,19,150,175]

Foster and coworkers found nerve laceration or entrapment in 9 of 14 open humeral shaft fractures they treated operatively.[64] However, Kettelkamp and Alexander found *no* surgically correctable lesions in any of the 16 radial nerves they explored.[92] In addition, Sonneveld and colleagues explored 14 cases and found only one "injured" (i.e., contused and not divided) nerve,[181] and Dabezies and coworkers encountered only one lacerated nerve in 15 patients.[56] No nerves were entrapped, and all intact nerves recovered.

The proximal spike of the Holstein-Lewis spiral fracture of the distal humerus may injure the radial nerve as it occurs within the area where the nerve is closely apposed to the bone and tethered by the lateral intermuscular septum.[78] Holstein and Lewis advised early operative intervention for patients with this fracture and an accompanying radial nerve palsy[78]; however, others have reported that early operative treatment is unnecessary, including Szalay and Rockwood.[188] They studied 15 patients with this combination of injuries and all 11 who were treated without exploration attained complete nerve recovery. The nerve was found to be in continuity in the 4 patients in whom exploration was carried out, and all regained normal radial nerve function.[188]

It used to be believed that a secondary radial nerve palsy (not present initially and present after fracture reduction) was an absolute indication for immediate nerve exploration. However, there is convincing evidence today that secondary radial nerve paralysis can be treated nonoperatively with a good expectation for full recovery in most cases.[19,175]

Nerve Exploration for Failure to Improve Spontaneously

Exploration of the radial nerve at 6 to 8 weeks after onset, if there is no evidence of recovery, had been advocated in the past, but Mast et al reported that less than half of the nerves that recovered spontaneously did so in less than 12 weeks.[113] Amillo and associates recommended surgical exploration at 3 months if there was no clinical or electrophysiologic signs of nerve recovery.[7] However, it is well documented that the initial signs of motor recovery may not appear until 4 or 5 months after a radial nerve palsy associated with a fractured humerus.

The work of Seddon regarding nerve regeneration after axonotmesis suggests nerve-fiber regeneration occurs at the rate of approximately 1 mm/day following a latent period of 30 days.[173] On this basis the maximum length of time that may be required for the first signs of motor recovery to occur can be estimated by measuring the distance on the radiograph from the fracture site to the point of innervation of the BR muscle,

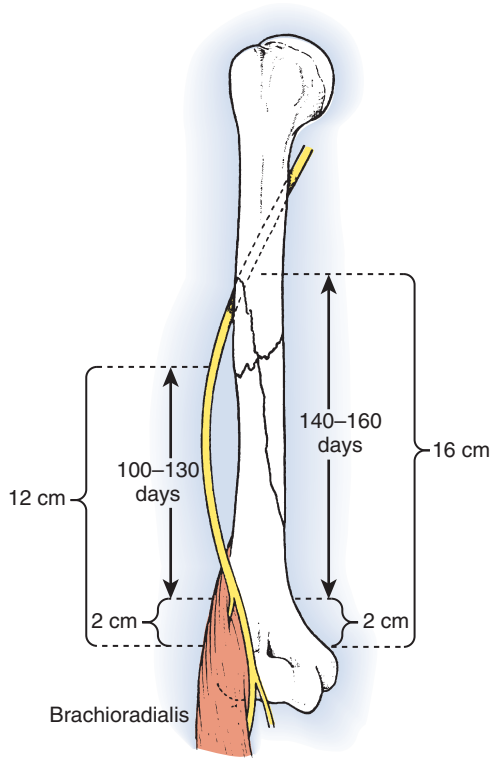

FIGURE 31.44 Calculation of time that must elapse before signs of recovery can be expected after fractures of the shaft of the humerus that cause axonotmesis of the radial nerve. The information on the left is for a transverse fracture, and the information on the right is for an oblique fracture. (From Seddon H: *Surgical disorders of the peripheral nerves*, ed 2, Edinburgh, 1975, Churchill Livingstone, with permission.)

which is approximately 2 cm above the lateral epicondyle. In most midshaft humerus fractures, this distance is 90 to 120 mm (Figure 31.44), indicating regeneration times of between 17 and 21 weeks.

Evidence of reinnervation on electromyography may precede the clinical appearance of motor function by approximately 4 weeks.[151] Therefore, if the decision is to treat the fracture nonoperatively, it is logical to wait 4 to 5 months before proceeding with exploration if there is no return of nerve function. The major advantages of this plan of management are: (1) unnecessary operative intervention is avoided in most patients, (2) most of these patients achieve full recovery of the radial nerve without surgical treatment, and (3) the humerus fracture usually heals.

A question that must be raised is whether the delay in nerve repair for the very few patients in whom neurorrhaphy becomes necessary is excessive and reduces the chance for good functional recovery. Historically, delays of 12 months or longer were not considered likely to jeopardize functional motor return after nerve repair, but this view has been challenged recently.

In the past most humeral shaft fractures were treated nonoperatively, but operative fixation is preferred now for a significant number of these injuries. It the surgeon feels that the fracture characteristics make operative fixation preferable, then the nonfunctioning radial nerve should be explored at the same time. In addition, there is currently the dilemma on how to manage a radial nerve palsy, which develops after operative fixation of a shaft's fracture of the humerus, using an operative field that puts the radial nerve at risk of damage from a retractor, scalpel blade, power drill, tap, or plate. The decision here will depend on many factors, including (1) the expertise of the surgeon who performed the fracture fixation, (2) the operation notes, (3) recollections (if any) of the condition of the radial nerve at the end of the surgery, (4) whether the radial nerve was seen during the procedure, and (5) patient preference for expectant treatment or reoperation.

A recent systematic review reported the overall prevalence of radial nerve palsy as a complication of fractures of the shaft of the humerus to be 12%.[176] Of the patients initially treated, 88% of 581, of which 149 underwent an exploration at least 8 weeks after injury, recovered. Of those treated with early exploration, 85% recovered. The time until onset of recovery ranged from 2 to 28 weeks (mean recovery time = 7 weeks), and the recovery rates were similar for primary and secondary (i.e., after reduction of fracture) palsies.

Overall, 397 radial nerves were explored at some time after fracture. The nerve was intact or contused in 46%, trapped within the fracture in 13%, and divided in 23%. It is obvious that the rate of nerve division does not represent the overall division rate because many of the injuries had been treated expectantly initially, and those explored later represented the subset in which the radial nerve had not recovered. Those who recovered spontaneously with expectant treatment are excluded and by definition had an intact nerve.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

My policy is to advise expectant treatment to most patients with radial nerve palsy associated with humeral shaft fractures that have been managed nonoperatively. I only consider exploration of the nerve after a realistic waiting period, estimated on the basis of Seddon's work (see Figure 31.44). If, however, the fracture requires plate fixation, the radial nerve should be identified and examined during the procedure. My biggest dilemma is the patient who presents with a radial nerve palsy after plate fixation of the humerus. In this scenario I review the operation notes to see whether the radial nerve was identified and protected throughout the procedure and also discuss the procedure with the surgeon who fixed the fracture.

This helps a surgeon estimate the likelihood of the nerve being intact and capable of spontaneous recovery with axonotmesis, or divided/crushed (by a plate) with no prospect of recovery. I then discuss the options of immediate reexploration, or expectant treatment for at least 12 weeks, with the patient and together we devise an agreed-on treatment plan that suits the patient's circumstances and psyche and reflects his or her preferences.

I agree with David Green that it is illogical to explore the radial nerve at 6 to 12 weeks. If the decision has been made to await spontaneous recovery of function, then sufficient time must be allowed and <12 weeks is insufficient.

Nerve Transfer as an Alternative to Tendon Transfer

Direct transfer of functioning, intact nerves to denervated muscles (neurotization) is used to restore function in patients with brachial plexus palsy when no other option is available. The same concept has been reported in a few cases to restore wrist, finger, and thumb extension in radial nerve palsy[107]; forearm pronation after median nerve palsy[79]; and finger intrinsic

muscle function after high ulnar nerve palsy.[131] The technique is based on one of the principles of tendon transfer: that the loss of the normal function of the muscle(s) used for harvest of the donor nerve(s) is not critical, and that its loss can be accommodated by other functioning musculotendinous units. Neurotization is not an option if: (1) the paralyzed musculotendinous unit with a function that is to be restored was damaged in the injury that caused the nerve palsy; (2) the musculotendinous unit is tethered by scar tissue; and (3) a prolonged time interval between nerve injury and neurotization has resulted in the inability of the recipient muscle to function after reinnervation.[197] The potential benefits of neurotization over tendon transfers are that it avoids the needs for prolonged splintage to protect transfers or multiple skin scars to fashion the musculotendinous transfers. However, the recovery of function is protracted in comparison to tendon transfer.

Restoration of Radial Nerve Function

Restoration of function is achieved by exposing: (1) the median nerve and its branches for FDS and FCR/PL; (2) the radial nerve and its branch to the ECRB and; (3) the posterior interosseous nerve. The FDS branch is neurotized to the nerve to ECRB, and the FCR/PL branch to the posterior interosseous nerve.[107]

Technique. Through a single volar-radial incision in the proximal forearm, the radial nerve, the posterior interosseous nerve, and the median nerve are exposed. The "donor" median nerve branches to the FDS, FCR, and PL visually and is confirmed with a nerve stimulator. The "recipient" radial nerve branch to the ECRB, and the posterior interosseous nerve, are also identified. The donor nerves are transected as distally as possible and the recipient nerves are transected as close to their muscle insertions as feasible, while allowing tension-free coaptation.

Outcome. Restoration of virtual full extension of the wrist and fingers with grade 4 power was reported in a single case, with the first evidence of reinnervation occurring at 6 months.[107] Restoration of median nerve extrinsic muscle function can be achieved by neurotization of: (1) the branches of the radial nerve to ECRB to the branch of the median nerve to pronator teres, and (2) the branch of the radial nerve to supinator to the anterior interosseous nerve. Reinnervation of PT commenced after 4 months and FPL and index FDP at 8 months. After 18 months, grade 4 strength was achieved.[79]

Spasticity
Cerebral Palsy and Traumatic Brain Injury

Scott H. Kozin and Nina Lightdale-Miric

Acknowledgment: The authors wish to acknowledge and thank Dr. Michele Gerwin Carlson. Her efforts in the previous edition of this text provided the foundation for this chapter.

Cerebral palsy and traumatic brain injury are upper motor neuron central nervous system diseases that result in decreased function, muscle imbalances, and deformity of the upper limb. Cerebral palsy, the most common childhood motor disability, results from brain injury occurring in a fetus or infant in the perinatal period (in utero, during birth, or in infancy) or in a premature infant in whom the brain is still developing. Traumatic brain injury is secondary to intracranial masses, sequelae following surgery to treat brain lesions, infection, vascular insult, or head trauma.

CEREBRAL PALSY

The incidence of cerebral palsy is approximately 2 to 4 per 1000 live births. The condition is considerably more prevalent in premature infants with a very low birth weight (<3.3 pounds). The development of neonatal intensive care, and the resulting increased rates of survival of these infants, may have led to a rise in incidence of cerebral palsy.[174] Typically thought of as an anoxic brain injury during birth, perinatal asphyxia describes a small percentage of cases. Neonatal encephalopathy, exposure to teratogens, genetic abnormalities, brain malformations, multiple births, intracranial hemorrhage, prematurity, metabolic diseases (jaundice and kernicterus), and infection have been identified as more common etiologic factors leading to the brain injury.

The classification of cerebral palsy is based on the location of the injury in the brain, number of involved extremities, level of spasticity, presence of associated movement disorders, and level of functional use. Some texts distinguish between congenital and acquired cerebral palsy based on age of onset. Spasticity, or hypertonicity, results from dysregulated reflex-arc messaging from the upper motor neurons of the medullary pyramid to the motor end plates of the limb musculature. The increased tone may be phasic or continuous and eventually results in myostatic contractures. Concomitant extrapyramidal involvement causing additional movement disorders such as dystonia, athetosis, ataxia, and flaccidity may also be present. Spastic involvement of one muscle is often coupled with flaccid involvement of its antagonist. Variable tone and muscle imbalance across limb segments result in abnormal upper limb position and function. Sensation and reflex feedback pathways are also invariably disrupted.

Cerebral palsy is considered an irreversible and nonprogressive brain injury. However, progressive muscular fibrosis, joint contracture, limb length differences, osteopenia, and atrophy occur over time. Spastic deformities in the upper extremity most often result in shoulder internal rotation, elbow flexion, forearm pronation, wrist flexion, finger flexion, intrinsic spasticity, and thumb-in-palm deformity. The age of the child at the time of the brain injury, as well as the extent and location of the cerebral involvement, is predictive of motor, sensory, and seizure involvement, as well as the child's ultimate intelligence, coordination, and prognosis.[82,180]

TRAUMATIC BRAIN INJURY

Traumatic brain injury is a leading cause of disability and death in the United States.[12,55,69,87,91] An estimated 1.5 million Americans sustain a traumatic brain injury annually, and about 50,000 of these people die.[3,110] Brain tumors and vascular malformations, sequelae from the surgical removal of such tumors or malformations, and infection are less common causes of traumatic brain injury. Approximately one third of traumatic brain injury survivors still require assistance with activities of daily living 1 year following injury. Most traumatic brain injuries occur in individuals who are younger (<45 years old), and those who survive have a normal life span.[55] The enormous lifetime costs of traumatic brain injury were estimated to be $56 billion in the United States in 1995.[3,110]

In traumatic accidents, falls, and abuse cases, the Glasgow Outcome Scale is frequently used to predict the outcome after brain injury.[95] Patients with lower scores have a substantially higher incidence of severe sequelae. Age and duration of coma are also important determinants of neurologic outcome after brain injury, regardless of its severity.[172] Brainstem involvement, as indicated by the presence of decerebrate or decorticate posturing, has a poor prognosis. Heterotopic ossification can be a complication of traumatic brain injury.[47]

When neurologic recovery has been optimized, the brain-injured patient often has residual limb deformities, including spasticity, movement disorders, contracture, and muscle imbalance similar but not equivalent to cerebral palsy. Surgical procedures for limb deformity and dysfunction can be performed after the patient plateaus in therapy-assisted recovery. Surgery can rebalance the remaining abnormal muscle forces, correct the residual deformities, and prevent joint contractures.[142]

TREATMENT CONSIDERATIONS

Treatment of the upper limb in children and adults with cerebral palsy and traumatic brain injury includes surgical procedures and pharmacologic and other nonsurgical therapeutic modalities. A multidisciplinary team is necessary to manage all elements of their care. Cooperative efforts of a caregiver team and the cumulative treatment of surgeons, neurologists, and therapists result in the best outcomes. All treatment options share the goals of increasing functional use, including communication and independence with daily living, decreasing pain, managing spasticity, and prevention and correction of deformity, as well as improving hygiene or self-confidence with limb repositioning. Importantly, patients with dystonia, athetosis, poor voluntary control, and limited sensory function may be made worse by surgical intervention. However, the focus of this chapter is surgical decision making and surgical technique.

Goldner and colleagues estimated that less than 20% of children with cerebral palsy and less than 30% of children with traumatic brain injury are potential candidates for surgical procedures of the upper extremity.[57,98] Surgery of the upper extremity in cerebral palsy is reparative and often palliative but not curative.[33,126] Historically, only 50% of operations of the upper extremity are performed to achieve functional improvement. Treatment aimed at improving function of the upper extremity cannot restore normal limb function. Appearance concerns and hygiene are other major factors that influence treatment.[27,28,113]

Surgery should address the entire extremity when formulating a plan. When possible, elbow, wrist, and finger flexion deformities should be corrected at the same setting (Figure 32.1). This may lead to a lengthy surgery, and the surgical team should prepare for and discuss the order of each individual component in order to maximize the limited tourniquet time and minimize the anesthesia time. Correction of the elbow deformity without correction of the wrist deformity or correction of the wrist deformity without correction of the finger deformity can decrease overall function and have distressing outcomes. Studies have shown improved use of the arm in functional activities and better incorporation into daily life after well-timed and well-planned upper extremity surgery has been performed.[20,188] A detailed evaluation combined with appropriate patient selection and careful decision making will reliably provide positive treatment outcomes.[101,201]

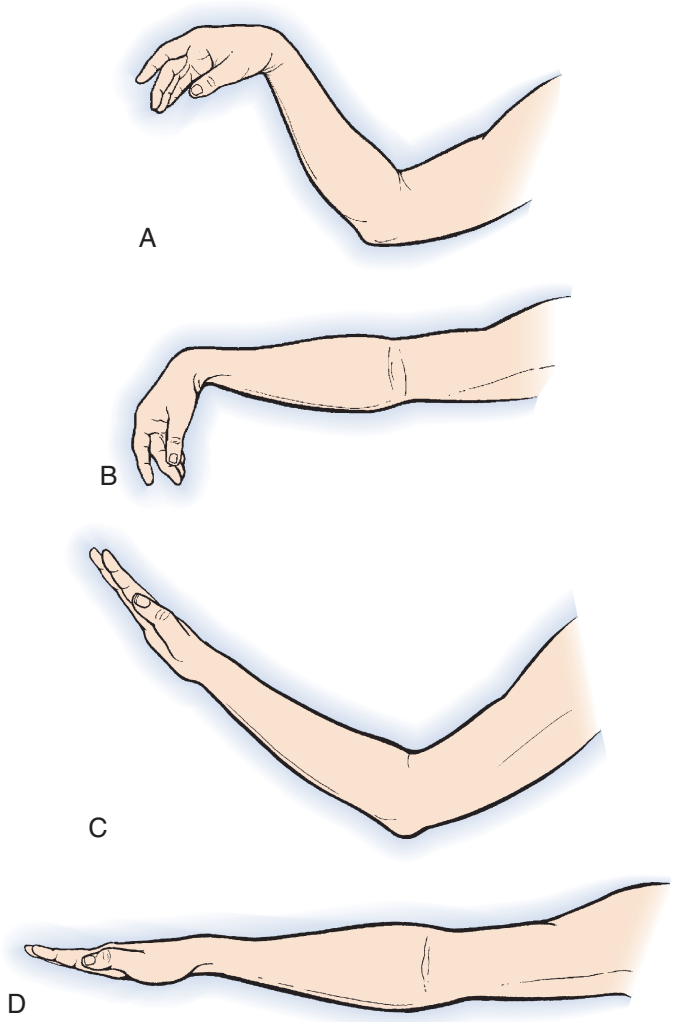

FIGURE 32.1 Concurrent correction of elbow and wrist flexion deformities is important to improve limb function. **A,** Wrist and elbow flexion deformity. **B,** Correction of the elbow alone leaves the wrist flexed. **C,** Correction of the wrist alone does not improve the patient's ability to position the hand in space. **D,** Correction of the wrist and elbow places the hand in a neutral position with maximal reach.

Evaluation

A careful and thorough examination of each patient is mandatory. The evaluation should include the patient's underlying disease, developmental stage, intellectual aptitude, motor function, and sensibility. The patient's ability to access therapy and support resources is equally important. An inventory of the patient's provider team is required (e.g., parents, caregiver, pediatrician, neurologist, occupational therapist, physical therapist, social worker). Surgical results will not be optimized unless the patient is able to obtain therapy, maintain hygiene, and obtain accommodations at home and in school. In addition, an essential component of the evaluation is to exclude other treatable diagnoses for cerebral dysfunction and to determine if the disorder is progressive. Multiple visits and examinations are required to accurately appreciate the extent of a movement disorder and to fully determine all the prognostic factors.

Evaluation of a patient with spasticity must include an accurate assessment and a documented list of treatment expectations. Asking the patient and/or caregiver what they expect to achieve is mandatory to avoid unrealistic hopes. The Canadian Occupational Performance Measure (COPM)[111] and Goal Attainment Scaling[13] are unlike other standardized patient-reported outcome instruments due to the individualized approach used to establish goals. The COPM capitalizes on a semistructured interview that reflects the usual interaction

between an occupational therapist, who approaches practice from a client-centered framework, and his or her client. Through this interview, parents and children identify performance activities that are perceived as important by the parent, child, and/or society; performance is rated on a scale between 0 (cannot do) and 10 (can do very well), and the activities are used to establish goals for treatment. Scores between baseline and reassessment are calculated to evaluate outcomes of treatment. Although individuals may differ in their ideas of what constitutes successful outcomes, research suggests that a change of two or more points reflects meaningful change.

It is important to identify patients who have little voluntary control, marked dystonia, or limited sensibility because these individuals will obtain limited functional benefit from surgical intervention. A simple interview of the patient (and the parent or caregivers) can elicit the activities that the patient can and cannot perform with the spastic extremity, but other procedures are also valuable in individualizing treatment, such as prognostic testing, including functional scores, video analysis, electromyography, and imaging studies.[202] Carlson and associates found that reviewing the videotape compared to the office visit examination will change the operative plan in 75% of patients.[22]

Evaluation is particularly challenging in nonverbal patients, families with language barriers, and young patients. In cerebral palsy, upper limb dysfunction is usually noted by 1 year of age, as the infant fails to obtain normal developmental milestones, such as crawling, pulling to stand, passing objects from hand to hand, or a developing oppositional pinch.[45] Infants may develop a more primitive key pinch (thumb to side of index finger) versus oppositional pinch.[46] Maintenance of primitive reflexes also reflects a central nervous system disease process.

Physical Examination

Physical examination of the spastic upper extremity is challenging and requires experience, a relaxed clinical atmosphere, multiple office visits, and a team approach. Recognition of contraindications to surgery and predictors of poor outcome via the physical examination directs treatment decision making. Despite their best intentions, patients often have difficulty cooperating during the examination. Asking patients to perform activities with both extremities can ensure that they comprehend instructions, even if they can only perform the task with one. Each extremity should be evaluated separately and any mirror movements noted. Although spastic deformities in the upper extremity most often result in shoulder internal rotation, elbow flexion, forearm pronation, wrist flexion, finger flexion, intrinsic spasticity, and thumb-in-palm deformity (Figure 32.2), many variations exist.

The examination must accomplish several tasks that serve as clinical guidelines. The surgeon's examination begins with casual conversation, such as asking the patient his or her age and assessing caregivers. The resting position of the limbs should be noted. Ask the patient and/or caregivers exactly why they are seeing a surgeon and identify treatment goals. If age and intelligence are appropriate, ask the child to perform active movements such as hands over the head, hands from knee to mouth, elbow flexion and extension, supination and pronation, open and closing of the hands, and clapping. Passive range of

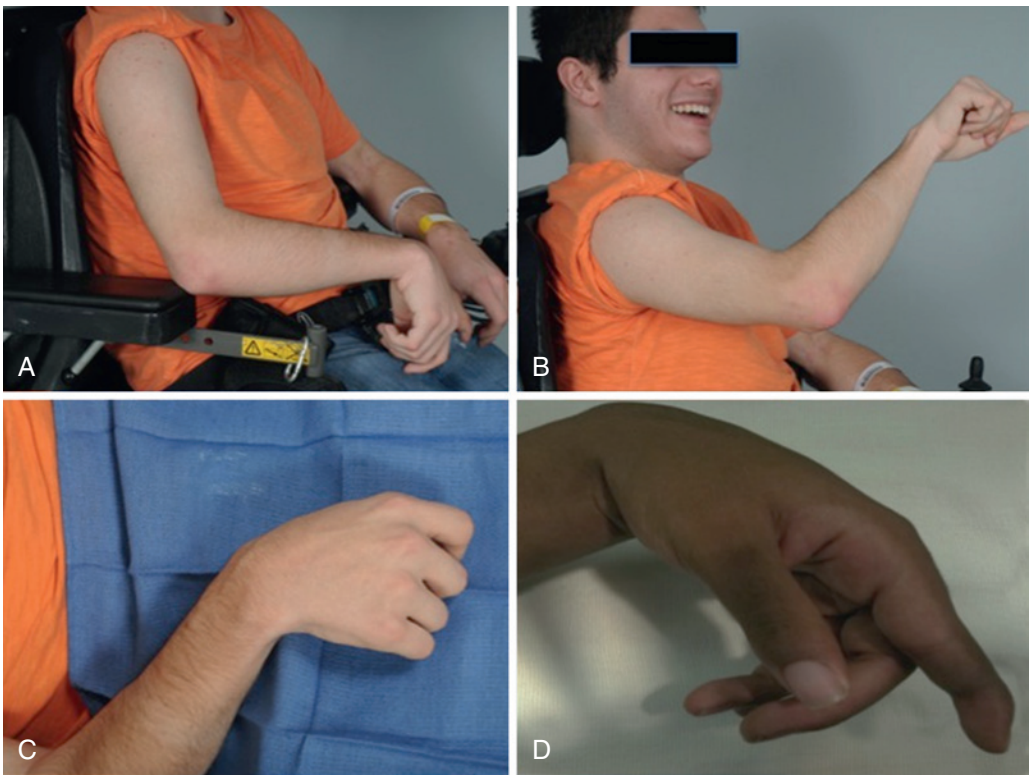

FIGURE 32.2 Spastic posturing in the upper extremity. **A** and **B,** Shoulder internal rotation, elbow flexion, forearm pronation, and thumb in palm and fist with active wrist extension. **C** and **D,** Wrist flexion and ulnar deviation with finger swan neck deformities. (Courtesy of Shriners Hospital, Philadelphia, and Children's Hospital, Los Angeles.)

motion of all joints is then measured. The muscle strength of all involved and the potential donor muscles for transfer are measured. Hyperreflexia and clonus are noted. Patterned hand function, as well as muscle spasticity and contracture, are identified. Spasticity must be distinguished from muscle and/or joint contracture.[155,211] When relaxed, patients with muscle spasticity demonstrate full passive range of motion of an affected joint, whereas in those with muscle or joint contracture the passive movement remains limited. Muscle contracture and joint contracture often coexist in older or skeletally mature patients; joint contracture is less common in younger children. Muscle spasticity can be overcome by applying gentle sustained resistance to the spastic force. Several grading systems for spasticity exist, such as the Modified Tardieu Scale[181] and Modified Ashworth Scale[10] (Table 32.1). Inspection for potential hygiene problems should include the axilla, antecubital fossa, volar wrist flexion crease, palm, and interdigital spaces.

Spasticity is classically classified by the number of limbs involved: monoplegia (one extremity), hemiplegia (one arm, one leg), diplegia (two legs), triplegia (two legs, one arm), and quadriplegia (all four extremities). Motor function is also classified as spastic, flaccid, and athetoid[211] (Video 32.1). Many patients have a combination of movement patterns. Spastic involvement of a muscle is often coupled with flaccid involvement of its antagonist, potentiating the deformity from imbalance. The surgeon should observe the patient for underlying movement disorders, especially dystonia. *Dystonia* is defined as "involuntary sustained or intermittent muscle contractions causing twisting and repetitive movements, abnormal postures or both."[158] Hypotonic, hypertonic, hyperkinetic, and mixed tone movement disorders should also be noted and are known to correlate with poorer surgical outcomes.

In addition to motor assessment, intellectual capacity and sensory function also correlate with severity and surgical outcomes in children with cerebral palsy and traumatic brain injury. In the cooperative child, stereognosis is easily tested with two or three simple objects such as a coin, poker chip, paperclip, or key in each hand.[96] The hand position and function may alter one's ability to perform sensory testing.[11,25,192,210] The child's intellectual or cognitive impairments are harder to assess in an office visit; asking the child to follow voluntary commands or perform tasks such as placing the hand to the mouth and noting the child's school level or integration into a normal or specialized classroom are ways of establishing a baseline.

A standardized task performance evaluation can assist in quantifying the severity of impairment and in identifying patterns of hand function. The House Classification and the Manual Ability Classification System describe how children with cerebral palsy use their hands to handle objects in daily activities and reflect the child's typical performance[66] (Tables 32.2 and 32.3). Videotaping or functionally evaluating the patient performing routine activities or using scored functional tests (e.g., Jebsen-Taylor hand function test, box and blocks test, pegboard test) may be helpful, although the child may perform well for the surgeon but use different functions at home or when unobserved. Other validated evaluation tools, including the Modified (Modified) Ashworth Scale, Modified Tardieu Scale, Melbourne Assessment of Unilateral Upper Limb

TABLE 32.1 Modified Tardieu Scale and Modified Modified Ashworth Scale

Grade	Modified Tardieu Scale	Modified Modified Ashworth Scale
0	No resistance to passive ROM	No increase in muscle tone with passive ROM
1	Slight resistance with no clear catch	Slight increase in tone; catch and release or minimal resistance with ROM
2	Clear catch at precise angle, halting passive ROM, followed by release	Marked increase in muscle tone, catch in middle range, and resistance through remainder of ROM, still easily moved
3	Fatigable clonus (<10 seconds with resistance) occurring at precise angle	Considerable increase in muscle tone, passive movement is difficult
4	Infatiguable clonus (>10 seconds)	Rigid in flexion or extension

ROM, Range of motion.

TABLE 32.2 Manual Ability Classification System (MACS) of Hand Function

Level	Description
I	Handles objects easily and successfully
II	Handles most objects but with somewhat reduced quality and/or speed of achievement
III	Handles objects with difficulty; needs help to prepare and/or modify activities
IV	Handles a limited selection of easily managed objects in adapted situations
V	Does not handle objects and has severely limited ability to perform even simple actions

TABLE 32.3 House Classification of Hand Function

Score	Designation	Activity Level
0	Does not use	Does not use
1	Poor passive assist	Uses as stabilizing weight only
2	Fair passive assist	Can hold onto object placed in hand
3	Good passive assist	Can hold object and stabilize for use by other hand
4	Poor active assist	Can actively grasp object and hold it weakly
5	Fair active assist	Can actively grasp object and stabilize it well
6	Good active assist	Can actively grasp object, stabilize it well, and manipulate it against other hand
7	Spontaneous use, partial	Can perform bimanual activities easily; occasionally uses hand spontaneously
8	Spontaneous use, complete	Uses hand completely independently, without reference to other hand

Function, Quality of Upper Extremity Skills Test, Shriners Hospital Upper Extremity Evaluation, and Assisting Hand Assessment, can grade upper extremity disability and guide treatment.[10,38,68,88,104,144,198] Many other instruments have been designed to quantify parent and child self-assessment of upper extremity function in children with cerebral palsy.[14] The correlation of three-dimensional motion analysis is still being studied as a prognostic and classification tool.

Physical Examination Key Points and Clinical Guidelines

Shoulder. The most common position of rest of the shoulder in a patient with spasticity is internal rotation. Internal rotation and adduction posturing of the shoulder is caused mainly by spasticity and/or contracture of the subscapularis and pectoralis major muscles. The latissimus dorsi and teres major muscles can also contribute. Over time, glenohumeral dysplasia, capsular contracture, and thickening of the surrounding fascia add to the deformity. Less frequently, a severe external rotation and abduction posture of the shoulder occurs secondary to spasticity or contracture of the rotator cuff muscles (Figure 32.3). The physician must determine whether the limitations in shoulder motion interfere with the patient's ability to position the hand in space for function.

Elbow. The physician may observe dynamic elbow position when the patient is walking, running, and performing activities with the contralateral extremity.[147] The predominant elbow spastic deformity is flexion. The initial cause is related to spasticity or contracture of any or all of the elbow flexors (biceps, brachialis, brachioradialis). Long-standing deformities can also result in soft tissue and joint contractures. The severity of the flexion deformity is variable. Some patients have only dynamic posturing (involuntary flexion with walking or effort) or a smidge of elbow contracture. Other patients have severe hyperflexion with antecubital skin breakdown and intertriginous infections.

Traditionally, an elbow flexion contracture was considered mostly an aesthetic or hygienic problem[77]; however, even mild dynamic posturing or contracture can be problematic for the patient and family. Appearance is an important factor, especially for hemiplegic patients, and correction is commonly requested. In contrast, a substantial flexion deformity interferes with activities of daily living and leads to skin breakdown in the antecubital fossa. Lessening a severe contracture can allow a patient to use the forearms to assist in wheelchair transfers, touch a picture board or use technology to communicate, reach the tray top of a wheelchair, or touch a wider sphere of objects in his or her environment (increase in workable reach space). In less severe flexion deformities, release of the contracture can allow for the use of crutches or walkers, facilitate two-handed manipulation of objects away from the body, and increase independence with activities of daily living.

FIGURE 32.3 External rotation and abduction posturing of the shoulder is rare and significantly limits function. (Copyright © Michelle Gerwin Carlson.)

Forearm. Pronation positioning of the forearm is mainly caused by spasticity of the pronator teres. The position is initially passively correctable; however, a fixed deformity occurs over time secondary to contracture of the interosseous membrane or disruption of the radioulnar joint(s). Pronation deformity may interfere with bimanual use of the extremity in two-handed manipulation of objects (e.g., carrying a tray). With a pronation contracture, the palms cannot face each other and the manipulation of small objects between the hands is also difficult. With severe spasticity, patients are forced to assume a reverse grasp posture, using the ulnar aspect of the hand to grasp objects, because they are unable to present the radial aspect of the hand.[119] Internal rotation contracture of the shoulder exacerbates the pronation deformity as the shoulder is unable to compensate. Rarely, radial head dislocation (in 2% of patients)[1] or distal radioulnar joint dislocation may occur and further limit the passive range of motion of the forearm.

Palpate the pronator teres during passive supination of the forearm to identify spasticity. Evaluate active supination, pronation, and the position of the forearm at rest. Examine the distal and proximal radioulnar joint for dislocation, subluxation, or instability. Palpate for the radial head in supination and pronation and determine radial head alignment. During task performance, determine if forearm rotation is adequate for workspace, midline, and overall task performance.

Wrist and Digits. The wrist often assumes a flexed posture. There are several potential causes, including weak wrist extensors, tight or spastic wrist flexors, and volar wrist capsular contracture. The flexed attitude of the wrist causes several functional problems. Wrist flexion weakens grip secondary to the decreased mechanical advantage of the digital flexors and shift of the length-tension curve. Severe contractures can lead to hygiene issues.

Observation of wrist position during hand use is critical to assess object acquisition and release. The physician can also determine patterns of usage and assess spastic muscles. For example, if the wrist deviates in an ulnar direction with flexion, spasticity of the flexor carpi ulnaris (FCU) is likely. Circumduction during attempted wrist extension implies that the patient is using the extensor carpi ulnaris (ECU) to augment wrist extension. Passive wrist motion should be measured and recorded. Incomplete passive extension implies contracture of the wrist flexors or even the radiocarpal joint. The muscles about the wrist should be palpated during active movement. An assessment of spastic muscles and/or those muscles firing excessively should be determined. For example, firing of the FCU or the flexor carpi radialis (FCR) during digital opening implies spasticity or an exaggerated response to facilitate digital opening.

The Volkmann angle is commonly used to assess digital flexor tendon tightness as it might be used in a patient with

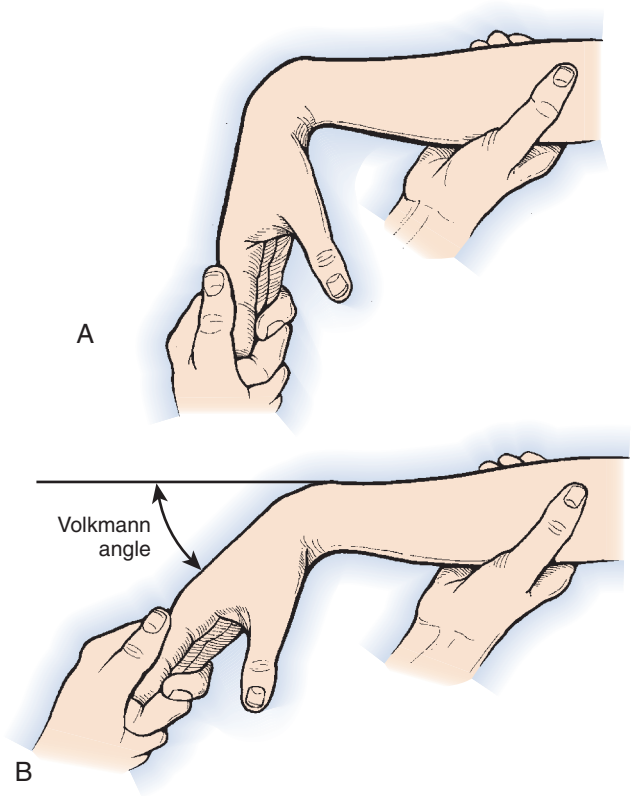

FIGURE 32.4 Volkmann test for digital flexor tendon tightness. **A,** The digits are held extended with the wrist flexed. **B,** The wrist is extended with the digits extended. With no flexor tendon tightness, full extension of the wrist should be possible. Wrist extension to less than neutral (Volkmann angle) indicates the need for surgical intervention.

compartment syndrome (Figure 32.4). The angle is measured with the wrist flexed and the digits held completely extended; the wrist is passively brought into maximal extension.[175] In the absence of flexor tendon tightness, composite full wrist extension and finger extension can be achieved. With digital flexor contracture, the wrist cannot be extended to neutral without flexion of the digits. Subsequently, one can assess whether the flexor digitorum superficialis (FDS) or flexor digitorum profundus (FDP) is spastic by holding the wrist in extension while passively extending the digits. When passive proximal interphalangeal (PIP) joint extension is limited, FDS spasticity should be suspected (FDP spasticity may also be present). If the PIP joints have full passive extension but the distal interphalangeal (DIP) joints remain flexed, FDP spasticity should be suspected.

Evaluate a patient's grasp and release ability with the wrist flexed and extended (Video 32.2). Poor grasp is often secondary to weak or absent wrist extension, because a flexed wrist slackens the digital flexor muscles and minimizes the potential for force production. Inability to extend the wrist may be caused by weak or absent wrist extensors or by spastic wrist flexors. The strength of grasp can be improved with a tendon transfer to increase wrist extensor power. Poor release is the result of weak or absent digital extensors. Patients with impaired release are unable to actively extend the digits or are only able to extend the digits when the wrist is flexed. When the wrist is passively held in extension, active digital extension is impossible. An isolated transfer to improve wrist extension in this case is contraindicated as the patient will be unable to extend the digits for object acquisition. The physician could consider a series of tendon transfers to augment wrist and digital extension.

Intrinsic muscle tightness leads to a resting position of metacarpophalangeal (MP) joint flexion and interphalangeal (IP) joint extension. When a patient with intrinsic tightness attempts digital extension, the MP joints periodically flex. If a patient is a candidate for digital flexor tendon lengthening, the intrinsic muscles must be carefully examined. If the intrinsics are spastic, release of the digital flexors without release of the intrinsics will result in a hand with flexed MP joints and extended PIP joints. Intrinsic tightness is best evaluated by the Bunnell test, which is performed by passive flexion of the PIP joints while the MP joints are held sequentially in full extension and in flexion. When fixed intrinsic tightness is present, passive motion of the PIP joint is greater with the MP joints flexed than when extended. This test should be performed in wrist flexion because if the digital flexors are tight, they can overpower the intrinsic muscles. If swan neck deformities of the PIP joints are present, they should be evaluated for cause and flexibility. Extrinsic extensor tendon over pull or intrinsic muscle spasticity can yield swan neck deformities. Local anesthetic block of the ulnar nerve at the wrist can be an effective way to demonstrate (both to the surgeon and the patient) the effect of intrinsic muscle release. Ulnar nerve block can also help differentiate intrinsic spasticity from fixed intrinsic or PIP contractures.

Thumb. The thumb-in-palm deformity is a challenging problem to rectify. Correction of the thumb-in-palm deformity is a careful balancing act among multiple muscles, tendons, and joints. Correction of the thumb-in-palm deformity is often performed concurrently with tendon transfer surgery to augment wrist extension. Hence, testing of the thumb-in-palm deformity should be done in wrist flexion and extension. Thumb extension occurs in a radial direction in the plane of the hand, and thumb abduction occurs in the plane perpendicular to the palmar surface (Figure 32.5). The adequacy of the first web space should be assessed with measurements of the passive and active web space angle. The muscles about the thumb should be assessed for spasticity or contracture, including the adductor pollicis brevis (APB), flexor pollicis brevis (FPB), first dorsal interosseous, flexor pollicis longus (FPL), abductor pollicis longus (APL), extensor pollicis brevis (EPB), and extensor pollicis longus (EPL). In addition, the thumb should be evaluated for hyperextension at the MP joint and volar plate laxity.

Diagnostic Testing

Imaging

There is a limited role for imaging in the treatment of patients with cerebral palsy or traumatic brain injury. Documenting joint subluxation or frank dislocation, especially of the radial head and distal ulna, may explain bony blocks to joint motion. Degenerative changes, fracture, infection, avascular necrosis, or concurrent congenital musculoskeletal disease may also be identified on imaging. Functional brain magnetic resonance imaging has been studied as an accurate predictor of upper extremity function in upper motor neuron disease and a useful outcomes measurement tool to document cortical reorganization after treatment.[74a,83]

FIGURE 32.5 **A** and **B,** Dynamic thumb-in-palm deformities flexion into the palm with digit extension and interfere with grasp and prevent the manipulation of large objects. **C** and **D,** Severe thumb contracture with fixed joint degenerative changes and skin and soft tissue contracture. Electromyography

Dynamic electromyography can be helpful in identifying spastic and flaccid muscles and determining phasic activity. Electromyography has been advocated in the decision-making process for surgery,[77,92,130,157,195] although some believe that the information gained is no more valuable than that obtained from serial physical examinations.[114a] Dynamic electromyography often requires a combination of surface electrodes and fine-wire examination of the deeper muscles of the elbow, forearm, and hand. Volitional activity as well as patterned activity should be evaluated to identify muscles that are firing normally in phase versus those that are firing out of phase, firing continuously, or not firing at all (Figure 32.6).

In the elbow, the biceps, brachialis, and brachioradialis can be evaluated by electromyography for spasticity and possible surgical release. Similarly, the adductor pollicis muscle can be assessed to determine its role in thumb-in-palm deformity. Weak or absent wrist extension to produce grasp or digital extension to yield release can be accessed via electromyographic response of the wrist extensors or digital flexor muscles, respectively. Dynamic electromyography can help identify inappropriate muscle firing, as well as those muscles that would be best for transfer. Out-of-phase or continuous firing of the FCU and digital flexors is frequently seen; this characteristic makes them poor donors for transfer. Activity of the digital and radial wrist extensors is often absent on electromyographic studies. The ECU findings are more variable.

Muscles firing during digital release are good candidates for transfers to improve digital extension, and those firing in grasp are good choices for wrist extension transfers.[77,195] The FCU, FCR, brachioradialis, pronator teres, ECU, and extensor carpi radialis longus (ECRL) can all be studied to determine which muscles are active in grasp and which muscles are active in release.[77,78] Continuous activity in a muscle is a relative, although not absolute, contraindication for transfer, because some data suggest that phasic activity can develop after transfer.[132,157]

Specially trained personnel are required to perform dynamic electromyographic tests, and many laboratories do not have this technical support. In addition, in the lower extremity, electromyography has been shown to alter performance due to discomfort.[4a] The overall applicability of upper extremity dynamic electromyography remains questionable.

NONOPERATIVE MANAGEMENT

Therapy

The role of nonoperative management in the treatment of cerebral palsy and traumatic brain injury cannot be overemphasized. The therapists play a critical role in the treatment paradigm and in the education of the patient and caregiver. Therapeutic intervention includes passive range-of-motion movements, splint fabrication, and implementation of adaptive strategies and devices. Passive range-of-motion movements and splinting are instituted to maintain supple joint structures and prevent fixed contractures. The therapist must be skilled in splint fabrication because the limbs are prone to skin breakdown secondary to spasticity and altered sensibility. In fact, severe spasticity is a contraindication to splint fabrication because "rebound" spasticity (Figure 32.7) can lead to skin breakdown.

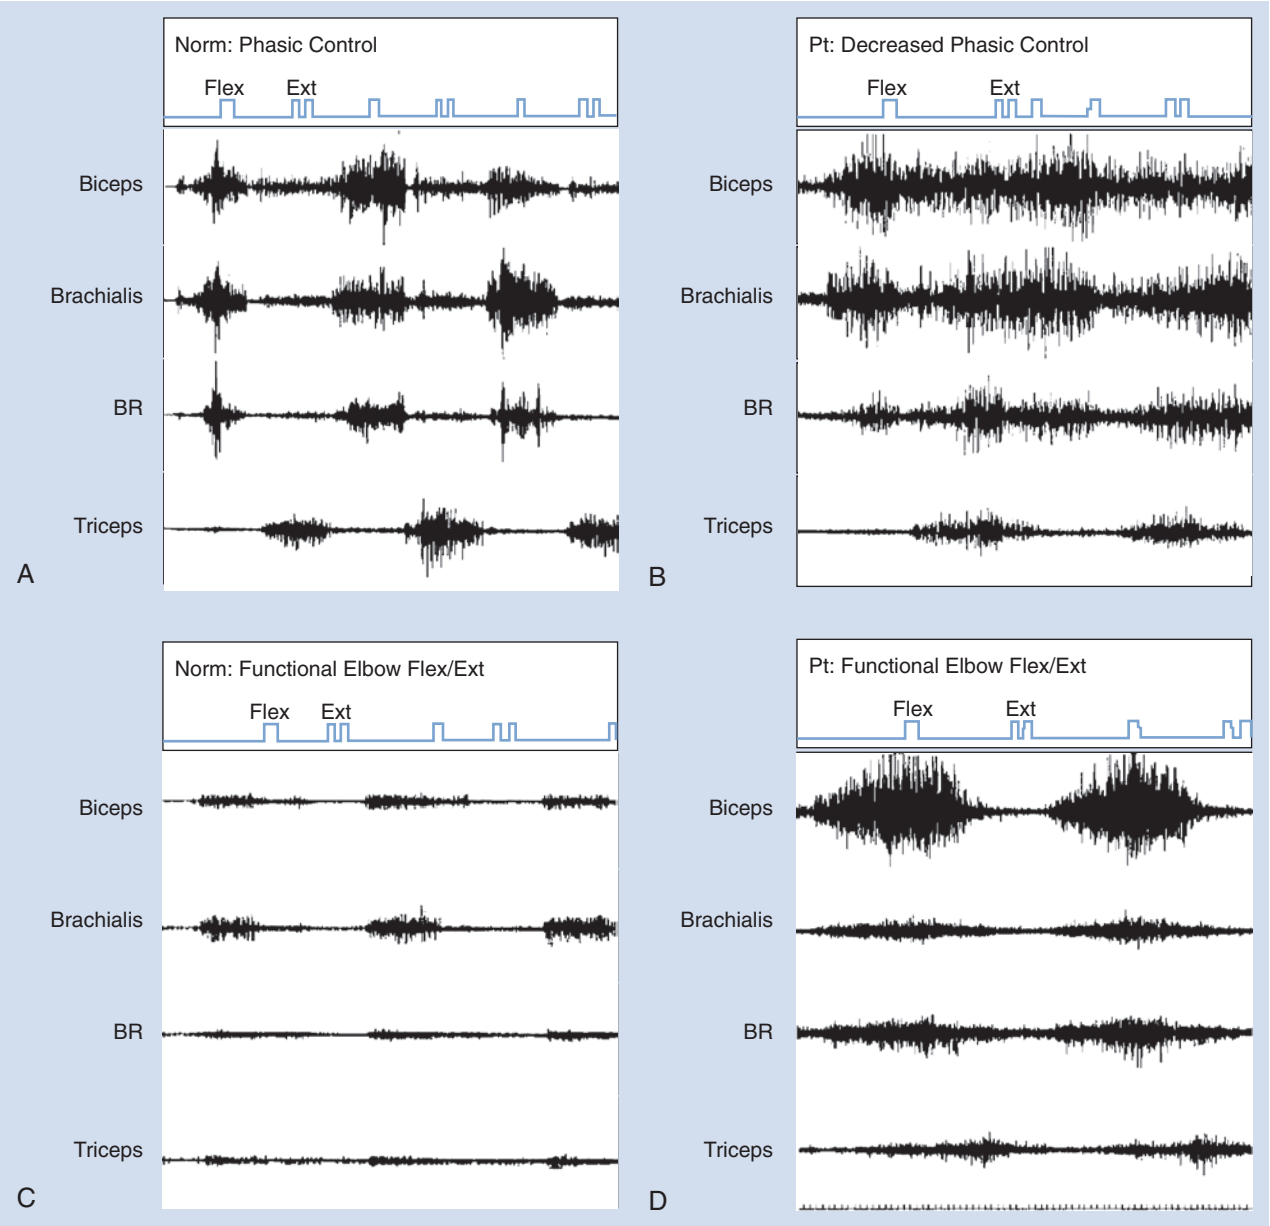

FIGURE 32.6 Dynamic electromyograms of the elbow. **A,** Normal phasic control in maximal contraction. Note the alternation in firing between flexion and extension. **B,** In this patient there is loss of phasic control, and the elbow flexors fire in flexion and extension. **C,** Normal functional use. A patient is asked to lift a light object, and the amount of contraction decreases from maximal effort (compare with **A**). **D,** In this patient there is loss of functional grading, because even when the patient lifts a light object, there is almost maximal contraction. *BR,* Brachioradialis; *Flex,* flexion; *Ext,* extension.

The therapist has a critical role in eliciting active movement and encouraging usage of the spastic limb. Incorporation of the spastic limb into daily activity is a challenging problem, especially in hemiplegia. Hemiplegic patients can perform tasks more easily, faster, and with more spontaneity with the uninvolved limb. The spastic hand is often dubbed the "helper hand." Nonetheless, active usage promotes activity within the sensorimotor cortex homunculus dedicated to the hand and is necessary to maintain these pathways. In the pediatric population, therapists will use play as a means of promoting limb usage. Grasping and manipulation of objects of different sizes and shapes are used to promote different prehension patterns. Constraint-induced movement therapy forces the use of the affected side by restraining the unaffected side. The constraint can be holding the uninvolved limb and allowing prehension only with the affected side.[36,112,139] The constraint also can be more restricting, such as splinting or casting of the unaffected side. Electrical stimulation of weak or neglected muscles combined with therapy may also provide additional benefits.[26,75,159,160,207,208]

The therapist also plays a role as an educator with respect to diagnosis and treatment and comprehension of the child's future level of independence, intellectual ability, and other abilities. In cerebral palsy, the parents are often overwhelmed and are searching for answers. A skilled therapist can answer most of the questions and defer to the physician with queries regarding surgical management. The parents do need to mourn the "loss of the perfect child," and grieving is a necessity. Some

FIGURE 32.7 Splinting of the severely flexed wrist is difficult. Volar splinting of the wrist stimulates the palm, increasing the pathologic flexion response, which tends to make the patient "flex out" of the splint. Dorsal splinting is mechanically ineffective. (Copyright Michelle Gerwin Carlson.)

parents are unable to cope with the added burden and should be referred to a psychiatrist, psychologist, or other mental health provider. In traumatic brain injury, the psychological burden can be overwhelming for both the patient and the caregiver; psychotherapy can be beneficial in handling the added stress.

The therapist also plays a critical role following surgery. Therapy protocols are established for tendon lengthenings, muscle releases, and tendon transfers. These involve three stages: immobilization, mobilization, and incorporation. A skilled therapist will maximize the outcome.

Medical Management

Medical management may include injectables, orals, or implantable intrathecal devices. Muscle relaxants such as benzodiazapenes and baclofen, as well as antiseizure medications, have a clear role in management of limb function and position but are rarely managed by the surgeon.[131]

Botulinum Toxin

Botulinum toxin (Botox®) is a useful adjunctive treatment for spasticity. Botulinum toxin type A blocks the release of acetylcholine at the presynaptic neuromuscular junction, which temporarily weakens the injected muscle.[8,48,99,100,103] When used in the appropriate dosage and carefully injected, botulinum toxin has a high safety profile. A maximum total dose of 10 U/kg is given. The use of botulinum toxin for spasticity is off-label and should be discussed with the patient and caregiver beforehand.

The indications for botulinum toxin injection are variable depending upon the patient and reasoning.[50,51,53] Botulinum toxin can be injected to temporarily decrease spasticity and allow more intense therapy to resolve any tightness. For example, children with cerebral palsy can have some increased spasticity and tightness during periods of rapid growth. Botulinum toxin injection can lessen the tightness and resolve any impending contracture. Botulinum toxin can also be used to assess and forecast the effect of lengthening a muscle-tendon unit. This assessment may prevent surgery that would not be beneficial and/or would result in diminished function.[35]

❖ Authors' Preferred Technique for Botulinum Toxin Injection

Botulinum toxin injection is performed in the clinic or the operating room, depending on the age of the patient and muscle(s) to be injected. Older patients and superficial muscles can be injected after the application of topical lidocaine cream or use of a ShotBlocker (Bionix Development Corporation, Toledo, OH). Younger patients and deeper muscles may require sedation or anesthesia. Deeper muscles can require electrical stimulation or ultrasound to verify appropriate needle placement. Botulinum toxin is prepared by diluting it with preservative-free saline. An insulated needle connected to an electrical stimulation unit or under direct ultrasound observation is inserted into the target muscle. Placement within the correct muscle is verified by stimulation prior to injection.

The protocol following injection varies with the indication. For patients with increasing tightness, a cast is applied for 3 week to maximize the stretch. For patients who require functional assessment, no daytime immobilization is required.

OPERATIVE MANAGEMENT

Shoulder

Types of Operative Procedures

A spastic shoulder that does not respond to therapy and botulinum toxin is typically treated by lengthening or release of the tight muscles.[109] Tendon transfers about the shoulder for cerebral palsy or traumatic brain injury have not been effective. In severe cases, humeral osteotomy can reposition the limb in space.[165] In athetoid patients, recurrent dislocation of the glenohumeral joint should be treated with glenohumeral arthrodesis.[79]

An inventory of the patient's spastic muscles will direct surgical management. Typically, the subscapularis and pectoralis major muscles are the major culprits and must be lengthened to lessen the internal rotation and adduction contracture. Less commonly, the latissimus dorsi and teres major muscles are released at the same time. External rotation spasticity can also be relieved by release of the supraspinatus, infraspinatus, and teres minor. Patients with severe external rotation spasticity are unable to maneuver through a doorway. Internal rotational humeral osteotomies may be required to improve wheelchair positioning.

Soft Tissue Release of Shoulder Internal Rotation Deformity

Indications. Mild axillary hygiene access or dynamic shoulder contracture can usually be treated with stretching. Failed nonoperative treatment and recurrent axillary hygiene issues or inability of a patient to position a functional hand in space are indications for surgery.

Contraindications. Release of the internal rotators should not be performed in patients with subluxation or dislocation of the shoulder, because this may exacerbate the instability.[98] These patients are better candidates for shoulder fusion. A relative contraindication to soft tissue surgery is weak external shoulder rotators. Contracture will recur soon after surgery if range of

motion is not maintained by therapy and strengthening of opposing muscles.

Preoperative Planning. Careful clinical examination of the muscles while the patient is awake is necessary to determine whether the shoulder muscle involvement is dynamic or passive. Once the patient is asleep, passive contractures can be detected. Preoperative imaging should be considered if glenohumeral subluxation, dislocation, or degenerative disease is suspected.

Technique. An axillary or deltopectoral incision is made in the anterior aspect of the shoulder. The tendon of the pectoralis major is identified along the posterior surface of the muscle. Fractional lengthening is performed by cutting the tendon at its musculotendinous junction. The deltopectoral interval is further divided to expose the underlying subscapularis. The subscapularis tendon insertion is identified as it inserts on the lesser tuberosity and is divided or "Z"-lengthened. A "Z"-lengthening is preferred primarily because it preserves some function of the tendon, prevents excessive external rotation posture, and helps prevent anterior dislocation of the shoulder. Subscapularis lengthening can also be accomplished using muscle slide through a longitudinal incision along the lateral border of the scapula. The subscapularis is elevated in an extraperiosteal plane from the anterior surface of the scapula beginning inferiorly and progressing superiorly.[18] The shoulder joint does not need to be opened unless one is performing a glenohumeral fusion. An external rotation abduction splint or shoulder spica cast is worn for 4 to 6 weeks, followed by range-of-motion exercises.

Rotation Osteotomy of the Humerus

Indications. An extremely contracted shoulder may not be amenable to soft tissue release. Humeral osteotomy can reposition the limb in space and enhance function. Humeral osteotomy will not address axillary hygiene issues.

Contraindications. Poor hand function is a relative contraindication to humeral osteotomy. However, concomitant surgery to improve hand function can be performed at the same setting.

Preoperative Planning. The amount of external rotation to improve function needs to be determined prior to surgery. A skilled therapist is invaluable to ensure the correct amount of rotation necessary. The right amount of rotation will enhance external rotation activities and preserve internal rotation and midline functions.

Technique. A medial, lateral, or deltopectoral approach can be used. We prefer the medial approach for numerous reasons. First, the approach is straightforward and goes between the median and ulnar nerves.[2,108] Second, the configuration of the medial humerus is suitable for plate and screw fixation. Third, the arm rests directly on the arm table after osteotomy, which facilitates fixation. Last, the medial incision heals nicely and is well concealed.

No tourniquet is used. The planned incision is infiltrated with bupivacaine and epinephrine prior to prepping and draping. A medial incision is made overlying the intermuscular septum and midshaft of the humerus. The superficial nerves are protected. The intermuscular septum is identified and excised. The ulnar nerve is retracted in a posterior direction while the median nerve and brachial artery are retracted in an anterior direction. The diaphysis of the humerus is exposed.

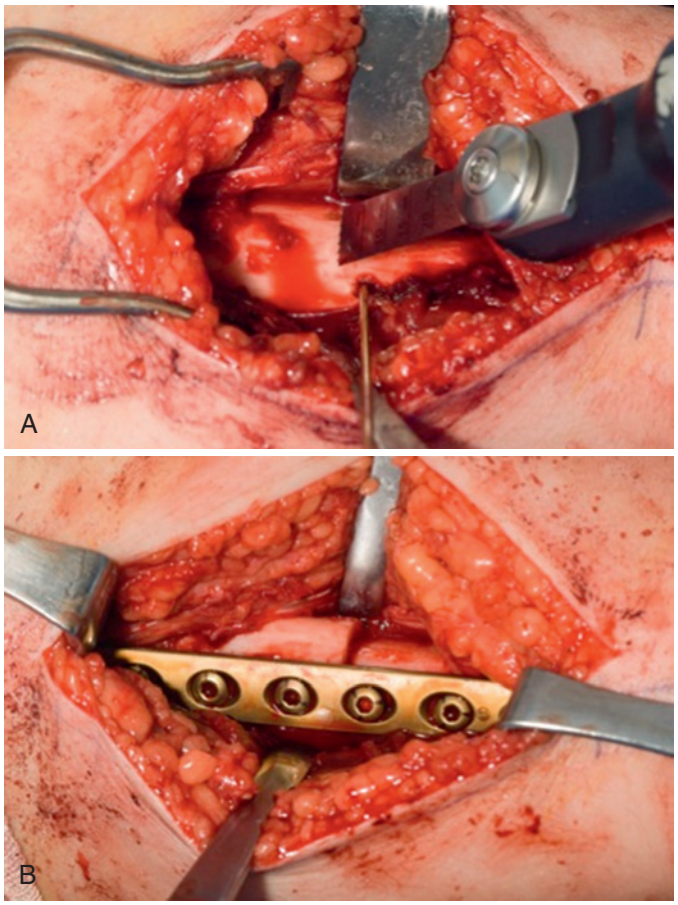

FIGURE 32.8 **A,** A Kirschner wire is drilled in an oblique angle to simulate the amount of correction, and a fine bladed saw is used for osteotomy. **B,** The humerus is externally rotated, the osteotomy is reduced, and the plate and screws are applied. (Courtesy of Shriners Hospital for Children, Philadelphia.)

A 6- to 8-hole plate is chosen for fixation. The size depends on the girth of the humerus; usually, 3.5 mm is sufficient in an adolescent or adult. The plate is placed over the humerus and the proximal 3-4 bicortical screws are placed through the plate and humerus. The periosteum is not incised along the entire humerus but only over the osteotomy site (Figure 32.8, *A*). Prior to performing the osteotomy, a Kirschner wire is placed in the distal fragment to mark the amount of desired correction. The wire is placed in line with a hole in the plate. The plate is removed and the humeral osteotomy performed using an oscillating saw; during the procedure, irrigation is necessary to minimize thermal necrosis. Following completion of the osteotomy, the humerus is rotated so that the screw holes and Kirschner wire are aligned. The wire is passing through a hole in the plate. By means of the predrilled screw holes, the plate is affixed to the proximal fragment. The osteotomy is reduced and the distal fragment is secured with screws using standard compression techniques (see Figure 32.8, *B*).

Following surgery, a large bulky dressing is applied from the hand to the axilla. No splint is used; however, a sling must be worn to prevent stress across the osteotomy site. The dressings are removed and a humeral brace is fabricated 3 weeks after surgery. The brace is worn for about 1 month until radiographic and clinical union is evident.

Glenohumeral Joint Arthrodesis

Indications. Instability or painful glenohumeral joint subluxation is the main indication for arthrodesis.

Contraindications. Absent scapular control is a contraindication for shoulder fusion. The patient must have ample parascapular muscles to control the fused glenohumeral joint.

Preoperative Planning. The goal is to determine the optimal position for fusion. The standard position is 30 degrees of abduction, 30 degrees of internal rotation, and 30 degrees of forward flexion (Figure 32.9, *A*). The position may vary, however, in the impaired patient, depending on the patient's function and overall needs.

Technique. Numerous operative techniques have been described to achieve union.[148] An extended deltopectoral approach provides wide exposure to the glenohumeral joint. The articular cartilage is removed from the humeral head and glenoid. Exposed cancellous bone is mandatory for union. Rigid internal fixation is preferred, using dual plate fixation (see Figure 32.9, *B*). One plate is placed across the scapular spine and onto the lateral humerus. A second plate is secured across the acromion and onto the humerus. Additional fixation can be obtained with large cancellous screws from the lateral humerus into the glenoid. Bone graft may be added to further promote healing. Postoperative immobilization varies from an abduction pillow to a shoulder spica cast, depending on the quality of the bone and rigidity of the fixation.

FIGURE 32.9 **A,** Glenohumeral arthrodesis using dual-plate fixation. **B,** Shoulder is positioned in 30 degrees of abduction, 30 degrees of internal rotation, and 30 degrees of forward flexion to allow hand-to-mouth activity. (Courtesy of Shriners Hospital for Children, Philadelphia.)

❖ Authors' Preferred Method of Treatment

Nonoperative management is the mainstay of treatment for shoulder spasticity. Spasticity and/or contractures that do not respond to stretching and botulinum toxin can be treated with surgery. An inventory of the potential spastic muscles is delineated by repeated physical examinations.

Moderate spasticity and contracture are treated by lengthening of the spastic and tight muscles. Lengthening of the subscapularis and pectoralis major is preferred to prevent overcorrection. Pectoralis major lengthening is performed by fractional lengthening of the muscle-tendon junction. Subscapularis lengthening is accomplished via "Z"-lengthening using a deltopectoral approach or muscle slide through a longitudinal incision along the lateral border of the scapula. The subscapularis is elevated in an extraperiosteal plane from the anterior surface of the scapula beginning inferiorly and progressing superiorly.[18]

If the latissimus dorsi and teres major muscles are spastic offenders, their tendons are released from the insertion on the humerus.

Severe contracture and limb malposition are treated by humeral osteotomy, with the caveat that axillary hygiene will not be altered. Glenohumeral joint arthrodesis is reserved for instability or painful glenohumeral joint subluxation.

Elbow

Types of Operative Procedures

Spastic dynamic elbow flexion contractures can be surgically addressed by denervation, lengthening, or myotomy of the muscles crossing the anterior aspect of the elbow. Muscle contracture release options include either individual lengthening or release of the biceps, brachialis, and/or brachioradialis. In addition, the flexor-pronator mass may be a contributor to the elbow flexion contracture. A concomitant flexor-pronator slide may be necessary.

Fixed, long-standing contractures result in additional skin, soft tissue, and joint factors. Release requires more extensive surgery, including skin "Z"-plasty and possible capsular release; the rate-limiting factor is often the stretch of neurovascular structures. Therefore, we try to avoid capsular procedures but favor serial casting following surgical lengthening and/or release of the skin, fascia, and muscles to make additional gains in elbow extension.

Musculocutaneous Neurectomy

Indications. Musculocutaneous neurectomy is rarely performed. Neurectomy is reportedly effective for spastic deformity of less than 30 degrees.[79,114,143,164] Neurectomy denervates the biceps and brachialis and results in active elbow flexion through the remaining brachioradialis. Full passive range of motion of the joint is necessary because this procedure does not correct contractures about the joint.

Contraindications. Musculocutaneous neurectomy is an "all-or-none" treatment, and no fine-tuning of tension in the muscles or separate biceps or brachialis release is possible. This

may explain its decline in usage. It is contraindicated in patients with functional elbows that bring the hand into positions necessary for activities of daily living. Neurectomy addresses only muscular spasticity and is contraindicated when fixed contracture exists. Additionally, musculocutaneous neurectomy results in a sensory deficit in the lateral arm in the distribution of the lateral antebrachial cutaneous nerve. Neurectomy of only the motor branches preserves this sensibility.

Preoperative Planning. Preoperative lidocaine or bupivacaine block of the musculocutaneous nerve along the proximal medial aspect of the biceps is often performed prior to formal neurectomy. The temporary paralysis assists in differentiating the contribution of abnormal muscle tone from fixed contracture and helps predict the results following neurectomy. The block also identifies the amount of elbow flexion possible through the brachioradialis muscle. A preoperative dynamic electromyogram (surface or fine wire) may also be helpful in determining patterns of spasticity.[92]

Technique. The musculocutaneous nerve is exposed through an axillary or medial arm incision. The musculocutaneous nerve is identified emanating from the lateral cord of the brachial plexus. Stimulation yields elbow flexion and confirms identification. A 1-cm segment of musculocutaneous nerve can be removed; however, isolation and resection of the motor braches are preferred. No postoperative immobilization is necessary.[114,167]

Elbow Flexor Lengthenings for Dynamic Spasticity

Indications. Lengthening or release of the biceps, brachialis, and brachioradialis is a direct approach to spastic flexion contracture of the elbow.[6,24,42,58,98,116,117,125,165] The procedure can increase elbow active extension by about 40 degrees, with minimal loss of flexion arc or functional flexion power.[126]

Contraindications. Contraindications to isolated lengthenings include skin, capsular, and joint contractures. Patients must have strong active elbow flexion preoperatively, or lengthening of the flexors may weaken the elbow and negate hand-to-mouth activities.

Preoperative Planning. Serial clinical examinations are necessary to properly identify the muscles that require lengthening. Results of previous treatments, including passive stretch therapy, splinting/casting, and botulism toxin injections, are useful in predicting the outcome and guiding surgical planning. Dynamic electromyography may again be helpful to distinguish the contributions of individual muscles to the deformity.[92]

Technique. The patient is placed supine on the operating room table. The entire extremity is prepped and draped. A sterile circular tourniquet is applied (HemaClear, OHK Medical Devices, Grandville, MI) that exsanguinates during application. For purely dynamic spasticity, a transverse incision across the antecubital fossa is made. Antecubital veins are mobilized or ligated. The lateral antebrachial cutaneous nerve, emerging from the interval between the biceps and brachialis lateral to the biceps tendon, is identified and retracted laterally. The lacertus fibrosus is identified and the median nerve and brachial artery are appreciated deep to the lacertus fibrosus. The radial nerve is isolated between the brachioradialis and brachialis muscles.

The brachioradialis is usually treated by myotomy. The muscle is isolated from the extensor carpi radialis brevis (ECRB) and the radial nerve. The muscle is cut using electrocautery for complete release. Deep to the biceps tendon, the brachialis muscle-tendon junction is identified. A fractional lengthening is performed by cutting the tendon, leaving the muscle alone (Figure 32.10). The biceps may or may not be lengthened

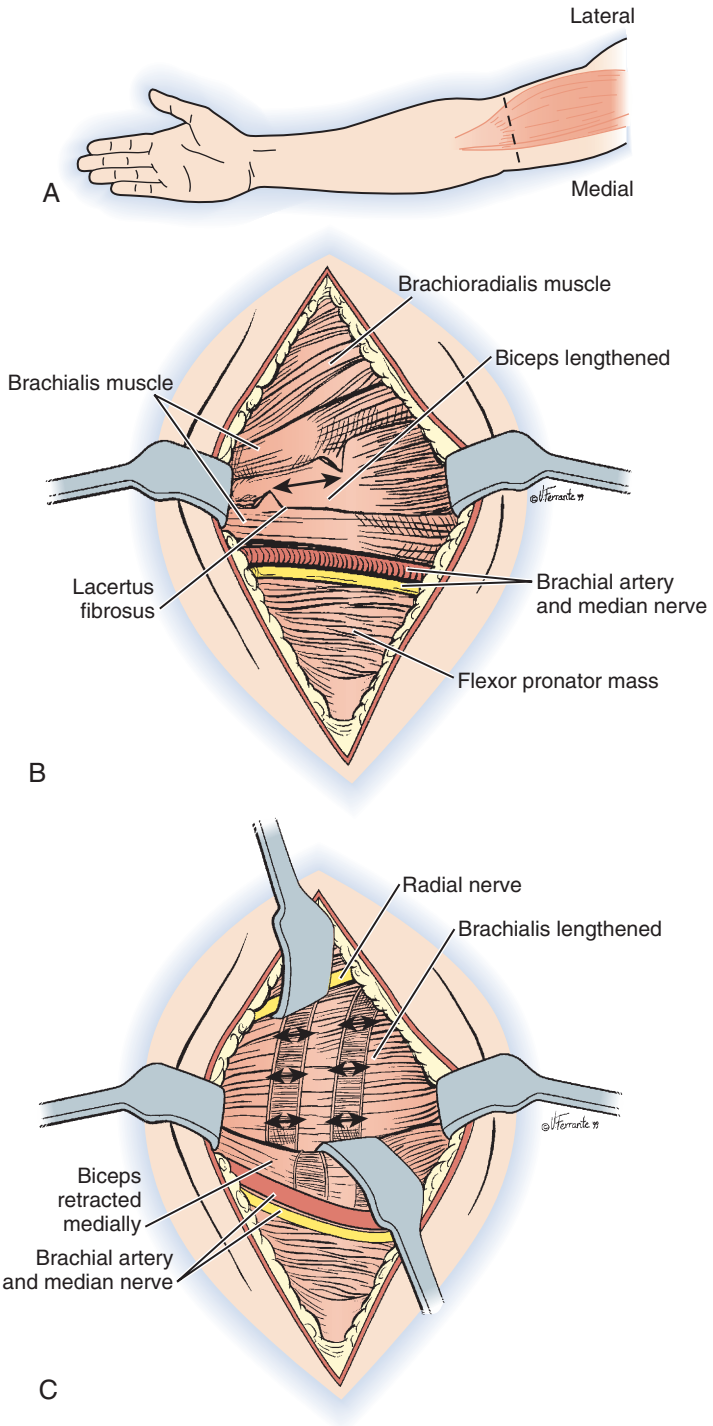

FIGURE 32.10 Fractional lengthening of the elbow flexors. **A,** Through a transverse incision in the antecubital fossa, the lacertus fibrosus is transected, and the neurovascular bundle and lateral antebrachial cutaneous nerves are identified and protected. **B,** "Z"-lengthening of the biceps tendon with medial and lateral tenotomies. **C,** Fractional lengthening of the brachialis through the musculotendinous junction and subperiosteal release of the proximal brachioradialis from the distal humerus through the same incision. After spreading of the tenotomies, the overlapping region of the biceps tendon is secured with three sutures.

depending upon the preoperative examination for spasticity and its contribution to forearm supination. The decision is not always straightforward. If the biceps is lengthened, a fractional lengthening is performed at the muscle-tendon junction.

The wound is closed with absorbable suture. A long-arm cast is applied with the elbow in full extension. The cast is worn for 3 weeks, followed by range of motion and splint fabrication.

Elbow Contracture Release for Fixed Deformity

Indications. Fixed elbow contractures require a more extensive release. In general, functional upper extremities with an elbow flexion contracture of more than 40 degrees should be addressed. In the nonfunctional upper extremity, a flexion contracture that results in difficulties in dressing or recurrent intertriginous infections should be treated. Release of a severe elbow flexion contracture often results in a satisfying improvement in function and hygiene. A 45-degree improvement in the flexion contracture of the extremity is usually obtained. Many patients are able to accomplish tasks that were difficult before surgery. In a wheelchair-bound patient, flexion deformities of more than 100 degrees make assistance during transfers difficult and manipulation of objects or technologic devices on a tabletop impossible. Elbow release improves the ability to work at a tabletop and assist in transfers. Ambulatory patients can expect an improvement in use of the arm in two-handed activities and in the workable reach space of the extremity.

Contraindications. Patients with weak elbow flexion may have a functional loss of elbow flexion after full elbow release. The risks of loss of elbow flexion must be weighed against the benefits of improved position and hygiene of the extremity. Therapy, splinting, serial casting, and stretching should be maximized prior to surgical intervention.

Technique. The patient is placed supine on the operating room table. The entire extremity is prepped and draped. A sterile circular tourniquet is applied (HemaClear, OHK Medical Devices, Grandville, MI) that exsanguinates during application. For a fixed contracture, an "S"-shaped or "Z"-plasty incision is made centered over the antecubital fossa (Figure 32.11). Antecubital veins are mobilized or ligated. The lateral antebrachial cutaneous nerve, emerging from the interval between the biceps and brachialis lateral to the biceps tendon, is identified and retracted laterally. The lacertus fibrosus is identified and incised from the biceps tendon. The median nerve and brachial artery are visualized. The radial nerve is isolated between the brachioradialis and brachialis muscles.

The brachioradialis is treated by myotomy. The muscle is isolated from the ECRB and the radial nerve. The muscle is cut using electrocautery for complete release. The biceps tendon is traced from its muscular origin to the radial tuberosity. The tendon is lengthened by "Z"-plasty along its entire length. Deep to the biceps tendon, the brachialis muscle-tendon junction is identified. A fractional lengthening is performed by cutting the tendon, leaving the muscle alone. The amount of extension gained is assessed. Any additional tight fascia is released. The neurovascular bundle is often the rate-limiting factor. Therefore, additional capsular release would not achieve considerable gains in extension. Additional gains in elbow position can be made by serial casting following surgery.

The biceps tendon lengthening is repaired with a tendon weave or end-to-end repair using a nonabsorbable suture. The wound is closed with absorbable suture. A long-arm cast is applied with the elbow in full extension. The cast is worn for 4 weeks, followed by range-of-motion movements and splint fabrication.[93,94]

❖ Authors' Preferred Method of Treatment

Treatment decisions are based on repeated examinations and frank conversations with the patient and family. Nonoperative measures should be exhausted prior to surgery. Dynamic elbow spasticity that is not responsive to therapy can be treated by surgery via a transverse incision across the antecubital fossa, as described above (see Figure 32.10). This procedure is often performed during concomitant procedures to address the wrist, fingers, and/or thumb. Fixed contractures are less responsive to therapy. Contractures that interfere with care or function require surgery. The details of a more extensive procedure are detailed above. An "S"-shaped or "Z"-plasty incision is necessary to allow ample skin for closure. The neurovascular

CRITICAL POINTS *Elbow Muscle Release and Lengthening for Dynamic Spasticity or Fixed Flexion Contracture*

Indications
- Dynamic elbow spasticity that has not been responsive to therapy
- Fixed flexion contracture greater than 40 degrees that interferes with function or hygiene

Preoperative Evaluation
- Individualize patient goals.
- Perform repeated clinical examinations.
- Maximize nonoperative modalities and consider botulinum toxin to predict surgical outcomes.
- Dynamic electromyography may be helpful in identifying spastic muscles.

Pearls
- Apply a sterile circular tourniquet (HemaClear, OHK Medical Devices, Grandville, MI) that exsanguinates during application and allows complete access to the elbow.
- Always identify and protect the neurovascular structures early in the procedure because they may be displaced by the spastic muscles and/or contracture.

Technical Points
- Make a transverse antecubital incision for dynamic spasticity and an "S"-shaped or "Z"-plasty incision for a fixed deformity.
- Identify the lateral antebrachial cutaneous nerve.
- Mild biceps lengthening via fractional technique; more extensive lengthening requires "Z"-lengthening.
- Mobilize the neurovascular bundle from the anterior surface of the brachialis prior to brachialis fractional lengthening.
- Identify the radial nerve in the interval between the brachialis and brachioradialis.

Pitfalls
- Failure to identify the neurovascular structures can lead to iatrogenic injury.
- Inadequate hemostasis can lead to postoperative hematoma.
- Careless skin handling can lead to wound dehiscence.

Postoperative Care
- Cast application is preferred to allow for wound and tendon healing.
- Begin active and passive range-of-motion exercises following cast removal.

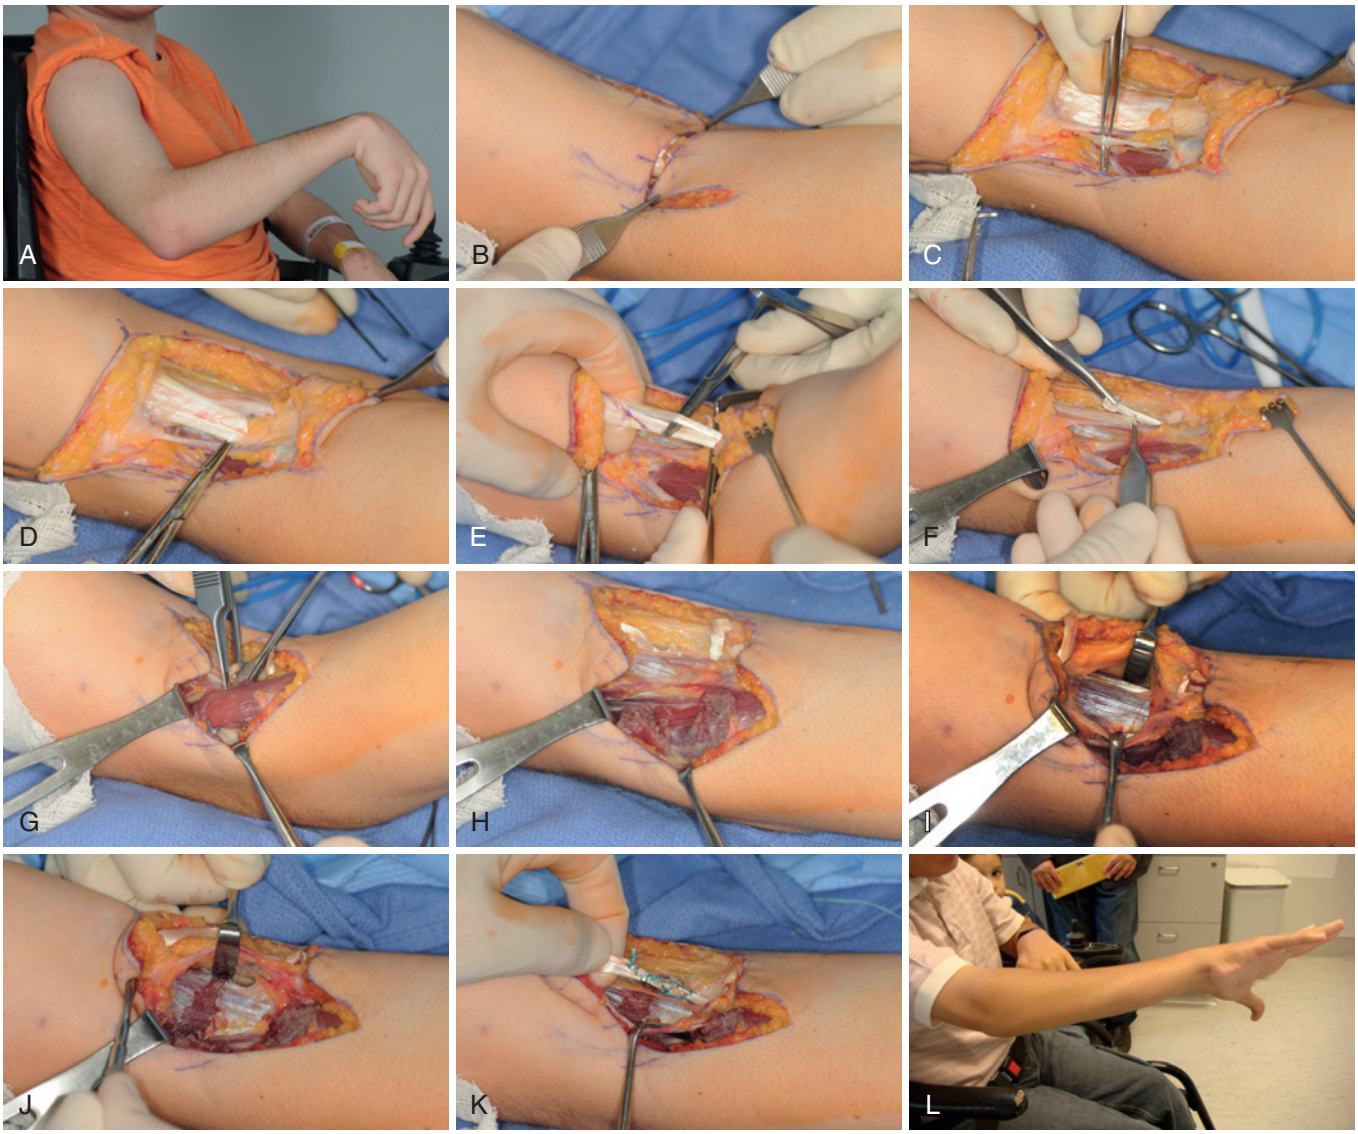

FIGURE 32.11 Elbow static contracture release. **A,** Preoperatively, the patient has a severe static flexion contracture of his elbow; passive extension is lacking at more than 90 degrees even with the patient asleep. **B,** "Z"-plasty incision in the antecubital fossa. **C,** The lateral antebrachial cutaneous nerve is protected. **D,** The lacertus fibrosus is transected. **E** and **F,** The biceps tendon is "Z"-lengthened. **G** and **H,** Myotomy and subperiosteal dissection origin of the brachioradialis. Note that the radial nerve branches to the brachioradialis are preserved. **I,** The brachialis tendon is visualized deep to the biceps, and the neurovascular bundle is retracted medially. **J,** Fractional lengthening and myotomy of the brachialis. **K,** After complete release of the anterior capsule, the "Z"-lengthened biceps tendon is repaired with ethibond suture. **L,** Postoperative elbow extension. (Courtesy of Shriners Hospital for Children, Philadelphia.)

structures must be identified and protected. Postoperative serial casting may be used to further improve elbow extension. Biceps lengthening may result in a "Popeye" deformity contour of the anterior arm.

Forearm

The forearm is the "forgotten joint" with regard to movement and balance in a child with spasticity. The forearm is articulated at its proximal and distal ends (proximal and distal radioulnar joints). The movement is balanced by two muscles that supinate (biceps and supinator) and two muscles that pronate (pronator teres and pronator quadratus).

Types of Operative Procedures

The spastic forearm is classically positioned in hyperpronation. Several operative procedures have been described to decrease the spastic pronation force on the forearm. Brachialis and brachioradialis transfers have also been described.[134,135] Release of the pronator teres can be performed at its origin by a flexor-pronator muscle slide or at its insertion by a pronator teres tenotomy or rerouting. Studies have reported that pronator rerouting results in an increase in active supination of between 46 and 78 degrees,[17,73,118] compared with 54 degrees for pronator tenotomy.[173] However, in these reports the arc of motion was unchanged after pronator rerouting. This suggests that pronator teres rerouting may only reposition the forearm versus function as an active supinator. This finding has changed our approach to the spastic forearm, and we less commonly perform pronator teres rerouting. The pronator quadratus should not be released during pronator teres release, because this may result in loss of pronation, which is critical for "tabletop" and many technology-based activities of daily living and communication.[153]

A forearm positioned in pronation for a prolonged period will become contracted in this position, with structural changes to the proximal and distal radioulnar joints. Tendon transfers are contraindicated with a fixed contracture or radial head dislocation.[140] Options include interosseous membrane release combined with tendon transfer, osteotomy of the radius and/or ulna, or the one-bone forearm procedure.[49,106]

The surgeon must consider the entire operative plan for the extremity because other operative procedures to improve wrist extension can also improve supination. In the laboratory, FCU to ECRB transfer achieved 84 degrees of supination, brachioradialis rerouting achieved 33 degrees of supination, and pronator rerouting was unable to achieve supination past neutral.[30] However, these numbers may be different in vivo and may depend on the amount of pronation spasticity and phasic activity of transferred muscles. For example, FCU to ECRB transfer for wrist extension clinically increased supination by an average of 22 degrees.[9,193]

Flexor-Pronator Origin Muscle Slide

Indication. The flexor-pronator origin muscle slide was initially designed to release the ischemic muscles after established forearm compartment syndrome.[44,86,136,182,204] The procedure releases the pronator teres as well as the wrist and digital flexors. In addition to releasing the pronation contracture of the forearm, the flexor-pronator mass that originates from the medial epicondyle can contribute to elbow flexion contracture. The procedure can be extended in a proximal direction to release other contractures about the elbow as well.

Contraindication. The flexor-pronator muscle slide is an "all-or-none," technically demanding procedure requiring surgical experience. The procedure can cause excessive weakness of the finger flexors and overcorrection of pronation deformity.[44]

Technique. The patient is placed supine on the operating room table. The entire extremity is prepped and draped. A sterile circular tourniquet is applied (HemaClear, OHK Medical Devices, Grandville, MI) that exsanguinates during application. A long incision is made along the medial corridor from above the elbow to the ulnar styloid. The skin is incised, and hemostasis is obtained with electrocautery. Loupe magnification is used throughout the procedure.

The ulnar nerve is identified and traced through the cubital tunnel. Proximal dissection is performed so that any investing fascia around the ulnar nerve and the arcade of Struthers is released. The nerve is released to the point where it can be transposed in an anterior direction (Figure 32.12).

The flexor-pronator mass is incised directly off the ulna down to the medial collateral ligament. The collateral ligament is carefully preserved. The muscle is sequentially released from the ulna all the way to the wrist.

Subsequently, the release continues in an ulnar to radial direction. The release courses superficial to the brachialis muscle, where the median nerve and brachial artery are identified. The bifurcation into the radial and ulnar arteries is protected.

Directly on the interosseous membrane, the anterior interosseous nerve and artery are protected. Dissection proceeds superficial to the nerve and artery until the radius is

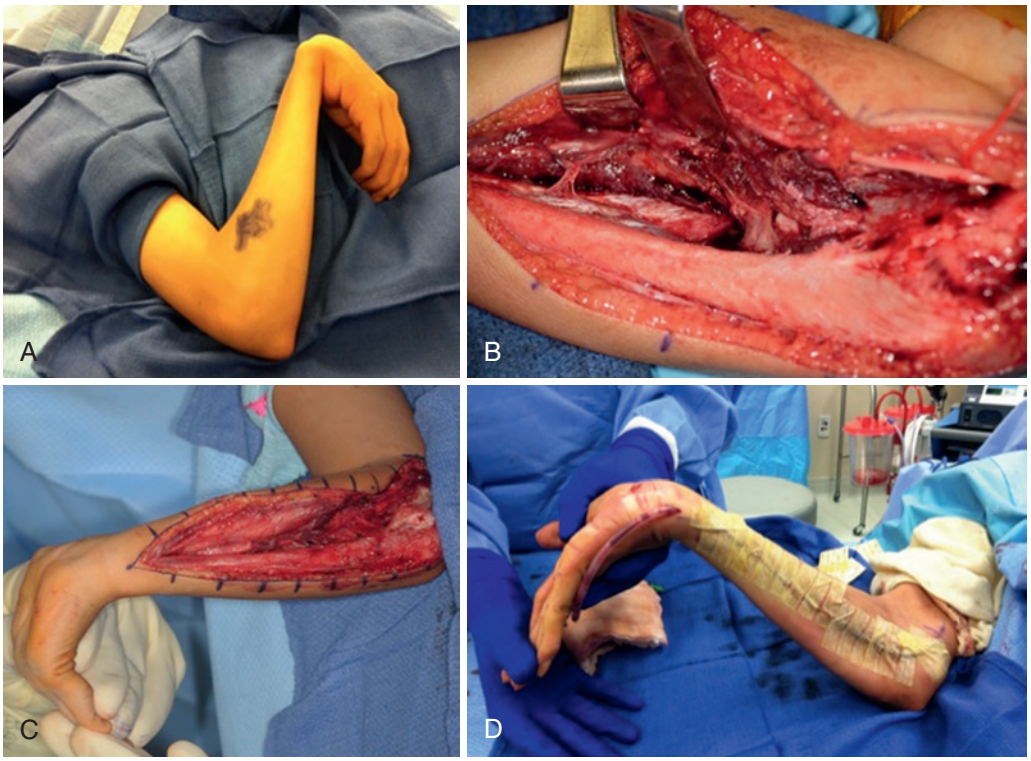

FIGURE 32.12 Flexor origin slide. **A,** Severe wrist and finger flexion deformity. **B,** Ulnar border incision with transposition of the ulnar nerve and dissection of all pronator and flexor forearm and finger muscle origins from the periosteum and interosseous ligament. **C,** Full extrinsic wrist and finger extension can be achieved; intrinsics may be released separately. **D,** Closure over a drain and casting in full finger and wrist extension. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles, and Shriners Hospital for Children, Philadelphia.)

encountered. Any taut muscle that originates from the radius (FDS, FPL) is released from its proximal origin.

The release is continued until the wrist and fingers can be extended completely. Closure is straightforward, leaving the ulnar nerve in an anterior position. We often place a deep drain beneath the flexor-pronator mass. A long-arm cast is applied with the wrist and digits in extension. The forearm is positioned in midsupination.

The arm is immobilized in a cast for 4 weeks with the elbow extended to 45 degrees, the forearm supinated, and the wrist and digits in extension. A removable splint is continued for 4 additional weeks, allowing removal for range-of-motion movements and therapy. After 2 months, splinting is converted for night use; it is discontinued 1 month later unless there is a tendency for recurrence of the deformity.

Release of Pronator Insertion

Indication. Pronator insertion release alleviates the deforming force of the pronator teres muscle.[58,72,73,173] Release alone is indicated in patients who have excessive pronation but no voluntary control of pronation. In patients who do not have active supination, a tendon transfer may be necessary to augment supination even after release of the pronator.

Contraindication. Isolated pronator release in patients who lack active supination will not improve the deformity. Fixed deformity requires additional interosseous membrane release, osteotomy of the radius and/or ulna, or a one-bone forearm procedure.

Technique. Topographically, the pronator teres insertion is just proximal to the radial sensory nerve as it exits from beneath the brachioradialis muscle.[106] A straight or curvilinear radial boarder incision allows direct access to the pronator insertion. Small branches of the lateral antebrachial cutaneous nerve are identified and protected. The radial sensory nerve is isolated between the brachioradialis and the ECRL. Proximal to the radial sensory nerve, the brachioradialis is elevated to expose the underlying radius. The tendon of the pronator is isolated inserting into the radius. A tenotomy of the entire tendon is performed under direct visualization.

After release, primary closure and an above-the-elbow cast or sugar tong splint is placed to keep the forearm in supination for 4 to 6 weeks. A removable supination splint is worn for an additional 4 weeks, with place-and-hold active and passive supination and active pronation exercises as part of the protocol.

Pronator Teres Rerouting

Indication. Rerouting of the pronator converts this muscle to a supinator.[17,41,73,118,153,173] Clinical results demonstrate a 50% increase in supination and correction of the reverse grasp position. It is indicated in patients who have active control of the pronator and lack active supination. The tendon can be released and rerouted through the interosseous space; alternatively, the pronator can be "Z"-lengthened and the distal portion brought around the radius and through the interosseous membrane from dorsal to volar, where it is woven into the proximal tendon.[72]

Contraindication. Pronator teres rerouting should be used sparingly in patients without active pronation control as the transfer will act only as a tether.

Technique. The patient is placed supine on the operating room table. The entire extremity is prepped and draped. A sterile circular tourniquet is applied (HemaClear, OHK Medical Devices, Grandville, MI) that exsanguinates during application. A longitudinal incision is made over the radial aspect of the forearm. The superficial branches of the lateral antebrachial cutaneous nerves are mobilized. The radial sensory nerve is identified emanating from the brachioradialis muscle-tendon. The nerve is traced in a proximal direction and the brachioradialis muscle is elevated. Just proximal to this point, the pronator teres tendinous attachment to the radius is identified.

The pronator muscle is released and dissected in a proximal direction to facilitate rerouting. A spacious window is made in the interosseous membrane to accommodate the transfer. The pronator teres tendon is lengthened in a "Z" fashion.[5] The distal part of the tendon is rerouted from dorsal to volar through the window in the interosseous membrane. The distal part is sutured back to the proximal part under slight tension. Alternatively, the pronator teres tendon is detached and transferred through the interosseous membrane and around the radius and reattached to its former insertion site with transosseous sutures or suture anchors with the forearm in supination.

❖ Authors' Preferred Method of Treatment

Mild pronation contracture of the forearm is treated by release or rerouting of the pronator teres insertion (Figure 32.13). In patients with active supination, we prefer a pronator tenotomy. If the patient has active pronation but no active supination, rerouting of the pronator is performed. In patients who have a pronation contracture combined with wrist and finger flexion deformity, a flexor-pronator muscle slide is preferred. In patients with a moderate to severe pronation deformity, an osteotomy of the radius and/or ulna or a one-bone forearm procedure is preferred.

Wrist and Digital Extension

Types of Operations

Balance of the wrist and digits is important to improve hand function in children with spasticity.[37,190] Decision making to match the best procedure with an individualized patient predominantly relies on the degree of wrist and finger joint contractures as well as tone and muscle spasticity of the wrist and digital flexors. If assessment is difficult, median and/or ulnar nerve blocks can temporarily eliminate the flexor spasticity and allow a better evaluation.[119] Ulnar deviation of the wrist may compound a flexion deformity and may be caused by a spastic or contracted FCU and/or ECU. The muscle causing the deformity can be cut, lengthened, or used as a transfer to augment its antagonist.

An integral part of the examination is the evaluation of digital function during wrist motion (Figure 32.14). If the patient cannot actively extend the wrist to neutral, the wrist should be held in neutral by the examiner while the patient attempts active digital extension. Grasp and release must be evaluated to ensure that improvements in wrist extension will not decrease digital extension and affect object acquisition (see Video 32.2). Similarly, the patient may rely on ulnar deviation of the wrist to increase thumb abduction for acquiring objects for pinch. If wrist ulnar deviation is lessened, a concurrent procedure to augment thumb abduction may be necessary.

A patient who would benefit from greater wrist extension may be helped by several available operative

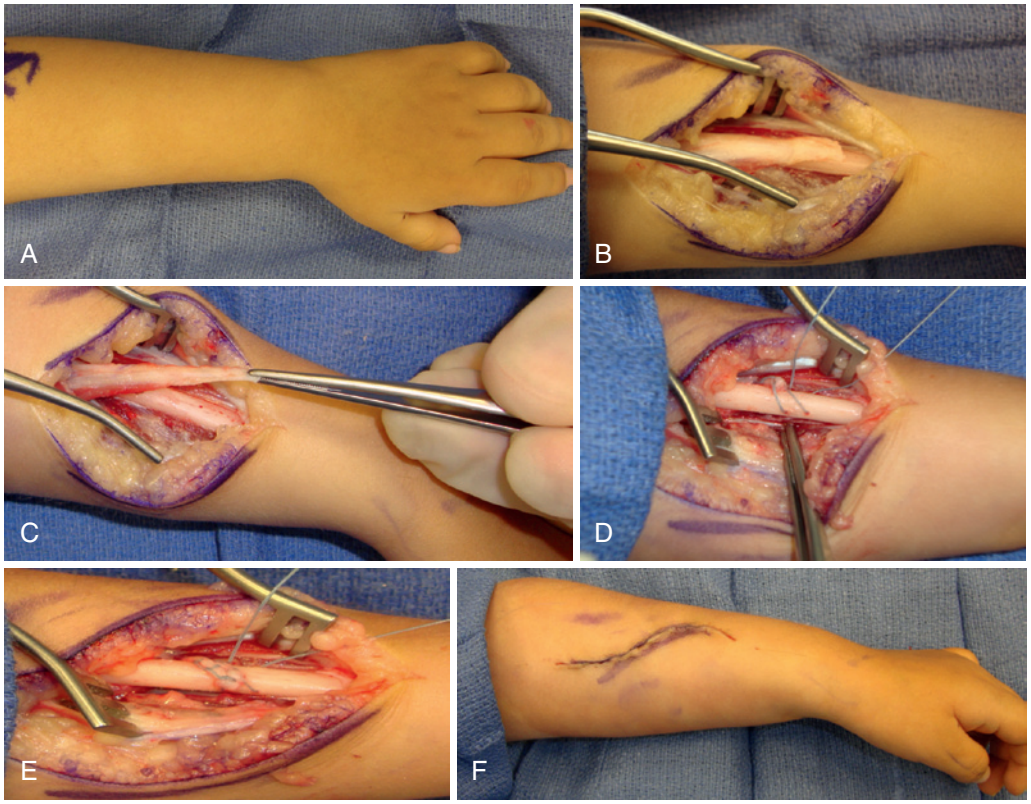

FIGURE 32.13 Pronator rerouting. Through a longitudinal incision in the middle aspect of the forearm **(A)**, the pronator is taken down from its insertion on the radius and routed through the interosseous septum (from volar to dorsal) **(B** and **C)** and reattached to a drill hole in the dorsal radial radius **(D** and **E)**. **F,** Closed incision with passively improved supination. (Reproduced with permission of Children's Orthopaedic Center, Los Angeles.)

CRITICAL POINTS *Pronator Teres Tenotomy or Rerouting*

Indications
- Pronator tenotomy: active supination short of neutral
- Pronator rerouting: weak to no active supination with volitional pronator teres

Contraindications
- No active pronation control
- Fixed deformity

Preoperative Evaluation
- Test for active supination and pronation.

Pearl
- Identify the pronator teres insertion just proximal to the radial sensory nerve as it exits from beneath the brachioradialis muscle.

Technical Points
- Make a longitudinal incision on the radial aspect of the midforearm.
- Protect the medial antebrachial cutaneous nerve.
- Identify the superficial radial nerve.
- Develop the interval between the brachioradialis and the wrist extensors.
- For pronator release, simply divide the tendon completely.
- For pronator rerouting, elevate the insertion of the pronator with a periosteal sleeve.
  - Expose the radius at the level of the insertion.
  - Incise the interosseous membrane at this level over a 2-cm distance.
  - Pass the pronator from volar to dorsal through the interosseous membrane with a right-angled clamp.
  - Suture the pronator to a drill hole in the radial aspect of the radius or use suture anchors in the radius.

Pitfall
- Pronator release or rerouting will not be efficacious in patients with substantial contracture of the forearm. Additional interosseous membrane release, osteotomy of the radius and/or ulna, or a one-bone forearm procedure is necessary.

Postoperative Care
- Use a sugar tong splint or long-arm cast for 1 month with the wrist and forearm in neutral position or midsupination.
- Remove immobilization at 1 month and fabricate a splint that positions the forearm in neutral position or midsupination.
- During the second month, the splint is removed only for therapy.
- Discontinue the splint at 2 months after surgery.

FIGURE 32.14 A patient with good active digital extension but absent wrist extension. (Copyright Michelle Gerwin Carlson.)

techniques that would accomplish this and improve function. Potential donors include the ECU,[54,98,116,119,151] FCU,[28,54,58,63,70-72,78,81,116,156,157,179,183,186,203,205] pronator teres,[32,54,137] and brachioradialis.[124,137] Donor tendons are usually transferred to the ECRB due to its central location on the third metacarpal. When transferring the FCU, an alternative route through the interosseous membrane has been described to decrease the ulnar-deviating force on the wrist,[137] but this also decreases the supination effect of the transfer.[194] The choice of donor is based on a careful physical examination and surgical experience.

In patients with severe fixed wrist capsular contractures, a proximal row carpectomy may be an adjunct to allow extension of the wrist to neutral before tendon transfers can be performed.[133,186] However, this combination is uncommonly performed because proximal row carpectomy yields a small gain in passive wrist extension. Wrist arthrodesis can be used to improve hygiene or function, however[4,67,74,146]; fusion may downgrade function due to loss of the tenodesis effect on the digital tendons.[156] In a child, an epiphyseal arthrodesis or chondrodesis (wrist fusion that preserves the physeal plate) can be performed to allow continued growth if the patient has adequate ossification of the epiphysis and carpal bones. However, fusion is difficult to achieve secondary to the abundant pediatric cartilage.[58]

Weak digital extension is less common than weak wrist extension and is associated with more severe disability.[119] Transfer of the FCU to the extensor digitorum communis (EDC)[58,64,98,116,123] has been recommended to improve digital extension while also improving wrist extension. Tendon transfers always perform best when "asked" to perform a single task, and the surgeon must be careful about "asking" too much from an already compromised muscle-tendon unit. Tendon transfers for digital extension are useful in patients who are unable to actively extend their fingers when the wrist is in extension. Zancolli and Zancolli defined three types of finger extension deformities and suggested a treatment algorithm[212] (Table 32.4). Patients with poor wrist and digital extension may benefit from a combination of tendon transfers, such as FCU to EDC and either ECU or pronator teres to ECRB.

Results of wrist extension transfers have demonstrated improved function in approximately 80% of patients.[9,71,78] FCU to ECRB transfer has shown good results, with an average

TABLE 32.4 Finger Extension Deformities and Their Treatment

Type	Deformity	Treatment
I	Active digital extension possible with wrist extended less than 20 degrees from neutral	No treatment or minimal fractional lengthening of digital and/or wrist flexors
II	Active digital extension possible with wrist flexed more than 20 degrees from neutral	Fractional lengthening of digital flexors in addition to augmentation of wrist extension and/or flexor carpi ulnaris tenotomy
III	No active digital extension	Augmentation of digital extension with flexor carpi ulnaris transfer to extensor digitorum communis

Zancolli EA, Zancolli ER, Jr: Surgical management of the hemiplegic spastic hand in cerebral palsy. *Surg Clin North Am* 61:395–406, 1981.

improvement in resting wrist posture from 41 degrees of flexion to 11 degrees and an improvement in the arc of motion, with increased wrist extension and a compensatory loss of flexion. The total range of motion is unchanged after this procedure, although wrist extension has been shown to improve by 35 to 45 degrees.[9,149,183,186,203] The greatest improvement in function of the hand is seen in patients without flexion contractures who use a wrist flexion to augment digital opening when attempting digital extension.[71] Children with dystonia, neglect, poor stereognosis, and little voluntary limb control will demonstrate inferior outcomes after all wrist extension tendon transfers.[205]

Flexor Carpi Ulnaris to Extensor Carpi Radialis Brevis Transfer (Green's Transfer)

Indication. FCU to ECRB transfer is indicated in patients who have a dynamic wrist flexion deformity, flexible wrist joint, intact although possibly weak finger extensors, and absent or weak wrist extension.[107]

Contraindication. A nonfunctioning FCR is a relative contraindication because the result will be loss of active wrist flexion and a wrist extension deformity. Preoperative FCU evaluation by electromyography can be helpful because children with dystonia and irregular phasic contractions will have unreliable results.[189] If the finger extensors are absent, the FCU may be more appropriately transferred to the EDC. If the wrist joint is inflexible and the digital flexors are tight, additional concurrent procedures need to be performed to provide reliable outcomes after FCU to ECRB transfer.[138]

Technique. The FCU can be harvested through multiple small incisions or a single long ulnar border incision (Figure 32.15). If smaller transverse or longitudinal incisions are used, the first incision is made over the FCU insertion on the pisiform at the wrist flexion crease. Tension on the tendon allows the proximal aspect of the tendon to be palpated. The more proximal incisions are made at proximal palpable points on the tendon in the forearm. Transverse incisions are more aesthetic, but care must be taken to protect the ulnar neurovascular bundle during harvest. In addition, the large muscular and sheath attachments of the FCU along the ulna may make passing the tendon beneath the skin difficult. Following FCU identification within each transverse incision, the FCU is transected at its insertion on the

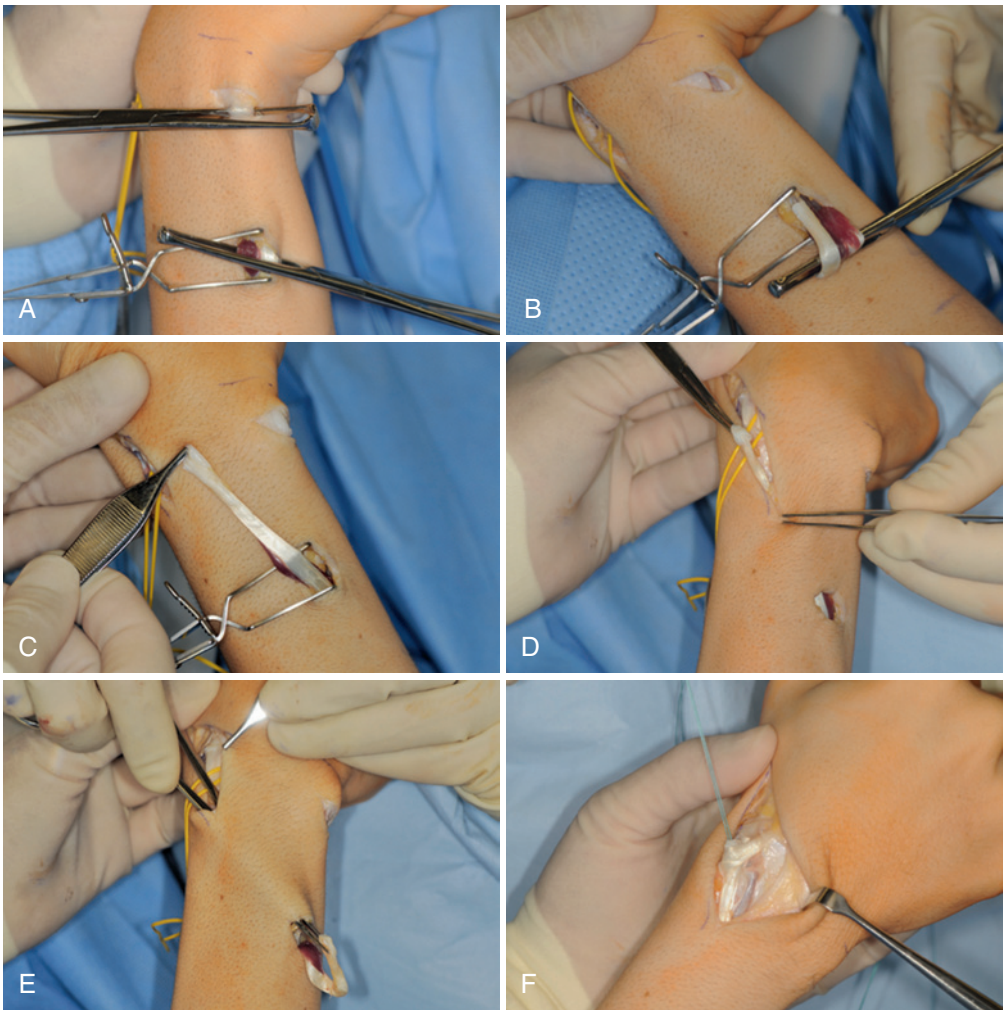

FIGURE 32.15 Flexor carpi ulnaris to extensor carpi radialis brevis transfer. **A** and **B,** The flexor carpi ulnaris tendon is harvested through two volar incisions, one distal at the pisiform and the other over the midforearm. The flexor carpi ulnaris can be harvested using a tendon stripper inserted distally. **C,** The tendon is wrapped over the forearm to mark the site of attachment to the extensor carpi radialis brevis tendon. **D** and **E,** An incision can then be made at this spot and the tendon tunneled subcutaneously. **F,** The length gained from the subcutaneous tunnel allows easy weaving in a Pulvertaft fashion. (Courtesy of Shriners Hospital, Philadelphia.)

pisiform and progressively mobilized through the proximal incisions. The transverse incisions are recommended for surgeons who have considerable experience. Alternately, the incisions can be made longitudinally. To ensure adequate length and estimate insertion location, the tendon is passed around the ulnar aspect of the forearm, over the skin, to the point where it intersects with the ECRB. The goal is to insert the tendon at the wrist rather than within the forearm. This maneuver also ensures ample tendon to allow a Pulvertaft weave. A transverse or longitudinal incision is made over the ECRB at the intended weave site. A subcutaneous tunnel is created from the dorsal incision to the volar ulnar wound. The tunnel should be deep to the subcutaneous tissue and sensory nerves but superficial to all tendons. Care should be taken to ensure that this tunnel is as direct as possible. Any fibrous septa between the FCU and ECU are opened widely to prevent kinking of the muscle as it passes along the ulnar border.

The FCU is passed through this tunnel toward the ECRB insertion. A Pulvertaft weave is performed between the two tendons, with each weave secured with nonabsorbable sutures. The weave should be done with maximal tension on the tendon ends while the wrist is held in neutral to slight extension. Usually, only one or two weaves can be performed. Following the initial weave, tension should be assessed by allowing the wrist to sit in its resting position. Neutral to slight extension is preferred; too loose or too tight is bad.[183] Care should be taken to ensure that the weave does not encroach on the intersection with the EPL or the extensor retinaculum. If this does occur, the EPL can be transposed and/or a portion of the retinaculum divided.

The wrist is immobilized in 30 degrees of extension for 3 to 4 weeks. A splint is worn for 4 to 6 weeks and removed for hygiene, activities, and range-of-motion exercises. Standard tendon transfer training is performed by a hand therapist. Electrical stimulation and biofeedback training can be helpful in patients having difficulty firing the transfer. Nighttime splinting is continued for an additional 3 to 4 weeks and then discontinued.

CRITICAL POINTS *Flexor Carpi Ulnaris to Extensor Carpi Radialis Brevis Transfer*

Indications
- Inability to actively extend the wrist to neutral with a functioning FCU and FCR
- Adequate finger extension with the wrist positioned in extension

Contraindications
- No active control of the FCR
- Dystonia

Pearl
- After tendon transfer, the wrist should passively rest in neutral to slight extension.

Pitfalls
- If weak digital extension is not addressed concurrently, wrist extensor transfer will worsen digital extension and object acquisition.
- Overtightening of the transfer will result in a fixed wrist extension posture and impair digital extension.

Technical Points
- Begin to harvest the FCU at the pisiform because length is always an issue.
- Mobilize the FCU muscle-tendon up to the midforearm.
- Drape the FCU over the skin from the volar wound to the dorsal forearm to assess the location of the tendon weave.
- Create a Pulvertaft weave of the FCU into the ECRB with maximal tension on the tendon and the wrist in neutral to slight extension.

Postoperative Care
- The wrist is splinted in 30 degrees of extension.
- One month after surgery, fabricate a removable wrist extension splint and begin therapy.

Extensor Carpi Ulnaris to Extensor Carpi Radialis Brevis Transfer

Indications. This transfer has become our preferred technique in patients who require augmentation of wrist extension. The ECU is poorly positioned to extend the wrist, however; transfer to the ECRB upgrades this function.

Contraindication. This procedure is contraindicated in patients without any active wrist extension or with existing resting radial deviation of the wrist.

Technique. The technique involves a series of transverse incisions. The first incision is over the ulnar head to isolate the ECU by incising the sixth compartment. The second incision is 6 cm proximal, and the ECU muscle-tendon junction is isolated. The ECU tendon is transected distally at its insertion at the base of the small metacarpal by rolling the tendon with an Allis tissue forceps (Jarit, Elmsford, NY) to deliver the distal tendon into the wound. The ECU is pulled into the proximal transverse incision. The tendon is passed over the skin to the point where it intersects with the ECRB. The goal is to insert the tendon distal to the retinaculum. A transverse incision is made over the ECRB at the intended weave site. A subcutaneous tunnel is created to pass the tendon. The ECU is woven through the ECRB and tension is set to maintain the wrist in slight extension. Following the weave, tension should be assessed by allowing the wrist to sit in its resting position. Neutral to slight extension is the goal. The coaptation is reinforced by an additional weave or side-to-side sutures (Figure 32.16).

This transfer is routinely performed in conjunction with fractional lengthening of the FCU. Immobilization and rehabilitation protocols are similar to those described for the FCU to ECRB transfer.

CRITICAL POINTS *Extensor Carpi Ulnaris to Extensor Carpi Radialis Brevis Transfer*

Indications
- Weak extension of the wrist, especially with ulnar deviation during attempted wrist extension
- Weak extension of the wrist, with the FCU used as a donor for EDC transfer

Pearls
- Routinely lengthen any spastic FCU.
- After transfer, the wrist should passively rest in neutral position or slight extension.

Pitfalls
- If weak digital extension is not addressed concurrently, wrist extensor transfer will hamper digital extension and object acquisition.
- Overtightening of the transfer will impair digital extension.

Technical Points
- Transverse incisions are preferred.
- Transect the ECU as distally as possible.
- Perform a Pulvertaft weave of the ECU into the ECRB with the wrist in neutral position to slight extension.

Postoperative Care
- The wrist is splinted in 30 degrees of extension.
- One month after surgery, fabricate a removable wrist extension splint and begin therapy.

Flexor Carpi Ulnaris to Extensor Digitorum Communis Transfer

Indication. The FCU to EDC transfer is indicated in patients with weak or absent active digital extension.

Contraindication. This transfer is contraindicated in patients with good digital extension and weak wrist extension. The FCR must be volitional. A constantly spastic FCR muscle is a poor donor.

Technique. The FCU is harvested as previously described. The point of attachment to the EDC is identified, with the FCU tendon draped across the skin. A transverse or longitudinal incision is made over the EDC, and the tendons to the index through little fingers are identified. A subcutaneous tunnel is created between the dorsal and ulnar incisions, and the FCU is passed through this tunnel and out the dorsal wound over the EDC. Tension is applied to the EDC tendons to position the MP joints in full extension with the wrist in neutral. The four EDC tendons are sutured together to allow a normal cascade to the fingers before transfer. The FCU is passed through the intact EDC tendons in an ulnar to radial direction, beginning at the small finger EDC tendon and progressing to the index finger

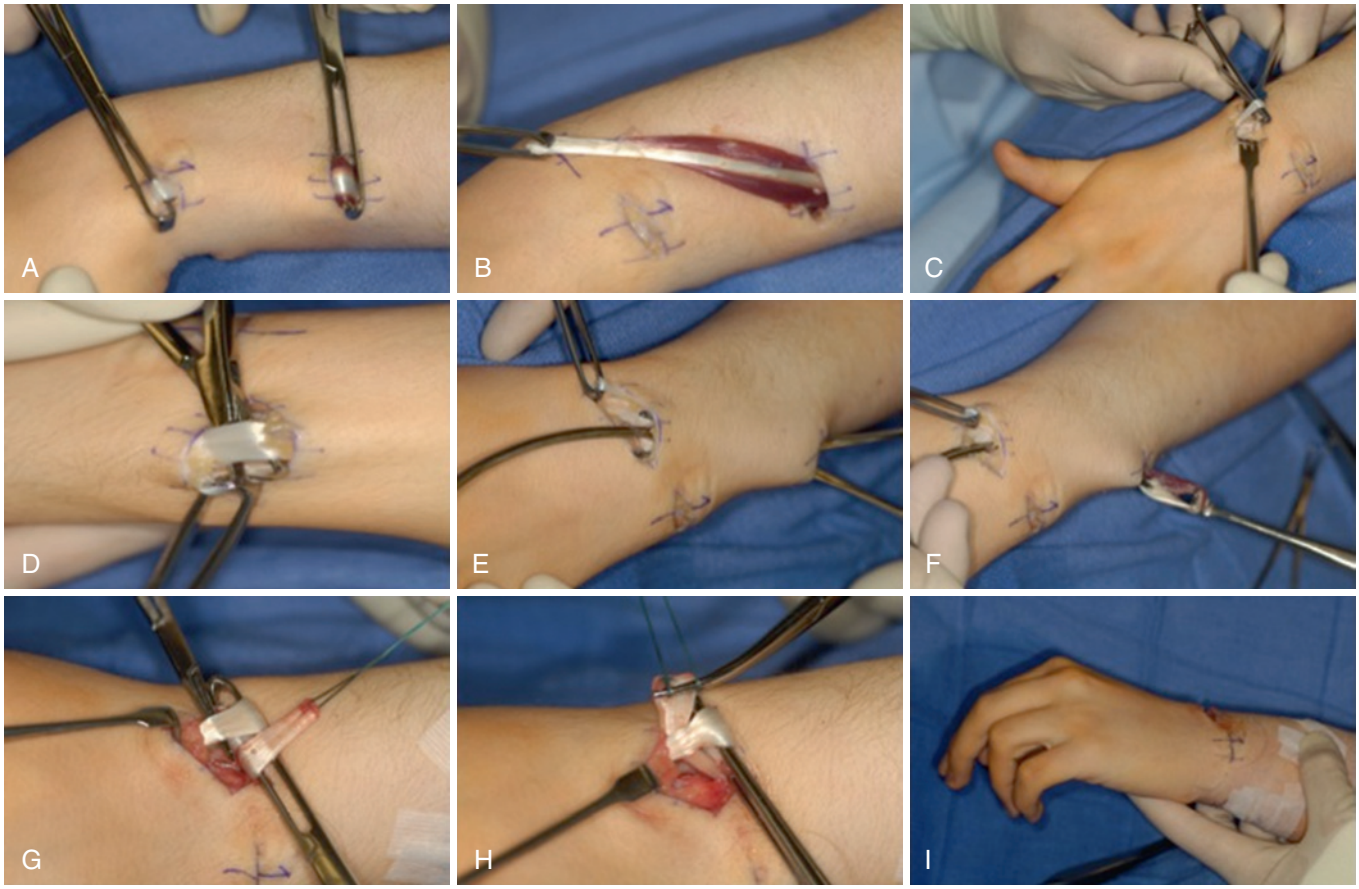

FIGURE 32.16 Extensor carpi ulnaris to extensor carpi radialis brevis transfer. **A,** The extensor carpi ulnaris tendon is harvested through two dorsal incisions, one distal at the carpal insertion and the other over the midforearm. **B,** The tendon is wrapped over the forearm to mark the site of attachment to the extensor carpi radialis brevis tendon. **C,** The incision can then be made at this spot, and the extensor pollicis longus is transposed from the third to the first compartment. **D,** The extensor carpi radialis brevis is identified, and the tendon is tunneled subcutaneously **(E** and **F)**. A Pulvertaft weave **(G** and **H)** is made to complete the transfer and stabilize the wrist **(I)** in a neutral position. (Courtesy of Shriners Hospital for Children, Philadelphia.)

tendon. This is done proximal to the retinaculum, with the retinaculum left in place to prevent bowstringing. Each weave is sewn into place with nonabsorbable sutures. The FCU is passed back in a radial to ulnar direction through the EDC tendons and sutured in place. If length permits, it may be passed a third time.

The extremity is immobilized for 4 weeks in a splint with the wrist in 30 degrees of extension and the digits fully extended. A removable forearm-based splint is fabricated, maintaining digital extension for another 4 weeks; it is removed for therapy and range-of-motion exercises. Night splinting is continued as necessary to avoid recurrence of the deformity.

CRITICAL POINTS *Flexor Carpi Ulnaris to Extensor Digitorum Communis Transfer*

Indications
- Weak or absent active digital extension, with full passive digital extension
- Functioning FCU and FCR

Pearl
- If digital flexors are tight, test for active digital extension with the wrist in flexion.

Pitfall
- The FCR must be strong, or a wrist extension deformity may result.

Technical Points
- Harvest the FCU tendon as for the FCU to ECRB transfer.
- Identify the location of transfer, as in the FCU to ECRB protocol.
- Make a transverse incision in the dorsal forearm over the EDC junction.
- Identify the EDC tendons to the index, long, ring, and little fingers, and suture them together distally, creating a normal cascade, while applying tension proximally.
- Make a subcutaneous tunnel from the volar wound to the dorsal wound and pass the FCU tendon.
- Weave the transected FCU into the intact EDC with the wrist in neutral and maximal tension on the EDC.

Postoperative Care
- Apply a dressing with a forearm-based digital extension splint for 4 weeks.
- Fabricate a removable splint for 4 weeks and begin range-of-motion exercises.
- Discontinue splinting at 8 weeks after surgery.

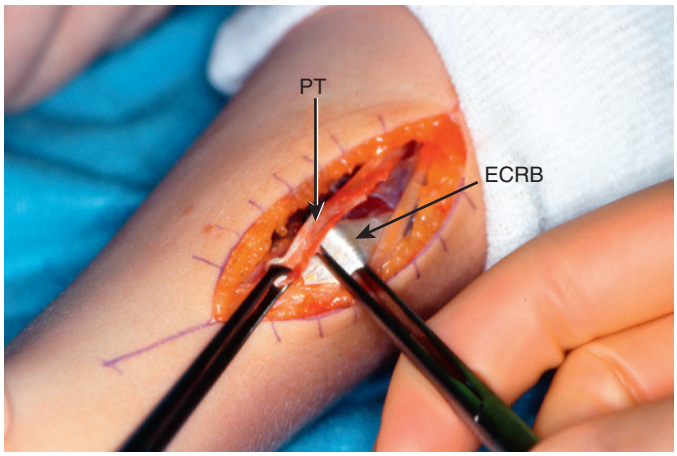

FIGURE 32.17 The pronator teres (PT) tendon is harvested with a strip of periosteum and transferred to the extensor carpi radialis brevis (ECRB) tendon. (Courtesy of Shriners Hospital for Children, Philadelphia.)

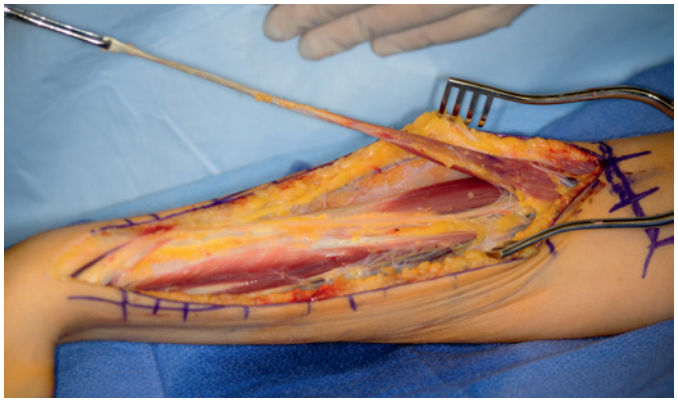

FIGURE 32.18 Brachioradialis tendon is released and mobilized into the proximal third of the forearm to maximize available excursion. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Pronator Teres to Extensor Carpi Radialis Brevis Transfer

Indication. This procedure is an option in patients without a functioning FCR, in whom harvest of the FCU is contraindicated. Fractional lengthening of a spastic FCU should be done in conjunction with pronator transfer. The pronator teres is a viable candidate for augmentation of wrist extension when the FCU or ECU is unavailable.

Contraindications. This procedure limits the arc of motion of the wrist as a result of the short excursion of the pronator and is relatively contraindicated in patients with pronator spasticity. Patients who are dependent on wrist flexion for digital extension may have increased difficulty opening the hand.

Technique. A longitudinal incision is made over the insertion of the pronator in the radial midforearm. The subcutaneous tissue is dissected, and the medial antebrachial cutaneous and superficial radial nerves are identified and protected. The interval between the brachioradialis and the wrist extensors is developed, and the insertion of the pronator is identified. The pronator teres is elevated from the radius with an extended periosteal sleeve (Figure 32.17). A Pulvertaft weave can be performed between the pronator teres and intact ECRB. Tension is set so that there is maximal tension on each tendon, and the wrist is in a neutral position to slight extension. The resting posture of the wrist should also be neutral position to slight extension.

Immobilization is as described for the FCU to ECRB transfer.

Brachioradialis to Extensor Carpi Radialis Brevis Transfer

Indication. The brachioradialis can be effective for transfer when other motor muscles are unavailable. The muscle originates above the elbow; firing requires concomitant active elbow extension to prevent unwanted elbow flexion. The muscle must be dissected into the proximal forearm to increase its excursion.[105a]

Technique. The brachioradialis is approached through a long longitudinal radial incision (Figure 32.18). The brachioradialis insertion on the distal radius is identified and transected while the radial artery and nerve are protected. The brachioradialis is mobilized proximally and freed from the ECRL and FCR. The tendon is placed adjacent to the ECRB. The brachioradialis is woven into the ECRB with the goal of establishing slight wrist extension with the elbow extended.

The arm is immobilized in a long-arm cast for 4 weeks. We prefer to have the elbow in flexion to lessen tension during the healing process. A short-arm removable splint is worn for another 4 weeks while range-of-motion exercises and therapy are initiated. Night splinting is continued as indicated.

❖ Authors' Preferred Method of Treatment

In the functional hand, the decision to perform a transfer to the wrist or digital extensors is based on the physical examination (see Video 32.2). First, testing of active digital extension is performed with the wrist held in a neutral position (Figure 32.19). If full active extension is possible, no transfer is necessary for the digital extensors. If full active digital extension is not possible but the digits can be extended passively, a transfer to motor the digital extensors is considered. We prefer an FCU to EDC transfer for this deformity. A transfer to the wrist extensors in this situation without addressing the fingers would worsen hand function because the patient would be unable to open the fingers and acquire objects.

If passive extension of the digits is limited when the wrist is held in full extension, a fractional lengthening of the digital flexors is necessary. Active digital extension is tested with the wrist flexed. Good digital extension indicates that a transfer will probably not be necessary after release of the tight digital flexors. Limited active digital extension with the wrist flexed, however, indicates that a transfer will be necessary to augment extension in addition to lengthening of the digital flexors. Usually, the FCU to EDC transfer is a good option.

After testing digital extension, wrist extension should be tested. It is helpful to think of wrist flexion deformities as being in three groups: functional, dynamic, and static. Patients with functional deformities of the wrist may have good active range of motion, but when they are performing activities, the wrist drops into flexion. Treatment involves fractional lengthening of the spastic flexors (usually, the FCU). No transfer for wrist extension is needed.

Dynamic deformities of the wrist, by definition, have no static contracture component. Patients may or may not have some limited active extension but cannot extend the wrist to

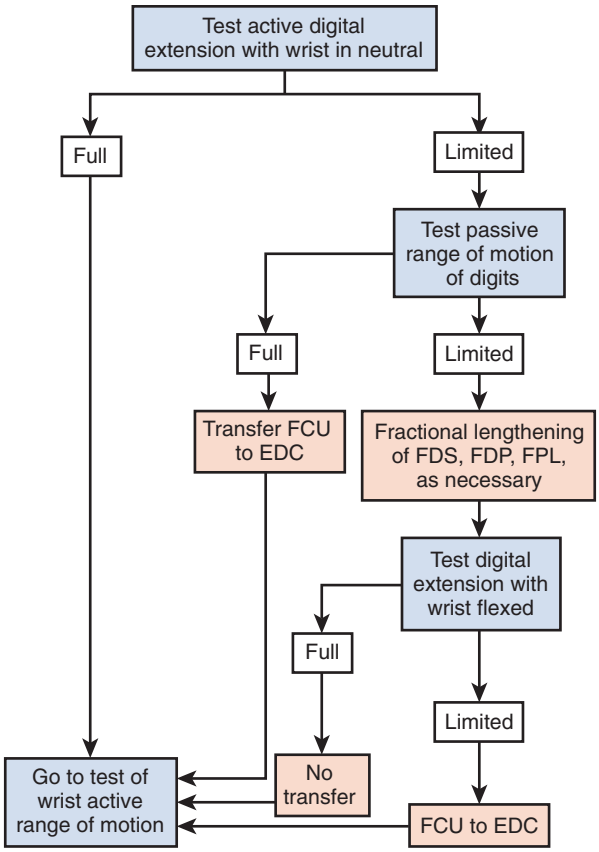

FIGURE 32.19 Algorithm for evaluation of digital extension. *EDC*, Extensor digitorum communis; *FCU*, flexor carpi ulnaris; *FDP*, flexor digitorum profundus; *FDS*, flexor digitorum superficialis; *FPL*, flexor pollicis longus.

neutral. Passive extension of the wrist and digits should be evaluated. If there is full passive extension of the wrist and digits, a transfer to augment wrist extension is indicated. We prefer an FCU to ECRB or ECU to ECRB transfer depending on the clinical examination findings and the amount of wrist extension force necessary. The FCU will provide more force but carries the risk of too much wrist extension. In contrast, the ECU has less force but has the risk of suboptimal wrist extension.

Fixed or static wrist flexion contractures usually occur in older children or adults. A contracture that interferes with function may warrant treatment. Rarely, a tendon transfer is possible; a decision about this can be made at the time of surgery. After release or lengthening of the wrist flexors, the passive extension of the wrist is assessed. If passive extension to neutral is possible, an FCU to ECRB transfer may be performed. In a wrist with no active flexion or extension prior to surgery, wrist arthrodesis is preferred following tenotomy of the FCR, FCU, and palmaris longus (Figure 32.20). The position of wrist fusion must be carefully designed to correlate with digit tenodesis.[67] A flat or neutral plate is most commonly used because digital extension is weak. Substantial weakness of digital extension requires fusion in some flexion to augment digital opening.

Wrist and Digital Flexor Tendon Tightness

Condition

Wrist and digital flexor tightness should be addressed concurrently with wrist and digit extension weakness to provide reliable outcomes. Wrist flexion deformity is caused primarily by spasticity or contracture of the FCU tendon, with lesser contributions from the FCR and the palmaris longus. Digital flexor tightness can also contribute to the wrist flexion deformity and is measured by the Volkmann angle (see Figure 32.4). In extreme digital flexor tendon tightness, no extension of the wrist is possible when the digits are held extended. Active or passive extension of the wrist to less than neutral identifies flexor tendon tightness that needs to be addressed surgically (Figure 32.21).

Types of Operative Procedures

There are several procedures for lengthening the flexor tendons, including the flexor-pronator slide,[85,136,186,204] fractional lengthening procedure,[54,63,116,122,123,186] "Z"-lengthening procedure,[63] and superficialis to profundus transfer.[16] Less commonly, bony shortening (proximal row carpectomy)[133,162,186] or wedge resection arthrodesis is done.[119] Wrist flexor tendons may be lengthened by fractional lengthening or "Z"-lengthening. If both the FCR and FCU are involved, at least one should be kept in continuity to enable active wrist flexion, although it may be lengthened.

All digital flexor tendon lengthenings temporarily if not permanently weaken the power of the muscle, but this is compensated for by an increase in grip strength secondary to improved extension of the wrist. Weakening of the flexors is minimized by fractional lengthening and is most pronounced with superficialis to profundus transfer. Superficialis to profundus transfer is used primarily when hygiene is the main goal because limited digital flexion and grasp are expected.[16] The effect of "Z"-plasty lengthening falls between these two lengthening techniques.

Bony procedures are reserved for skeletally mature patients. Maintenance of wrist mobility and tendon transfers are desirable when possible.

Flexor-Pronator Muscle Slide

Indications. A flexor origin slide is indicated when substantial function of the digits is not expected and the forearm is contracted into pronation. In addition, selective lengthening of the digital and wrist flexors is not possible.

Technique. See the description earlier in the section on the forearm.

Fractional Tendon Lengthening

Indications. Fractional flexor tendon lengthening is indicated in the functional hand when the digits cannot be fully straightened with the wrist held passively at neutral but they can be fully straightened when the wrist is flexed. Fractional flexor tendon lengthening is the optimal way to lengthen the flexor tendons, with the least risk of excessive lengthening of the tendons and a weakened grip.

Contraindication. If the digits cannot be fully extended with the wrist flexed, fractional tendon lengthening is not likely to produce enough length. "Z"-lengthening or superficialis to profundus transfer should be considered in these cases.

Technique. The musculotendinous junctions of the digital flexor tendons can be palpated on the midaspect of the volar forearm. Exposure is gained through a 4-cm longitudinal incision centered over the musculotendinous junction. Enough of the musculotendinous junction must be exposed to allow two

FIGURE 32.20 Wrist arthrodesis. Indications for skeletally mature static contracture **(A** to **C)** may require additional volar tenotomy of the flexor carpi radialis, flexor carpi ulnaris, and palmaris longus. **D** to **H,** Dorsal incision with transposition of the extensor pollicis longus and elevation of the fourth and second compartments**;** proximal row carpectomy, and removal of cartilage from surfaces; plate fixation of the wrist in neutral under compression. (Courtesy of Shriners Hospital for Children, Philadelphia.)

tenotomies in this region. Two oblique tenotomies are made at least 1 cm apart in the musculotendinous junction of each tendon to be lengthened (Figure 32.22). The distal tenotomy should be at least 2 cm proximal to the distal aspect of the musculotendinous junction. The muscular portion of the musculotendinous junction must be kept intact. The wrist is held in neutral, and gentle passive extension of the digits just short of the desired length is performed. The digits should not be fully extended. Overcorrection of the digits during surgery will result in excessive weakening of the flexor tendons and possible swan neck deformities of the fingers.

The arm is immobilized in a plaster splint with the wrist in neutral for 4 weeks. Unrestricted finger motion is allowed immediately postoperatively, and the patient is instructed on the use of digital extension exercises to actively adjust the fractional lengthening. The plaster splint is removed at 4 weeks, and a removable wrist splint is applied to allow wrist range of motion and therapy. At 8 weeks, splinting is discontinued unless recurrence of the deformity requires night splinting. Postoperatively, if the patient has difficulty actively extending the digits, a volar digital stretching splint may be added.

Tendon "Z"-Lengthening

Indication. "Z"-lengthening produces a greater amount of tendon lengthening than fractional lengthening. Z"-lengthening is frequently used to lengthen the FPL tendon when it cannot be fully extended even with the wrist fully flexed. In this situation, it is unlikely that fractional lengthening will be sufficient. For the FPL, the amount of lengthening performed should be 0.5 mm for every degree of desired correction (e.g., 2.5 cm for a 50-degree contracture).[60] However, the formula is based on clinical experience without scientific evidence.

Contraindication. "Z"-lengthening is not used for individualized digital flexors when the procedure is deemed inadequate to provide sufficient length. A flexor origin slide or superficialis to profundus transfer is effective and unlikely to cause uneven lengthening.

Technique. A longitudinal incision is made in the volar forearm over the tendon to be lengthened. As much of the tendon as possible is exposed. A longitudinal split is made in the tendon in a proximal to distal fashion, extended as long as possible. The effective lengthening of the tendon will be twice the length of this longitudinal split minus the length needed for

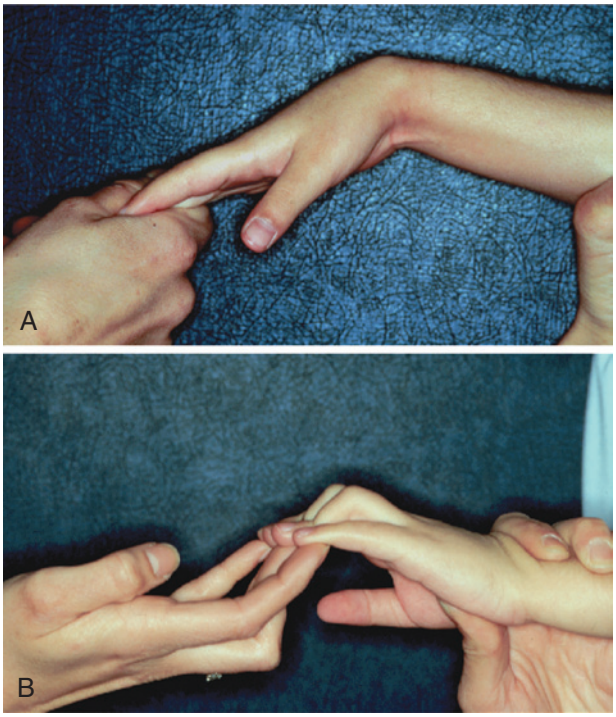

FIGURE 32.21 Flexor tendon tightness. **A**, Tight digital flexors allow wrist extension to only minus 45 degrees with the digits held extended. **B**, With the wrist held extended, the digits cannot be passively fully extended. (**A** and **B**, Copyright Michelle Gerwin Carlson.)

CRITICAL POINTS *Fractional Tendon Lengthening*

Indication
- For patients unable to fully passively extend their fingers with the wrist in neutral

Pearl
- If the surgeon cannot fully passively extend the patient's fingers with the wrists flexed, fractional lengthening will not produce adequate tendon lengthening.

Pitfall
- Resist the temptation to fully passively extend the digits intraoperatively because this may lead to overlengthening that will impair grasp.

Technical Points
- Make a 4-cm longitudinal incision centered over the musculotendinous junction of the digital flexors in the forearm.
- Perform two oblique tenotomies in the musculotendinous junction of each tendon spaced 1 cm apart.
- Perform tenotomies at least 2 cm proximal to the most distal aspect of the musculotendinous junction.

Postoperative Care
- Immobilize the wrist in neutral position for 4 weeks with the digits not included.
- Immediately begin digital active and passive range-of-motion exercises.
- If the patient has difficulty extending the digits, add a volar digital extension splint.

the repair. The hemitendon is divided radially at one end and ulnarly at the other to complete the transection of the tendon. The ends are woven with a Pulvertaft or side-to-side technique at the desired tension. For the wrist flexors, the tension should be set with the wrist in a neutral position. For the thumb, the tension should be set with the wrist at neutral and the thumb MP and IP joints in slight flexion. With extension of the wrist, the thumb should cross the index finger. With flexion of the wrist, the thumb should be able to be fully extended out of the palm.

After wrist flexor tendon lengthening, the wrist is immobilized in slight flexion for 4 weeks. For the FPL, the wrist is immobilized in slight flexion and the thumb in neutral for 4 weeks. After 4 weeks, a removable splint is applied, and therapy and range-of-motion exercises are begun. Splinting is discontinued at 8 weeks.

CRITICAL POINTS *Tendon "Z"-Lengthening*

Indications
- Tight wrist flexors or for FPL tendon lengthening
- Produces more tendon lengthening than fractional lengthening

Pearls
- Always make the arms of the "Z" as long as possible.
- Effective lengthening is two times the length of the split minus the length of the repair.

Pitfall
- If the arms of the "Z" are too short, sufficient lengthening of the tendon will not occur.

Technical Points
- Make a longitudinal split in the tendon.
- Divide the hemitendon slip on opposite sides of the tendon proximally and distally.
- Overlap the proximal and distal ends of the tendon in a side-to-side fashion with the desired tension, and use horizontal mattress sutures or a running suture.

Postoperative Care
- Immobilize the wrist and thumb (for FPL lengthening) in neutral position for 4 weeks.
- Begin active and passive range-of-motion exercises at 4 weeks.
- Wear a removable splint for 4 weeks.

Superficialis to Profundus Tendon Transfer

Indication. The superficialis to profundus transfer is indicated when substantial contracture of the digital flexors is present and the fingers cannot be passively extended even with the wrist fully flexed. If the FPL is contracted, it is usually treated with "Z"-lengthening as described above.[15]

Contraindication. This procedure should be used with extreme caution in patients with functional use of the hand because it results in substantial weakening of grip.

Technique. Through a longitudinal incision in the distal forearm, the superficialis and profundus tendons are identified. With the fingers in a normal cascade, the profundus tendons are sutured together distally and the superficialis tendons are

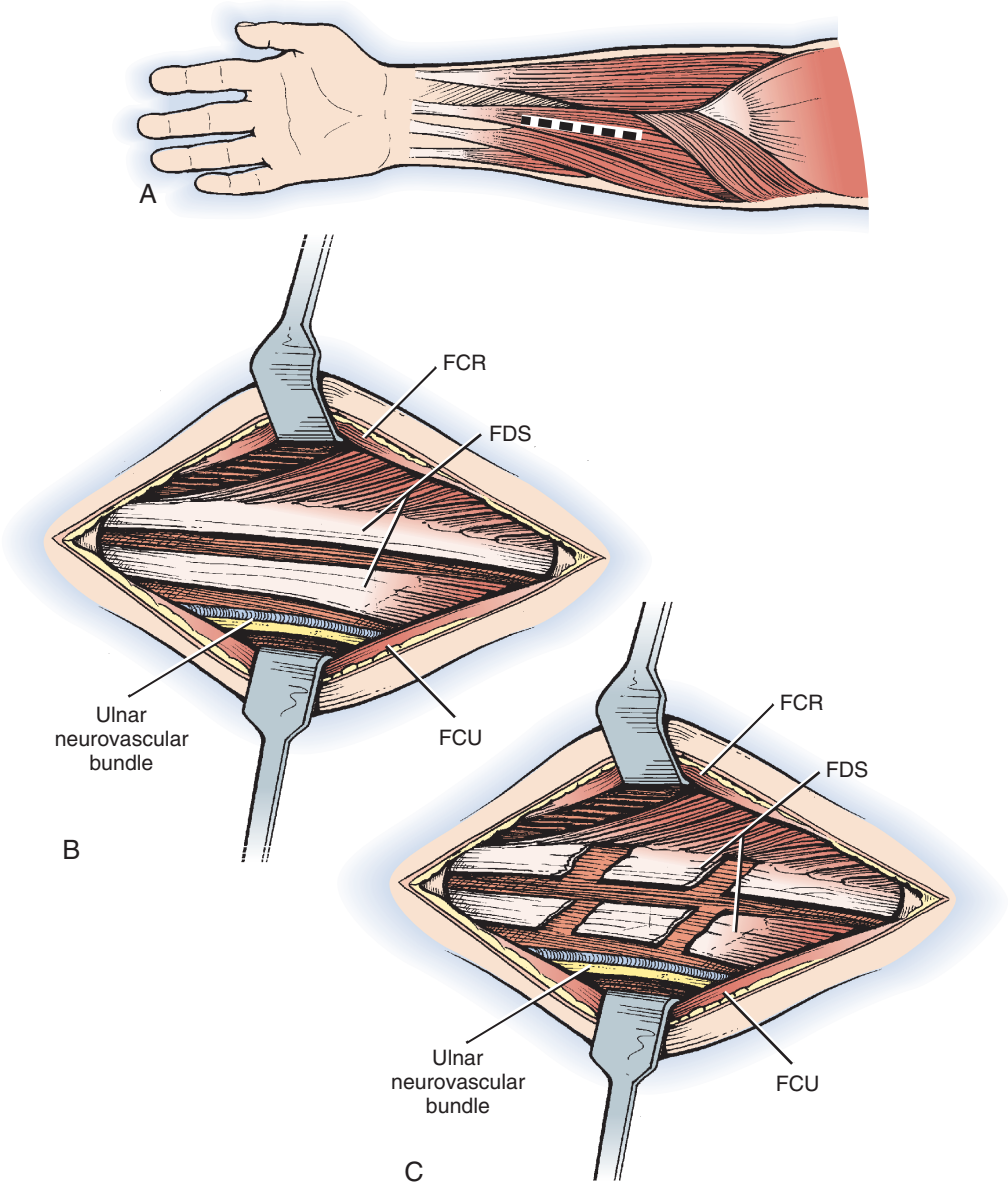

FIGURE 32.22 Fractional lengthening of the digital flexors. **A,** The incision is planned over the musculotendinous junction of the digital flexors. **B,** The ulnar neurovascular bundle and flexor carpi radialis (FCR) are retracted, and the superficial flexors (flexor digitorum superficialis [FDS]) are exposed. **C,** Two oblique incisions are made in the tendinous portion of each musculotendinous junction (see text for precise locations). The bridging muscle fibers are preserved. The flexor digitorum superficialis can then be retracted, and the flexor digitorum profundus is addressed in a similar fashion. *FCU,* Flexor carpi ulnaris.

sutured together proximally before transection. The superficialis tendons are transected distally, and the profundus tendons are transected proximally. Tension during repair is set with the wrist at neutral and the digits flexed 45 degrees at the MP and PIP joints (alternatively, the wrist is flexed 20 degrees and the MP and PIP joints are flexed 20 degrees). With the wrist extended 45 degrees, the digits should touch the palm; with wrist flexion, the digits should be able to be fully extended. The repair is performed in a side-to-side fashion (Figure 32.23).

The arm is immobilized for 4 weeks with the wrist in neutral, the MP joints flexed 90 degrees, and the PIP joints in extension. A removable splint is then used for 4 weeks, and range-of-motion exercises and therapy are begun. At 8 weeks, splinting is discontinued.

❖ Authors' Preferred Method of Treatment

If the wrist cannot be extended at all from the fully flexed position, "Z"-lengthening of the wrist flexor tendons (FCR, FCU) is usually necessary. If partial extension is possible, fractional lengthening is usually sufficient.

If the fingers can be fully passively extended with the wrist flexed, we perform fractional lengthening to allow extension of the digits with the wrist extended. Fractional lengthening has the added benefit of permitting minute adjustments in tension and allowing the patient to increase the lengthening with active digital extension in the immediate postoperative period. If the digits cannot be fully extended with the wrist flexed, "Z"-lengthening or superficialis to profundus transfer is necessary.

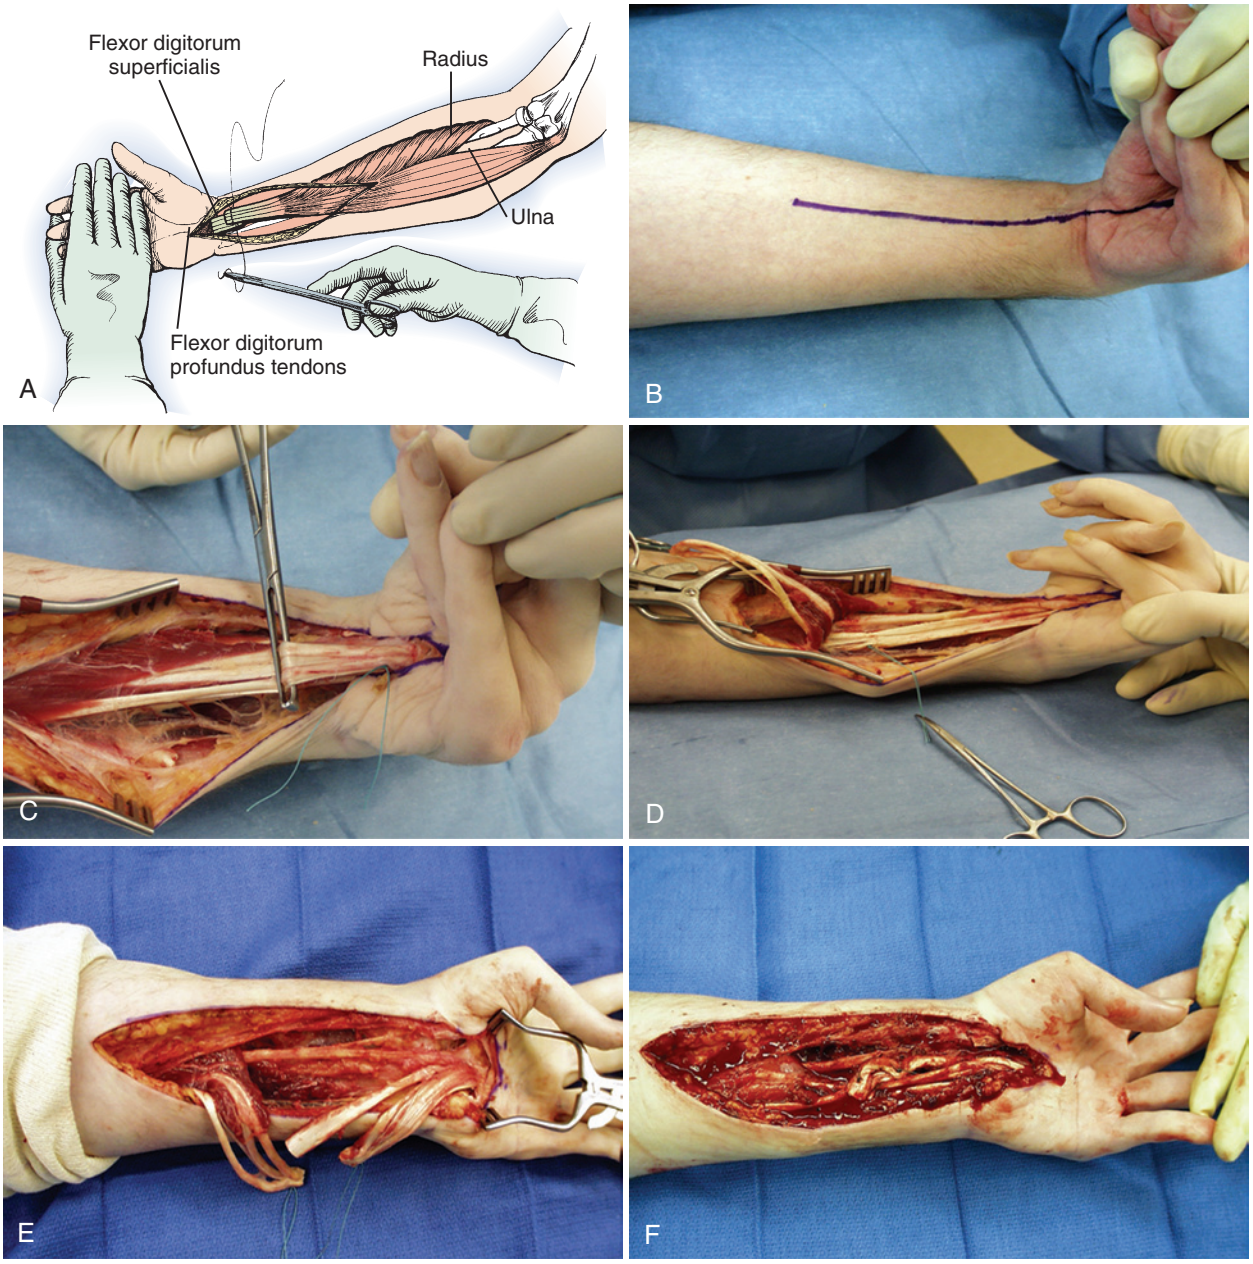

FIGURE 32.23 **A,** Superficialis to profundus tendon transfer. The four superficialis tendons are sutured together distally and transected for transfer. The profundus tendons are sutured together proximally and cut. The fingers are extended, and the distal ends of the superficialis tendons are sutured en masse to the proximal end of the profundus tendons. **B** to **F,** Intraoperative photographs of a superficialis to profundus tendon transfer. (**A,** From Keenan MA, Kozin SH, Berlet AC: *Manual of orthopaedic surgery for spasticity,* New York, Raven Press, 1993.)

"Z"-lengthening of the digital flexors is tedious, because nine "Z"-lengthenings are usually required (four FDS, four FDP, one FPL). We prefer superficialis to profundus transfer with "Z"-lengthening of the FPL. In a nonfunctional hand with tight wrist and digital flexors, carpal wedge resection and wrist arthrodesis provide a stable platform, improve position/hygiene, and effectively lengthen the finger flexors (see Figure 32.20).

Thumb-in-Palm Deformity

Condition

Flexion of the thumb into the palm of the hand is one of the greatest obstacles to good hand function in patients with spasticity. The cause of thumb-in-palm deformity is multifactorial and often difficult to decipher. When evaluating a child with this deformity, four key elements must be considered: (1) spastic flexors and adductors, (2) flaccid extensors and abductors, (3) hypermobile MP joint, and (4) web space skin contracture. The spastic thumb flexors and adductors are the FPL, adductor pollicis, first dorsal interosseous, and FPB. Spasticity of these muscles can be identified by examining the extremity during use and by passively abducting the thumb while palpating the tendons. During use, the thumb metacarpal assumes an adducted position when the adductor and first dorsal interosseous are spastic. Similarly, the spastic FPB flexes the MP joint. FPL spasticity is examined with the wrist held in both flexion

CRITICAL POINTS *Superficialis to Profundus Transfer*

Indications
- Substantial contracture of the digital flexors
- No ability to passively extend the fingers even with the wrist flexed
- Difficulties with hygiene

Pearls
- In patients with comorbidities, this procedure can be done under regional anesthesia.
- If the FPL is contracted, it will require "Z"-lengthening.

Pitfall
- Overlengthening of the transfer will weaken the digits and can result in a hyperextension deformity of the fingers.

Technical Points
- Make a longitudinal incision over the volar forearm centered over the musculotendinous junction.
- Transect the superficialis tendons distally and the profundus tendons proximally.
- Suture the tendons individually if there is function of the digits, and suture them together if there is little function.
- If tendons are to be sutured as a group, suture the profundus tendons together distally and the superficialis tendons proximally before transection to maintain the normal cascade.
- Tension the repair with the wrist in neutral position and the digits flexed 45 degrees at the MP and PIP joints.
- With wrist extension, the fingers should touch the palm, and with wrist flexion, full extension of the fingers should be possible.
- Repair the tendon ends in a side-to-side fashion.

Postoperative Care
- Immobilize the wrist in neutral with the MP joints flexed 90 degrees and the PIP joints in extension for 4 weeks.
- Use a removable splint for 4 weeks and begin active and passive range-of-motion exercises.

and extension, to demonstrate flexion of the thumb MP and IP joints. If the thumb IP joint is fixed in full flexion when the wrist is positioned at neutral and the thumb metacarpal is gently abducted, the FPL needs to be lengthened.[84]

Extensor and abductor functions of the thumb are performed by the EPB, EPL, and APL. Function of each of these muscles should be tested with the wrist flexed and extended. Often the EPL functions well, and when the patient reaches for an object, the IP joint extends, despite the flexion and adduction of the thumb metacarpal.[115]

MP joint hypermobility is a concern when considering tendon transfers to augment abduction and extension. If the MP joint can be passively extended beyond neutral, these transfers may produce undesirable hyperextension of the MP joint instead of abduction and extension of the thumb ray. In addition, any release of the adductor pollicis lessens MP joint flexion. Last, a soft tissue contracture of the skin of the web space can exacerbate the deformity.

Several classification systems of thumb-in-palm deformity have been developed.[84,120,151] (House and colleagues[84] and Sakellarides and coworkers[151] both described four-part classifications (Tables 32.5 and 32.6).

Types of Operative Procedures

Operative procedures are directed at each of the four elements of the deformity: (1) release of the spastic intrinsic and extrinsic flexor and adductor muscles, (2) augmentation of the weak extensor and abductor muscles, (3) stabilization of the thumb MP joint, and (4) release of the skin web space contracture.[21]

Spasticity of the thumb intrinsics is present in almost all thumb-in-palm deformities. Attention should be directed to the adductor pollicis, FPB, and first dorsal interosseous muscles. If flexion of the thumb MP joint is not a noteworthy component of the deformity, the FPB is probably not involved. Release of the adductor can be performed at its origin or insertion.[56,65,80,84,86,90,98,116,121,137,151,163,177,185,191,212] Hoffer and colleagues[80] recommended that if selective control of the adductor can be demonstrated by dynamic electromyography, release of its origin to preserve function should be performed. If there is no

TABLE 32.5 House Classification of Thumb-in-Palm Deformity

Type	Description	Involved Elements
1	Simple metacarpal adduction contracture	Spastic adductor and first dorsal interosseous
2	Metacarpal adduction contracture with MP flexion deformity	Spastic adductor, first dorsal interosseous, flexor pollicis brevis
3	Metacarpal adduction contracture with MP hyperextension and instability	Spastic adductor, first dorsal interosseous, extensor pollicis brevis

TABLE 32.6 Sakellarides Classification of Thumb-in-Palm Deformity

Type	Elements	Treatment
1	Weak extensor pollicis longus	Transfer of palmaris or flexor carpi radialis to extensor pollicis longus
2	Spastic or contracted thumb intrinsics	Release of thenar muscles, first dorsal interosseous, contracted thumb release, web space release as needed
3	Weak abductor pollicis longus	Rerouting of abductor pollicis longus around flexor carpi radialis
4	Spastic or contracted flexor pollicis longus	"Z"-lengthening of flexor pollicis longus

Sakellarides HT, Mital MA, Matza RA, Dimakopoulos P: Classification and surgical treatment of the thumb-in-palm deformity in cerebral palsy and spastic paralysis. *J Hand Surg [Am]* 20:428–431, 1995.

voluntary control of the adductor, release of the muscle from its insertion should be performed. The spastic FPL should be lengthened.[157]

Augmentation of thumb extension and abduction with a variety of tendon transfers has been described, including the brachioradialis,[56,124,149,163] palmaris longus,[56,84] FCR and FCU,[56,65,84,86,90,157,163,177] ECRL and ECRB,[121,163] and FDS.[27,54,56,63,137,157] Results of brachioradialis to APL transfer have not demonstrated significant improvement in active abduction,[163] but transfer to the EPB may be more successful.

Other procedures to improve extension include rerouting of the EPL and FPL abductorplasty.[19,39,56,119,145,151,157,167,169,185,191] Imbrication of the APL and EPB has also been described and is effective when EPL function is weak.[54,62,121,129,179]

Augmentation of thumb extension and abduction causes undesirable MP joint hyperextension and is less effective for thumb ray abduction if the MP joint can hyperextend passively more than 20 degrees. Arthrodesis or chondrodesis of the MP joint prevents hyperextension,[54,58,84,86,105,156,178,179] and the resulting limitation of flexion is an advantage in the correction of thumb-in-palm deformity. MP joint capsulodesis has been described but is less reliable.[29,52,161,167] Metacarpal bone block with fusion of the thumb carpometacarpal (CMC) joint has been described,[27,56,141,156,171] but it is seldom performed because it markedly decreases pinch and makes it difficult for the hand to get into smaller openings such as shirtsleeves.

Finally, in hands with no functional motors available for transfer to abduct the thumb, transfer of the abductor end to side to the FCR tendon can provide a passive tenodesis.[84] However, this tenodesis may attenuate over time. Soft tissue contracture of the skin of the first web space should be addressed in these patients.[19,39,54,84,86,137,185,191]

Release or Slide of the Origin of Spastic Thumb Intrinsic Muscles

Indication. Release of the origin of the thumb intrinsic muscles is indicated when there is selective control of the muscles but they are contributing to the deformity.

Contraindication. If there is no selective control of the adductor pollicis, release of the muscle from its origin is less likely to be effective, and release of its insertion should be performed.

Technique. Under tourniquet control, a curved incision is made along the thenar crease extending from the wrist to the base of the index finger (Figure 32.24).[119,120] The thenar muscles (abductor pollicis, opponens pollicis, and FPB) are sharply elevated from their origins on the transverse carpal ligament. The thumb is progressively abducted to maintain tension on the thenar muscles as they slide in a distal direction. The recurrent motor branch of the median nerve must be identified and protected. Once the superficial thenar muscles have been released, attention is directed to the deeper adductor muscle.

The adductor pollicis is exposed in the interval between the common digital nerve of the index and long fingers and the flexor tendons of the long finger. The origin of the muscle from the third metacarpal is dissected free in a distal to proximal direction. The deep palmar arch and motor branch of the ulnar nerve are identified between the oblique and transverse heads of the adductor and protected. Complete detachment of the muscle origin from the metacarpal is necessary. The proximal extent of the deep exposure is limited by the deep vascular arch.

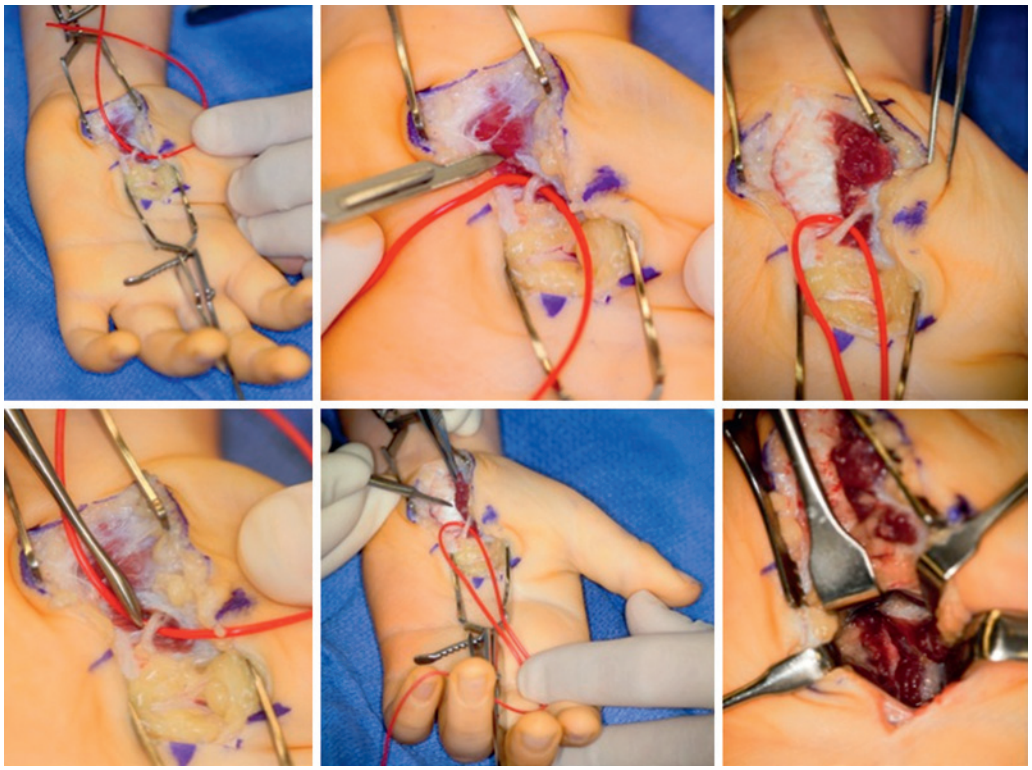

FIGURE 32.24 Nine-year-old with spastic thumb-in-palm deformity treated with slide of the origin of the thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 32.25 Correction of thumb-in-palm deformity. **A,** Thumb-in-palm prevents this patient from grasping a bottle. **B,** Double-opposing "Z"-plasty for release of the adductor pollicis and the first dorsal interosseous. **C,** The adductor is visualized volarly, and the first dorsal interosseous dorsally. **D,** Release of the tendinous portion of the adductor with the muscular attachment left intact. **E,** Complete release of the adductor and first dorsal interosseous muscles. **F,** Postoperative appearance of the hand. **G,** The patient is now able to grip a bottle. (**A** to **G,** Copyright Michelle Gerwin Carlson.)

The FPB can be identified in the proximal part of the incision and detached from the transverse carpal ligament if an MP flexion deformity is present. The origin of the first dorsal interosseous can be released through this incision or through a separate longitudinal incision over the dorsal aspect of the thumb metacarpal. The muscle's origin is dissected off the metacarpal, with care taken to protect the princeps pollicis vessels at the base of the metacarpal.

The thumb and wrist are immobilized for 4 weeks in neutral position with the thumb abducted and the MP joint in neutral. A removable thumb spica splint is worn for 4 more weeks while therapy and range-of-motion exercises are begun. Splinting is discontinued at 8 weeks, unless a tendency for recurrence of the deformity requires night splinting.

Release of the Insertion of the Spastic Thumb Adductor

Indications. If there is no voluntary control of the adductor pollicis, tenotomy at its insertion is effective. If selective control of the muscles is present, release of the myotendinous junction (fractional lengthening) or muscle slide can be performed, leaving muscle fibers in continuity.

Technique. The adductor pollicis and first dorsal interosseous are approached through a double opposing "Z"-plasty of the thumb web space (Figure 32.25). The oblique and transverse heads of the adductor tendon are identified and detached from the metacarpal and sesamoid or fractionally lengthened. To fractionally lengthen the adductor, an oblique incision of the tendon is made near the myotendinous junction, and the thumb is gently abducted to allow sliding of the muscle fibers. The first dorsal interosseous origin from the first metacarpal can be visualized in the depths of the wound dorsal to the adductor and can be dissected off the metacarpal. The princeps pollicis artery must be protected. If the MP joint is unstable, a capsulodesis or arthrodesis can be performed through this incision. Arthrodesis is preferred over capsulodesis. For a capsulodesis, the capsule is incised just proximal to the ulnar sesamoid and pulled in a proximal direction. Two nonabsorbable sutures are placed between the sesamoid and the periosteum of the metacarpal with the MP joint in slight flexion. Immobilization can be augmented by Kirschner wire fixation. A 0.045-inch Kirschner wire can stabilize the CMC joint in maximal extension and abduction. Another 0.045-inch Kirschner wire can stabilize the MP joint in 10 degrees of flexion.

The wrist is immobilized for 4 weeks in neutral position with the thumb abducted. At 4 weeks the Kirschner wires are removed, and a removable thumb spica splint is worn for another 4 weeks while therapy and range-of-motion exercises are begun. Splinting is discontinued at 8 weeks, unless a

CRITICAL POINTS *Release of the Insertion of Spastic Thumb Intrinsic Muscles*

Indication
- For adduction deformity of the thumb without voluntary control of the adductor. If selective control of the adductor muscle is present, fractional lengthening or muscle slide is preferred.

Preoperative Evaluation
- The thumb should be examined in wrist flexion and extension to note the contribution of FPL spasticity.
- The dimension of the thumb web spaces should be assessed with active motion and passive stretch to differentiate spasticity from contracture.
- Patients should be evaluated during functional activities because thumb adduction spasticity may be exacerbated with use.

Pearls
- If spasticity of the FPL is shown by flexion of the IP joint when the wrist is held in neutral, the tendon must be lengthened.
- Fractional lengthening of the FPL is sufficient if the IP joint is not tight when the wrist is positioned in flexion.
- If the FPL is tight in wrist flexion, a "Z"-lengthening of the tendon is necessary.

Pitfall
- Be prepared to augment thumb abduction-extension if this movement is weak.

Technical Points
- Make a double opposing "Z"-plasty of the first web space.
- Detach the adductor tendon from the metacarpal and sesamoid.
- Elevate the origin of the first dorsal interosseous muscle from the thumb metacarpal.
- Protect the princeps pollicis artery.
- If necessary, perform MP joint capsulodesis by advancing the volar capsule, producing 10 degrees of flexion of the MP joint.
- MP arthrodesis is more reliable than capsulodesis.
- Fix the CMC joint in maximal extension with a 0.045-inch Kirschner wire.
- Stabilize the MP joint in 10 degrees of flexion if a capsulodesis has been performed.

Postoperative Care
- Apply a short-arm thumb spica splint for 4 weeks.
- Remove pins at 4 weeks and begin active and passive range-of-motion exercises.
- Use a fabricated thumb spica splint for 4 more weeks.
- Discontinue splinting at 8 weeks.

tendency for recurrence of the deformity requires additional night splinting.

Extensor Pollicis Longus Transfer

Indication. This procedure is indicated in patients who have a functioning EPL and thumb metacarpal adduction posture. The normal EPL has an adductor moment, and rerouting redirects this vector onto extension. EPL transfer is performed in conjunction with release or slide of the thumb intrinsic muscles. More commonly, EPL rerouting rather than transfer is performed. Rerouting avoids cutting the tendon (see the following).

Contraindication. Absence of a functioning EPL is a contraindication.

Technique. The EPL is exposed through a longitudinal incision radial to the Lister tubercle, just proximal to the extensor retinaculum.[19,115,167,185,191] A second incision is made over the dorsal aspect of the MP joint to expose the EPL and extensor aponeurosis. The EPL is transected at this level with a strip of extensor aponeurosis that is 10 by 4 mm, which has been dissected out from the proximal phalanx in its midportion. A running 4-0 monofilament suture is used to close the defect in the extensor aponeurosis. The tendon is withdrawn through the proximal wrist incision. A hemostat or small tendon passer is passed from the thumb incision, through the first dorsal compartment, and out the dorsal wrist incision. The instrument grasps the EPL and pulls the tendon out of the first dorsal compartment and out of the thumb wound. The EPL is passed through the MP joint capsule and sutured into place. If the MP joint passively hyperextends, the repair should be done into the proximal metacarpal to decrease its hyperextension effect. The repair should be done with enough tension to hold the thumb metacarpal in extension.

The hand is placed in a short-arm thumb spica cast for 1 month with the wrist in 30 degrees of extension. The thumb metacarpal is positioned in maximal extension and abduction and the MP joint in slight flexion. A removable splint is applied for an additional 4 weeks, and range-of-motion exercises and therapy are begun. The splint is discontinued at 2 months, and night splinting is instituted only if there is a tendency for recurrence of the deformity.

Extensor Pollicis Longus Rerouting

Indication. EPL rerouting is indicated in patients lacking thumb abduction and extension with active EPL function.[19,191] This procedure should be performed concurrently with a release or slide of the insertion of the thumb intrinsic muscles. The procedure is simpler than EPL transfer and favored by most surgeons.

Contraindication. Absence of active EPL function is a contraindication to this procedure.

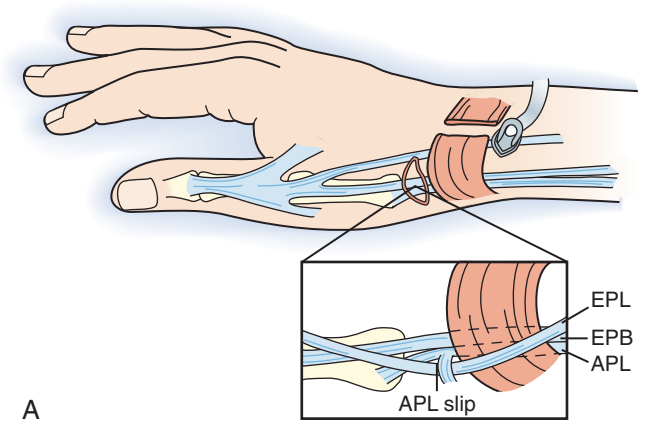
Technique. Through a transverse or longitudinal incision at the Lister tubercle, the retinaculum over the third dorsal compartment is incised (Figure 32.26). The EPL is removed from its compartment and allowed to migrate in a radial direction by releasing any subcutaneous septa. A radially based piece of retinaculum or a proximally based slip of APL is harvested. The retinaculum or slip of abductor is looped about the EPL and sewn to the most volar aspect of the retinaculum or the volar radial periosteum.

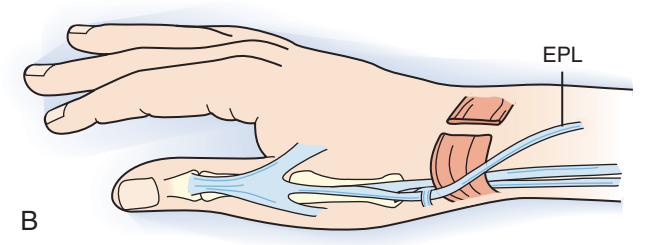
Patients are placed in a short-arm thumb spica splint for 4 weeks. The Kirschner wires are removed, and a removable splint is fabricated. Hand therapy is recommended. After 4 weeks, the splint is removed and activities of daily living are encouraged.

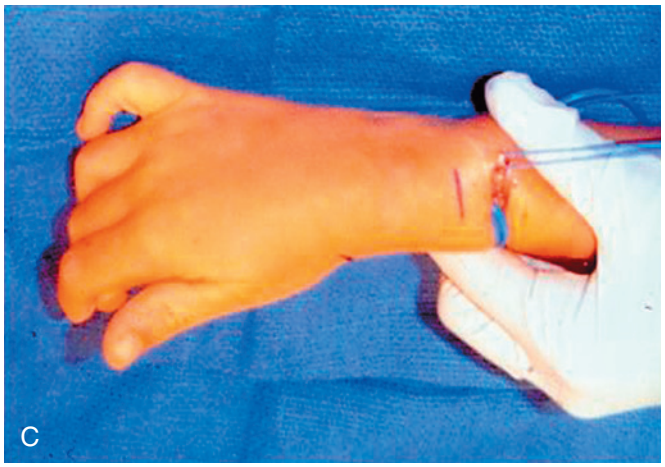
Brachioradialis to Extensor Pollicis Brevis Transfer

Indication. Brachioradialis to EPB transfer is indicated in patients who lack thumb extension and abduction and have poor EPL function.

Contraindication. This procedure is contraindicated in patients who lack voluntary control of the brachioradialis with elbow flexion.







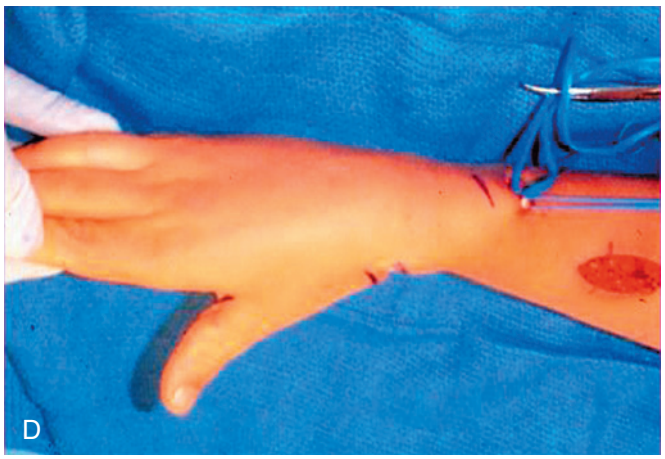


FIGURE 32.26 Extensor pollicis longus (EPL) rerouting. **A,** After release of the extensor pollicis longus from the third dorsal compartment, the extensor pollicis longus is identified through a radial incision distal to the styloid. A proximally based slip of abductor pollicis longus (APL) is harvested and sutured to the radial periosteum, creating a radial pulley for the extensor pollicis longus. **B,** After rerouting, the extensor pollicis longus has an abduction-extension line of pull. **C,** Intraoperative photograph demonstrating the pull of the untreated extensor pollicis longus, causing adduction of the thumb ray and interphalangeal extension. **D,** After rerouting of the extensor pollicis longus, its pull causes thumb abduction. *EPB*, Extensor pollicis brevis. (**C** and **D,** Copyright Michelle Gerwin Carlson.)

CRITICAL POINTS *Extensor Pollicis Longus Rerouting*

Indications
- Poor thumb abduction-extension
- Release or slide of the thumb intrinsic muscles at the same time

Preoperative Evaluation
- Patients must have good active EPL function with the wrist held in neutral position.

Pearl
- Mobilize the EPL in a radial direction as much as possible.

Technical Points
- Make an incision at the Lister tubercle.
- Open the retinaculum of the third dorsal compartment.
- Translocate the EPL tendon in a radial direction.
- Use the extensor retinaculum or a proximally based slip of APL to construct a pulley.
- Wrap the extensor retinaculum or the slip of APL around the EPL and suture it to the volar periosteum of the radius or the volar first dorsal compartment.

Postoperative Care
- Manage as for thumb intrinsic release.
- Encourage thumb usage early; concerns about tendon healing are less important than concerns about EPL redirection.

Technique. The brachioradialis is approached through a long longitudinal radial incision. The brachioradialis insertion on the distal radius is identified and transected while the radial artery and nerve are protected. The brachioradialis is mobilized proximally and freed from the ECRL and FCR into the proximal forearm (Figure 32.27).

The first dorsal compartment is opened, and the EPB is confirmed via traction. The APL has no effect on the MP joint, whereas the EPB tendon extends the MP joint. The EPB is transected as proximally as possible at the musculotendinous junction and woven into the brachioradialis tendon. During the weave, maximal tension is placed on the two tendon ends with the wrist in neutral and the elbow flexed.

The postoperative regimen is the same as for EPL transfer, with occasional reeducation necessary to reinforce thumb extension with elbow flexion against resistance.

Flexor Pollicis Longus Abductorplasty

Indication. This procedure is indicated for patients with a supple thumb metacarpal adduction contracture when the FPL is spastic and needs to be released or when the EPL is not functioning and cannot be used for transfer.

Contraindications. It is contraindicated in patients who already have a weak pinch. FPL abductorplasty is also contraindicated in patients who have an MP fusion, because IP fusion or tenodesis is required after this procedure.

Technique. The FPL tendon is identified through a radial midlateral incision from the middle of the distal phalanx to the neck of the thumb metacarpal. The FPL is transected midway over the proximal phalanx. The distal stump can be used as a tenodesis of the IP joint or a formal arthrodesis can be

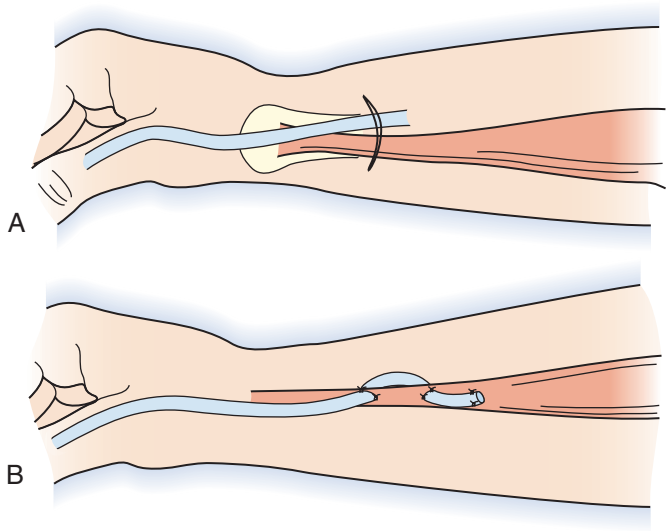

FIGURE 32.27 Brachioradialis to extensor pollicis brevis (EPB) transfer. **A** and **B,** Through a transverse incision, the brachioradialis is harvested distally and the EPB proximally. The EPB is woven into the brachioradialis; alternatively, a surgeon's knot can be placed between the two tendons.

CRITICAL POINTS *Brachioradialis to Extensor Pollicis Brevis Transfer*

Indication
- Patients lacking thumb abduction and extension with poor EPL function

Preoperative Evaluation
- Patients should have voluntary control of the brachioradialis with elbow flexion.

Pearl
- The EPB tendon is identified as the most ulnar tendon in the first dorsal compartment.

Pitfall
- This transfer must be tight; if it is too loose, adequate thumb abduction will not be accomplished.

Technical Points
- Release the brachioradialis at its insertion into the radius and mobilize it into the proximal forearm.
- Transect the EPB tendon as proximally as possible at the musculotendinous junction.
- Weave the EPB into the brachioradialis with maximal tension on the two tendons with the wrist in neutral.

Postoperative Care
- Manage as described for EPL transfer.
- Reeducation is occasionally necessary to reinforce thumb extension with elbow flexion against resistance.

performed. A second longitudinal incision is made over the volar wrist radial to the tendon of the FCR and proximal to the wrist flexion crease. The FPL is identified deep in this wound and withdrawn. A subcutaneous tunnel is created from the proximal wound to the distal wound through which the FPL is passed. The FPL is sutured to the MP joint capsule as described for EPL redirection.

The arm is immobilized in a short-arm thumb spica cast for 4 weeks with the wrist in 30 degrees of flexion and the thumb metacarpal fully extended and abducted. A removable splint is worn for an additional 4 weeks while range-of-motion exercises and therapy are started. After 8 weeks, night splinting is used as needed if there is a tendency for recurrence of the deformity.

Imbrication of the Abductor Pollicis Longus and Extensor Pollicis Brevis Tendons

Indication. Imbrication of the APL and EPB tendons can augment thumb abduction and extension in patients with weak EPL function who are not candidates for EPL rerouting. This procedure is truly relegated to the status of a second-tier procedure.

Technique. A skin incision is made over the first dorsal compartment, and the retinaculum is incised along its dorsal aspect. The tendons of the APL and EPB are plicated with a hemostat and sewn together with a nonabsorbable suture.

Alternatively, the tendons can be plicated distally, through a small incision at the APL's insertion on the metacarpal base, thus avoiding release of the first dorsal retinacular pulley and the attendant loss of abduction moment. The tendons can also be joined proximally in the forearm if another procedure necessitates a proximal forearm incision.

The wrist is immobilized for 4 weeks in 30 degrees of extension with the thumb metacarpal in full abduction and extension. A removable splint is used for 4 weeks to allow for therapy and range-of-motion exercises. Splinting is discontinued at 8 weeks, and night splinting is used only for recurrence of the deformity.

Thumb Metacarpophalangeal Joint Epiphyseal Arthrodesis (Chondrodesis)

Indication. MP joint epiphyseal arthrodesis is indicated for a hyperextensible MP joint in a growing child, when tendon transfers to augment extension or abduction are planned.

Contraindication. Arthrodesis is contraindicated when an IP arthrodesis is contemplated.

Technique. The MP joint is approached through a dorsal incision.[65,191] The interval between the EPL and EPB is split, and subperiosteal dissection of the articular surface of the proximal phalanx and metacarpal head is performed. Care should be taken not to extend the resection of the joint surface too distal on the proximal phalanx to protect the physes. The articular surface is removed with a knife to expose the ossification center of the proximal phalanx; the subchondral bone of the metacarpal can be removed with an oscillating saw. The osteotomies are performed to position the joint in neutral. The MP joint is fixed with one or two Kirschner wires.

Immobilization of the wrist and MP joint is accomplished with a thumb spica cast until bony union is observed at 4 to 6 weeks.

❖ Authors' Preferred Method of Treatment

The spastic thumb-in-palm deformity remains one of the most difficult and frustrating problems to treat. We find that the best approach is to identify and address the four key elements: spastic or contracted flexors and adductors, weak or absent extensors and abductors, MP hypermobility, and skin web space contracture. The spastic muscles are lengthened or released. The

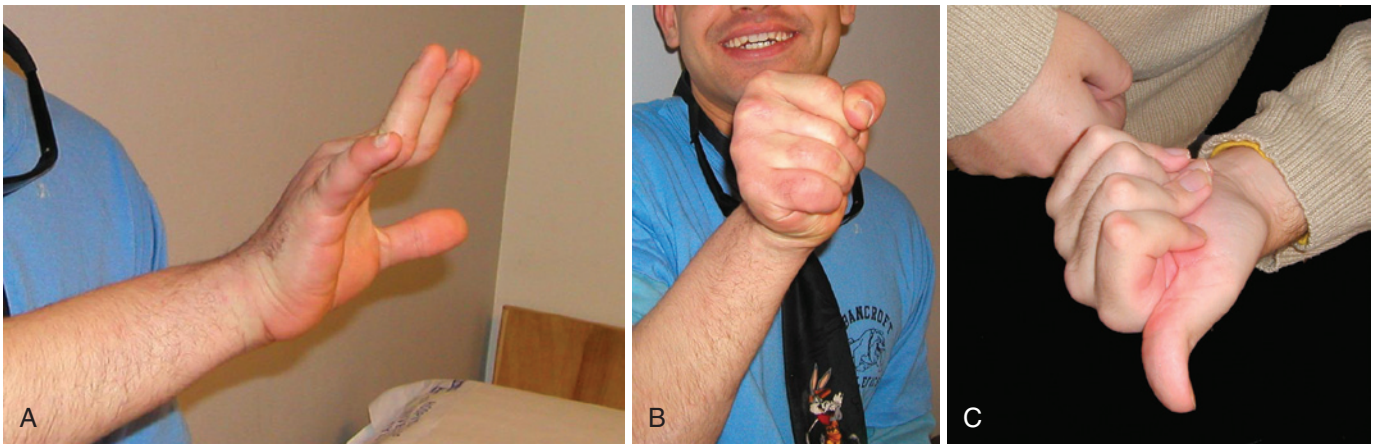

FIGURE 32.28 **A,** Multiple swan neck deformities of the fingers after traumatic brain injury. **B,** Note that combined flexion is not lost. **C,** Multiple boutonnière deformities.

weak extensors are augmented by rerouting or tendon transfer. MP hypermobility is stabilized by chondrodesis or arthrodesis. Any web space contracture is released and the skin is reoriented by "Z"-plasty.

Despite attention to detail, some recurrence is frequent and frustrating. Problematic recurrence requires reassessment of the persistent deforming forces and repeat surgery. In some cases, fusion of the MP and CMC joints is necessary to position the thumb as a stable post for prehension.

Intrinsic Muscle Spasticity and Digital Swan Neck Deformity

Condition

Intrinsic spasticity in the hand causes flexion at the MP joints and extension at the PIP joints. Over time, swan neck deformities of the digits result, although overpull of the digital extensors to augment lack of wrist extension contributes to this deformity.[168,175,187] Swan neck deformity is rarely a functional problem unless the PIP joints lock into hyperextension secondary to the dorsally dislocated lateral bands. The patient will complain of difficulty initiating flexion (Figure 32.28). More commonly, the deformity is an appearance concern. The functional and aesthetic benefit of correcting PIP hyperextension can be demonstrated to the patient preoperatively with the use of figure-of-eight extension block splints. Figure-of-eight splints may be the sole method of treatment.

Similarly, the MP flexion component causes difficulty only if severe, because it is usually overpowered by the EDC. However, the MP flexion deformity may become more pronounced after correction of a wrist flexion deformity because of the effective weakening of the EDC tendons. Lengthening procedures for the digital flexors may also unmask intrinsic spasticity, especially in patients with traumatic brain injury (Figure 32.29).

Types of Operative Procedures

Intrinsic spasticity can be treated by three methods: intrinsic muscle origin slide, ulnar motor neurectomy, and fractional lengthening of the intrinsics.[123,168] Intrinsic muscle lengthening or origin slide corrects the spasticity of the muscle, decreases the contracture, and retains some function. Ulnar motor neurectomy eliminates the spasticity of the intrinsics[164] at the expense of all intrinsic function. Neurectomy does not reduce any component of myostatic contracture. The effectiveness of an ulnar motor neurectomy can be assessed with an ulnar nerve block at the wrist.

FIGURE 32.29 This patient has had release of the long flexors, but the intrinsic muscles were not addressed. The severe metacarpophalangeal flexion and proximal interphalangeal extension of the fingers significantly limit function, and he still has an interdigital hygiene problem. (Copyright Michelle Gerwin Carlson.)

PIP hyperextension can also be corrected with lateral band translocation, superficialis tenodesis or central slip tenotomy.[18a,23,40,187] The superficialis tendon can be repaired either to bone[150,175] or to the fibroosseous pulley.[119,187]

Interosseous Muscle Slide

Indication. This procedure should be performed when MP flexion is inhibiting hand function or causing interdigital hygiene problems. Some intrinsic function is retained, and the contracture across the MP joint is decreased.

Contraindication. This procedure should not be performed to improve appearance alone.

Technique. A transverse incision is made on the dorsum of the hand at the midmetacarpal level, or two longitudinal incisions are made in the interspaces between the index and long fingers and ring and little fingers. The interosseous muscles are identified with retraction of the extensor tendons. Subperiosteal

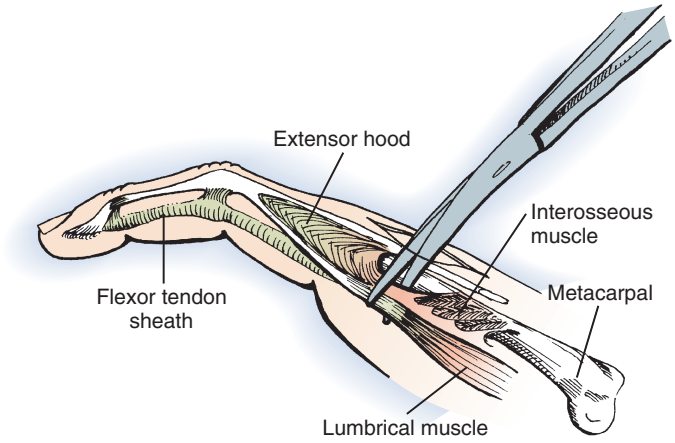

FIGURE 32.30 Isolation and release of the intrinsic interosseous and lumbrical muscles. (From Keenan MA, Kozin SH, Berlet AC: *Manual of orthopaedic surgery for spasticity*, New York, 1993, Raven Press.)

FIGURE 32.31 Photographs of intrinsic-plus **(A)** and intrinsic-minus **(B)** deformities.

dissection is performed to release both the dorsal and the volar interosseous muscles. The MP joints are brought into full passive extension with the PIP joints flexed. If MP joint extension is still tight, a Kirschner wire can be used to hold the MP joints extended for 4 weeks.

The MP joints are immobilized in full extension for 4 weeks. A removable splint is then applied for 4 weeks, and therapy and range-of-motion exercises are begun. Splinting is discontinued at 8 weeks, and night splinting is instituted only if there is a tendency for recurrence of the deformity.

Intrinsic Lateral Band Release

In a hand that has intrinsic muscle contractures and for which a dynamic electromyogram shows no volitional activity, lateral band releases are performed (Figure 32.30). A midline longitudinal incision is made over the dorsum of the MP joint and proximal phalanx of each finger. Dissection is carried out on both the ulnar and radial sides of the extensor mechanism. The palmar edge of the lateral bands is identified. The lateral band and oblique fibers of the extensor hood are transected on each side. Care is taken to preserve the transverse fibers of the sagittal extensor hood.

Recurrent intrinsic-plus deformities are common (Figure 32.31, *A*). This is thought to be secondary to residual attachment of the interosseous muscles to the base of the proximal phalanges. To prevent recurrent deformities, the surgeon should consider concomitant neurectomy of the motor branch of the ulnar nerve in the Guyon canal.

Ulnar Motor Neurectomy

Indication. Ulnar motor neurectomy is a straightforward approach to decrease intrinsic muscle spasticity, but it results in complete loss of intrinsic function. It should be used when good digital function is not anticipated and hygiene is the primary goal. A primary indication is improvement in hand function after ulnar nerve block.

Contraindication. This is contraindicated when good digital function is expected. It may result in a clawhand deformity.

Technique. A 3- to 4-cm incision is made over the ulnar nerve and artery in the Guyon canal (Figure 32.32). The ulnar neurovascular bundle is identified proximally and traced distally after releasing the volar carpal ligament. The ulnar nerve divides into a superficial sensory branch and a deep motor branch within the Guyon canal. The deep motor branch is isolated as it courses around the hook of the hamate, and a section of the motor branch is excised. A nerve stimulator can be used to confirm the identity of the motor branch before transection. No postoperative immobilization is necessary.

Flexor Digitorum Superficialis Tenodesis of the Proximal Interphalangeal Joint

Indication. This procedure is indicated for PIP hyperextension that is hindering active flexion of the digit.

Contraindication. This procedure is contraindicated if the FDP in the involved finger is nonfunctional.

Technique. A midaxial or Bruner incision can be performed. The radial slip of the FDS tendon is identified. The radial slip of the FDS tendon is identified beneath the A1 pulley and transected proximally. The radial slip is secured to the middle to distal third of the proximal phalanx using a transosseous or suture anchor technique. The PIP joint is stabilized to produce a 20-degree flexion contracture The PIP joint is held in this position with a Kirschner wire.

The Kirschner wire is removed at 2 to 3 weeks, and range-of-motion movement is begun with active and passive flexion and an extension block splint that limits extension to 20 degrees. Full range of motion is allowed after 8 weeks.

Fractional Palmar Intrinsic Lengthening

Indication. This procedure is indicated for mild intrinsic spasticity. The digits are best examined with the wrist flexed, because digital flexor tightness can mask intrinsic spasticity. This procedure seems simple but is relatively difficult to perform.

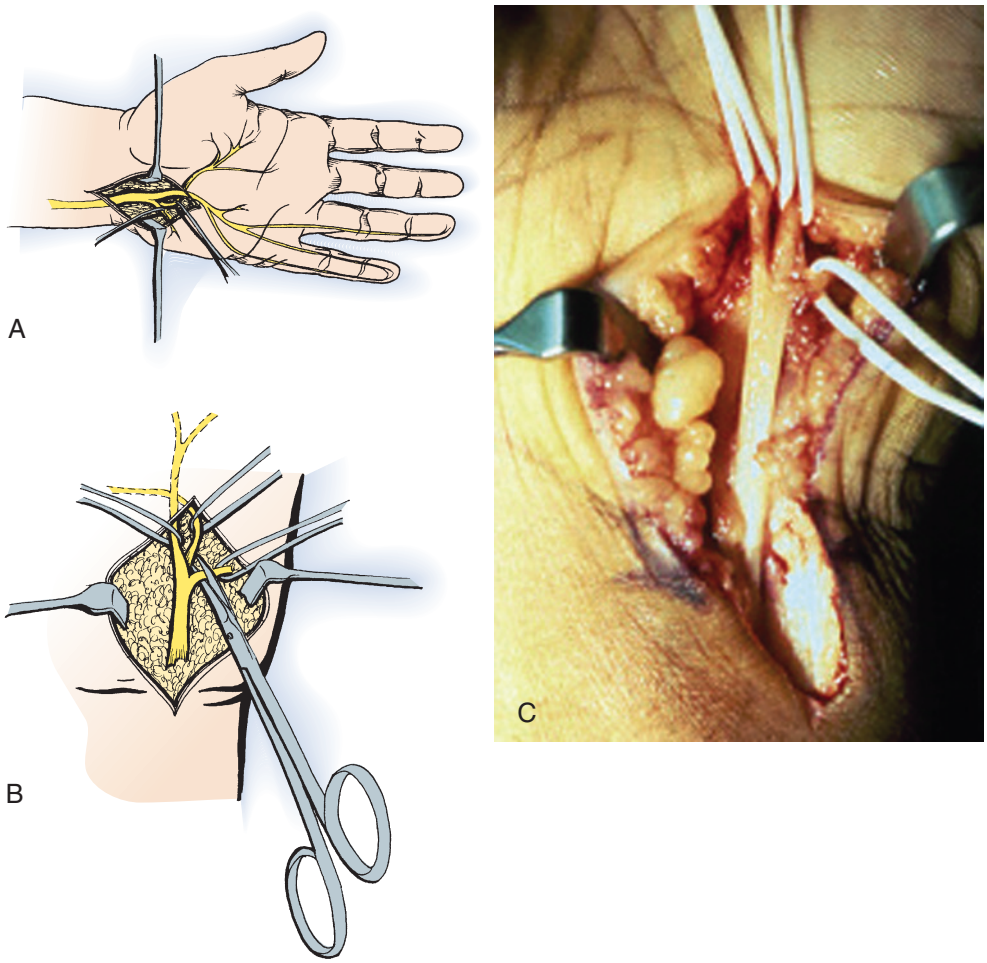

FIGURE 32.32 **A** to **C,** Isolation of the motor branches of the ulnar nerve distal to the Guyon canal. (From Keenan MA, Kozin SH, Berlet AC: *Manual of orthopaedic surgery for spasticity,* New York, 1993, Raven Press.)

Contraindication. This procedure is contraindicated in patients with long flexor weakness. They may be relying on their intrinsic muscles for MP function and functional use of their fingers.

Technique. A transverse incision is made at the level of the distal palmar crease of the hand. It should extend from radial to ulnar, that is, from the index flexors to the little finger flexors. The interosseous spaces between the flexors and metacarpals are developed, and care is taken to protect the neurovascular bundles. The volar interosseous muscles are identified and fractionally lengthened (cutting the tendinous portion of the musculotendinous junction). The deep fascia is divided, and the dorsal interosseous muscles can be similarly lengthened.

No postoperative immobilization is necessary, and early range-of-motion movement is encouraged.

Central Slip Tenotomy

For swan neck deformity of the PIP joints, central slip tenotomy can be an effective treatment.[18a,23] Patients must have active digital flexion when the digits are held passively in the corrected position or recurrence of the deformity is inevitable because the lateral bands remain dorsal. PIP tenodesis is effective to treat the deformity, but it is difficult to set the appropriate tension, and the procedure does not rectify the underlying problem.

Indication. This procedure is indicated in patients with active swan neck deformity of the PIP joints greater than 20 degrees.

Contraindication. Patients who cannot actively flex their PIP joints when the digit is held in the corrected position are likely to have a recurrence of the deformity. In patients who use their EDC to obtain wrist extension, tendon transfer for wrist extension is the solution.

Technique. A transverse incision is made dorsally, approximately 1 cm proximal to the PIP joint, and the extensor mechanism is identified (Figure 32.33). A forceps is used to grasp the center of the tendon, and gentle traction facilitates identification of the separation between the central slip and the lateral bands. The central slip is transected transversely, and the lateral bands are left intact. As the central slip is transected, the demarcation between it and the lateral bands becomes more apparent. The skin is closed with absorbable sutures, and the PIP joint is fixed with a Kirschner wire in slight flexion.

The digits are splinted for 4 weeks, at which point the splint and Kirschner wires are removed. Molded oval figure-of-eight splints are applied to the PIP joints, and active flexion is begun. Active extension should be limited to minus 10 degrees by the figure-of-eight splint. At 8 weeks postoperatively, the splints are discarded and full range of motion is allowed. Patients are informed that they can expect correction of the deformity to within 10 degrees of neutral.

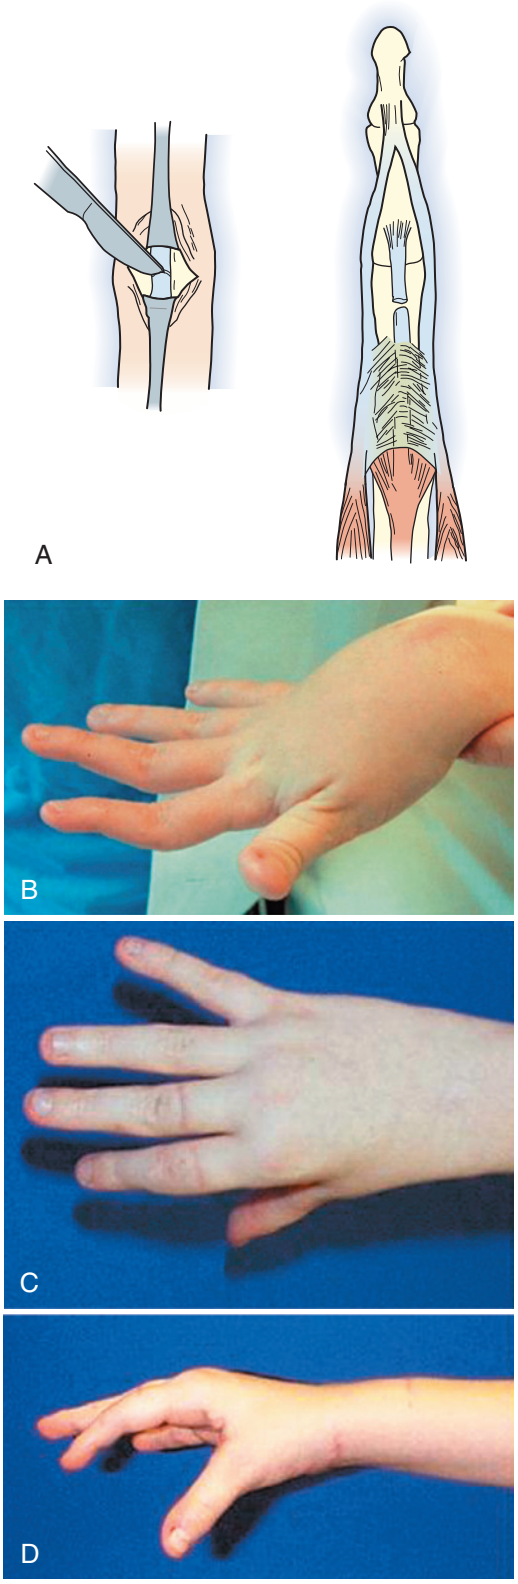

FIGURE 32.33 Central slip tenotomy for swan neck deformity. **A,** A transverse incision is made just proximal to the proximal interphalangeal joint, and a tenotomy of the central slip is performed, leaving the lateral bands intact. **B,** Preoperative swan neck deformity. **C,** The healed incision is visible proximal to the proximal interphalangeal joint. **D,** Postoperative correction of the swan neck deformity. (**B** to **D,** Copyright Michelle Gerwin Carlson.)

CRITICAL POINTS *Central Slip Tenotomy*

Indication
- Patients with active swan neck deformity greater than 20 degrees

Preoperative Evaluation
- Check for active digital flexion when the PIP is held in neutral position.

Pearl
- Grasping the extensor mechanism and lifting with a forceps can facilitate identification of the demarcation between the central slip and the lateral bands.

Technical Points
- Transect the central slip, leaving the lateral bands intact.
- Transfix the PIP joint in slight flexion with a Kirschner wire.

Pitfall
- Be sure to transect the entire central slip but not the lateral bands.

Postoperative Care
- Splint the digit for 4 weeks.
- Remove the pin at 4 weeks and apply an oval figure-of-eight splint.
- The splint should limit extension to –10 degrees.
- At 8 weeks, allow full range of motion and discontinue splinting.

Metacarpophalangeal Joint Arthrodesis

Indication. Patients with marked MP flexion deformity and fixed contracture that does not improve with ulnar nerve block.

Contraindication. Patients must have functioning long digital flexors or MP fusion will eliminate any functional flexion of the digit.

Technique. A longitudinal incision is made over each MP joint to be fused. The extensor hood is incised and the capsule is incised longitudinally. The collateral ligaments are released from the metacarpal head, and the articular surface of the metacarpal head and base of the proximal phalanx are removed with an oscillating saw. The metacarpal osteotomy should be performed to create a cascade of flexion through the arthrodesis from 20 degrees for the index finger to 40 degrees for the little finger. Care must be taken not to produce a radial or ulnar angular deformity through the fusion site. A 2.0-mm plate is contoured and used to fix the metacarpal to the proximal phalanx with two or three screws proximally and distally. Alternatively, a headless compression screw can be used, avoiding the plate and screw construct (Figure 32.34). The capsule is closed and the extensor hood is repaired with interrupted nonabsorbable suture.

The hand is immobilized for 4 weeks in a forearm-based extension splint with the wrist in neutral and the digits extended. Subsequently, a fabricated palm-based splint across the MP joints with the PIP joints free is worn until union is demonstrated on radiographs. We inform the patients to expect improved use of the hand because of the ability to place objects in the palm with the MP joints extended. As long as patients have digital flexion, the improved position of the MP joints outweighs the loss of MP motion.

❖ Authors' Preferred Method of Treatment

We treat mild intrinsic spasticity with fractional lengthening of the intrinsics with good results and little loss of function. We

FIGURE 32.34 Anteroposterior and lateral x-rays following metacarpophalangeal arthrodesis and internal fixation with headless screws. (Courtesy of Shriners Hospital for Children, Philadelphia.)

CRITICAL POINTS *Metacarpophalangeal Joint Arthrodesis*

Indication
- Patients with MP flexion deformity not improved by ulnar nerve block

Preoperative Evaluation
- Ulnar nerve block identifies flexible deformities.
- Function of the long digital flexors should be assessed.

Pearl
- If there is considerable spasticity of the flexors or extensors, intraoperative botulinum toxin may lessen postoperative spasticity and ease the postoperative course.

Technical Points
- Make a longitudinal incision over each MP joint.
- Incise the extensor hood.
- Incise the capsule longitudinally, and release the collateral ligaments.
- Remove the articular surface of the metacarpal and phalanx with an oscillating saw.
- Produce a cascade of flexion of 20 degrees in the index finger to 40 degrees in the little finger.
- Fix MP fusion with a 2-mm plate or headless compression screw.
- Close the capsule and extensor hood.

Pitfall
- Arthrodesis in too much MP flexion, especially of the fifth finger, will make it difficult to acquire objects.

Postoperative Care
- Apply a forearm-based splint for 4 weeks.
- Use a fabricated palm-based splint across the MP joints with the PIP joints free until union is demonstrated.

often perform this procedure along with lengthening of the long flexors. Swan neck deformities of the digits without intrinsic spasticity (from overpull of the digital extensors) and with adequate active wrist extension are treated with central slip tenotomies at the PIP joints. Severe MP flexion deformity from intrinsic spasticity is very difficult to correct. Ulnar motor block identifies the amount of correction possible with ulnar motor neurectomy. We prefer neurectomy to interosseous muscle slide in patients with poor hand function. Ulnar block often incompletely corrects the deformity because of fixed capsular contractures of the MP joints. In these patients, MP arthrodesis may be necessary to improve the position of the fingers; its use retains some hand function at the IP joints. Additionally, shortening can be accomplished through the arthrodesis, helping to lengthen the tight extrinsic flexors. Prior to any intrinsic release or ulnar neurectomy, it is imperative to determine that the intrinsic muscles are not contributing to function; otherwise, hand function will be adversely affected.

Intrinsic-Minus Deformities

A less common deformity pattern is the intrinsic-minus hand. In these patients, the intrinsic muscles have normal or weakened tone but there is spasticity of the extrinsic finger flexors. There may be increased tone in the extrinsic extensors as well. This pattern results in a clawhand posture, with hyperextension of the MP joints and flexion of the PIP and DIP joints (see Figure 32.31, *B*). Ulnar nerve compression or disease must be considered in the differential diagnosis. Resultant hyperextension contracture of the MP joint capsule is common and may require surgical release. Following release, excessive tension on the dorsal skin should be avoided to prevent subsequent wound breakdown and skin necrosis. The MP joints are pinned in the

reduced position for 4 weeks. Treatment of an MP hyperextension deformity may also require lengthening of the extrinsic digital flexors or superficialis to profundus transfers, as described earlier. A volar plate capsulodesis may also be necessary to maintain MP flexion for function and appearance.

On occasion, hyperextension deformities of the MP joints are not correctable with soft tissue releases. This can usually be determined preoperatively by placing the wrist in maximum extension and assessing MP flexion. If this position does not alter the tension across the hyperextended MP joints, soft tissue release alone is unlikely to correct the deformity. In these cases, a closing wedge flexion osteotomy of the distal metacarpal corrects the deformity and lessens the chance of compromising the viability of dorsal skin over the MP joint. The osteotomy is fixed with a small dorsal plate or wires.

OUTCOME STUDIES

Accurate quantitative and qualitative assessment of outcomes after treatment of spasticity of the upper extremity involves diagnostic tests, standardized observation, performance measures, and patient-reported outcome instruments. These tools are used for spasticity diagnostics, classification of severity, identification of treatment goals, longitudinal monitoring, design of treatment decision-making algorithms, and evaluating and comparing outcomes. Few studies of spasticity have been rigorous enough to be level 1 evidence in this field.[197,211] A rare multicenter prospective study recently compared therapy alone, botulinum toxin, and surgery in children with hemiplegia. The surgical group had a more significant improvement in the upper limb.[188] Computerized adaptive testing is an emerging measurement technology that provides a scale for future research and clinical studies.[130a]

The current treatment of the spastic limb is both challenging and rewarding. The surgeon and patient can find the outcome gratifying but also sometimes frustrating.[138] Improving limb posture, position, and gross motor function is possible in limbs with controlled spasticity and some volitional control.[89] Improving movements such as elbow flexion/extension, forearm supination/pronation, wrist flexion/extension, and gross grasp/release is a realistic goal. In contrast, it is not possible to enhance limb function in the face of uncontrollable spasticity (e.g., athetosis) or lack of volitional activity.

Restoring fine motor function and dexterity is a far-reaching goal. The surgeon's ability to restore the fine balance between coordinated intrinsic and extrinsic hand action is hampered by the disconnect between afferent and efferent signals. The restoration of these coordinated tasks has frustrated surgeons for decades and will continue to exasperate surgeons in the future until the root cause problem can be solved.

The annual incidence of spinal cord injury is approximately 12,000 new cases each year in the United States. The patient's age at the time of injury has increased over time; since 2010, the average age at injury has been 28.7 years. Demographics of spinal cord injury patients since 2010 show that 80% of injuries occur in males and 20% in females; 52% in single persons and 48% in married persons; and 67% in Caucasians, 24% in African-Americans, 8% in Hispanics, and 2% in Asian-Americans. The most common causes of spinal cord injury since 2010 have been motor vehicle accidents (37%), falls (29%), violence (14%), and sports trauma (9%). Since 2010, the most frequent neurologic categories of spinal cord injury, at the time of discharge, have been incomplete tetraplegia (41%), incomplete paraplegia (19%), complete paraplegia (18%), and complete tetraplegia (12%). *Tetraplegia* refers to a spinal cord injury sustained to one of the eight cervical segments of the spinal cord, whereas *paraplegia* refers to spinal cord injury in the thoracic, lumbar, or sacral segment of the spinal cord. This chapter will deal with patients sustaining tetraplegic spinal cord injuries that leave a neurologic deficit in hand function.[74]

GENERAL CONSIDERATIONS IN TETRAPLEGIA

Pathogenesis

The cervical spinal cord contains eight cervical segments encased in the seven cervical vertebrae. The bone and ligamentous structure of the cervical spine allows a wide range of motion, thus exposing the cervical spinal cord to increased risk of injury. Injury occurs most commonly through a flexion deformity with bone or disk compression of the cord after fracture or dislocation or through traction on the cord with translation due to spine instability.[39] Over days and weeks, acute hemorrhage and edema subside, followed by local reparation and finally scar formation. The area of injured spinal cord can vary in width and length and is termed the *injured metamere.* Nerve function above the injured metamere is normal; nerve function within the injured metamere is absent; nerve function below the injured metamere may be stimulated if the lower motor neuron unit is unharmed.[16]

The muscles that are innervated above the level of injury have normal strength. The muscles that are innervated below the level of injury may be flaccid or have some elements of spasticity. The strength of muscles at the level of injury may improve over time, most commonly within a year of injury. Ditunno and colleagues[24] and Waters and associates[89] reported upper limb strength recovery rates using manual muscle testing and the British Medical Research Council grading system (Table 33.1).[17] One third of muscles classified as grade 0 at 1 month after injury improved to grade 3 at 4 to 6 months after injury; improvement was documented in some cases up to 24 months after injury. All upper limb muscles with an initial strength of grade 1 improved to at least grade 3 by 1 year after injury, with the exception of the triceps. If a muscle's strength was grade 2 or better at 1 month after injury, the median time for full recovery was 6 months.

Preoperative Evaluation

The reconstructive surgeon is less concerned with the specific level of cervical injury than with the remaining strength of each muscle in the upper limb. Classically, tetraplegic patients have been classified by the injured cervical spine segment of C1-C7. Formerly, it was assumed that the level of paralysis and sensory loss coincided with the bony injury, producing a precise transverse spinal cord lesion. Careful examination of tetraplegic patients has shown that there is frequently little relationship between the level of the skeletal lesion and the spinal cord lesion; lesions may be asymmetric, and there may be unusual patterns of spared sensory or motor function. A classification

for spinal cord injury commonly used by surgeons other than hand surgeons is the American Spinal Injury Association (ASIA) classification.[64] This classification is based on intact muscle groups.

The classification used in this chapter was developed by an international group of hand surgeons in 1978 in Edinburgh[62,63] and modified in 1984 at Giens, France. The International Classification for Surgery of the Hand in Tetraplegia (ICS) grades the level of the spinal cord injury based on the number of muscles with grade 4 strength below the elbow and includes ICS levels 0 to 9 (Table 33.2). The ICS level characterizes the most common patterns of presentation, based on the number of functional muscles below the elbow. A muscle is defined as functional if it demonstrates grade 4 or better strength by manual muscle testing.

Another aspect of patient evaluation includes assessment of the general suitability for surgery. An assessment based on age, occupation, interests, level of education, learning capacity, economic support, family and agency support, personality type, and understanding of what can and cannot be expected from surgical treatment needs to be explored with the patient and the spinal cord injury management team.

Physical Examination

After a thorough history of the injury and associated medical conditions is obtained, a physical examination is performed, including sensory and motor testing to establish the patient's group (ICS level 0 to 9). Manual muscle testing (see Table 33.1) is performed on all muscle groups in the upper extremity. The surgeon can make a working list of which tendons are available for transfer (those having grade 4 strength or higher) and which muscles are paralyzed (those having grade 1 strength or lower). Once the muscles with grade 4 strength have been identified, the patient is assigned a group number (see Table 33.2). For example, a patient with grade 4 strength of the brachioradialis (BR), both radial wrist extensors, the pronator teres (PT), and the flexor carpi radialis (FCR) would be classified as a group 5 patient. One of the difficulties in physical examination is distinguishing between group 2 and group 3 injuries. In group 2 patients, only the extensor carpi radialis longus (ECRL) has

TABLE 33.1 Muscle Grading System of the British Medical Research Council

Grade	Description
0	No contraction
1	Flicker or trace of contraction
2	Active movement with gravity eliminated
3	Active movement against gravity
4	Active movement against gravity and resistance
5	Normal power

TABLE 33.2 International Classification for Surgery of the Hand in Tetraplegia*

Sensibility†	Motor Group‡	Characteristics	Function
O or Cu	0	No muscle below elbow suitable for transfer	
O or Cu	1	BR	Flexion and supination of the elbow
O or Cu	2	ECRL	Extension of the wrist
O or Cu	3§	ECRB	Extension of the wrist
O or Cu	4	PT	Pronation of the wrist
O or Cu	5	FCR	Flexion of the wrist
O or Cu	6	Finger extensors	Extrinsic extension of the fingers
O or Cu	7	Thumb extensor	Extrinsic extension of the thumb
O or Cu	8	Partial digital flexors	Extrinsic flexion of the fingers
O or Cu	9	Lacks only intrinsics	Extrinsic flexion of the fingers
O or Cu	X	Exceptions	

*Developed at the First International Conference on Surgical Rehabilitation in the Upper Limb in Tetraplegia, Edinburgh, Scotland, 1978, and modified at the Second International Conference, Giens, France, 1984. This classification does not include the shoulder; it is a guide to the forearm and hand only. Determination of patient suitability for posterior deltoid to triceps transfer or biceps to triceps transfer is considered separately.

†Afferent input, both ocular (O) and cutaneous (Cu), is recorded using the method described by Moberg. When vision is the only afferent available, the designation is "O." Assuming there is 10-mm two-point discrimination or less in the thumb and index finger, the correct classification is "Cu," indicating that the patient has adequate cutaneous sensibility. If two-point discrimination is more than 10 mm (i.e., inadequate cutaneous sensibility), the correct designation is "O." The sensibility designation precedes the motor group (e.g., O2).

‡Motor grouping assumes that all listed muscles are Medical Research Council grade 4 or better, and a new muscle is added for each group; for example, a group 3 patient's BR, ECRL, and ECRB are rated at least grade 4.

§Caution: To determine the strength of the ECRB, see text.

BR, Brachioradialis; *ECRL,* extensor carpi radialis longus; *ECRB,* extensor carpi radialis brevis; *FCR,* flexor carpi radialis.

From Moberg EA, McDowell CL, House JH: Third international conference on surgical rehabilitation of the upper limb in tetraplegia (quadriplegia), *J Hand Surg [Am]* 14:1064–1066, 1989; McDowell CL, Moberg EA, House JH: The second international conference on surgical rehabilitation of the upper limb in tetraplegia (quadriplegia), *J Hand Surg [Am]* 11:604–608, 1986.

FIGURE 33.1 To determine whether a patient is in group 2 or group 3, the physician can palpate the extensor carpi radialis brevis (ECRB), a long flat muscle, and the extensor carpi radialis longus (ECRL), a more bulbous muscle. In thinner individuals, both muscles can be palpated as muscle strength is tested (Bean sign). If the Bean sign is present, indicating that both the ECRL and ECRB are firing, and the patient has wrist extension strength of grade 4 or 5, the patient is in group 3, and the muscle belly of the ECRL can be palpated.

TABLE 33.3 Preoperative Workup for the Assessment of Muscle Strength Testing

Function Needed by the Patient	Muscles to Be Tested and Graded
Elbow flexion	Biceps, brachialis
Elbow extension	Triceps
Wrist extension	ECRL, ECRB, ECU
Wrist flexion	FCR, FCU
Finger extension	EDC, EIP, extensor digiti quinti
Finger flexion	FDP, FDS
Thumb extension/abduction	EPL, EPB, APL
Thumb flexion/opposition	FPL, APB, opponens, flexor pollicis brevis
Intrinsics	Adductor pollicis, interossei, lumbricals

APB, abductor pollicis brevis; *APL,* abductor pollicis longus; *ECRL,* extensor carpi radialis longus; *ECRB,* extensor carpi radialis brevis; *ECU,* extensor carpi ulnaris; *EDC,* extensor digitorum communis; *EIP,* extensor indicis proprius; *EPB,* extensor pollicis brevis; *EPL,* extensor pollicis longus; *FCR,* flexor carpi radialis; *FCU,* flexor carpi ulnaris; *FDP,* flexor digitorum profundus; *FDS,* flexor digitorum superficialis; *FPL,* flexor pollicis longus.

strength of grade 4 or higher, and physical examination reveals significant radial deviation of the wrist with resisted wrist extension. In group 3 patients, both the ECRL and the extensor carpi radialis brevis (ECRB) have strength of grade 4 or higher. In a group 3 patient, the wrist extends with less radial deviation and often grade 1 to 3 strength is present in the PT, the next most caudal muscle. In thinner patients, the ECRL, a flat muscle, and the ECRB, a more bulbous muscle, can be palpated while muscle strength is being tested (Figure 33.1).

In addition to manual muscle testing, the surgeon must also examine the passive range of motion to evaluate joint and muscle contractures and the resting posture of the hand. The examiner can induce a tenodesis effect by passively flexing the wrist while observing passive myostatic tensioning of the digital extensors; the reverse effect of passive digital grasp can be induced with passive wrist extension. The hand must have passive mobility or tenodesis ability to achieve what the patient needs; for example, if the thumb rests in a fully supinated position and lacks any tenodesis for thumb flexion or opposition, tendon transfers will be ineffective without skeletal stabilization (carpometacarpal [CMC] fusion) in a key pinch position.

The next step is to determine the patient's needs, as shown in Table 33.3, and match the needs with the muscles available for transfer. For example, in a group 4 patient, the BR is available because the patient has the biceps and brachialis for elbow flexion (and, therefore, no function will be lost with the transfer); the ECRL is available because the patient has the ECRB for wrist extension. The PT can also be used for transfer, but this could result in diminished pronator power and loss of strength for manual wheelchair function. To complete the assessment, the muscles available for transfer (BR, ECRL) are matched with the needed functions (thumb extension and abduction, finger extension, thumb flexion and opposition, finger flexion, intrinsics) using principles of tendon transfer surgery (see Chapter 31), combined with other surgical options such as arthrodesis and tenodesis. In a group 4 patient, strength of grasp and pinch is deemed most important; thus the BR and ECRL are selected for finger and thumb flexion. The BR will be transferred to the flexor pollicis longus (FPL) because it has (and needs) less excursion, and the ECRL will be transferred to the flexor digitorum profundus (FDP) tendons, which need greater excursion. Surgical adjuncts will be used to pre-position the thumb in key pinch with a CMC fusion and to provide thumb and finger extension through an extensor pollicis longus (EPL) and extensor digitorum communis (EDC) tenodesis. If necessary, intrinsic reconstruction can be added during a second staged surgery if joint imbalance manifests. By evaluating what the patient has, what the patient needs, and what is available, the surgeon can determine the optimal combination of transfers and adjunctive procedures to restore function.

Diagnostic Imaging

At the time of the acute spinal cord injury, advanced diagnostic imaging is performed to determine the extent of spinal cord and skeletal injury and to assess the patient for spinal column stabilization procedures. Most patients with spinal cord injury have a rehabilitation team responsible for their care during the acute injury phase and subsequent rehabilitation. As noted in the pathogenesis section above, neurologic recovery after spinal cord injury does not fully stabilize until 12 months after the injury. Most hand surgeons become involved in the rehabilitation process for hand reconstruction 1 year after the spinal cord injury has occurred; at this stage, no further diagnostic imaging is routinely indicated.

PERTINENT ANATOMY

Injuries of the spinal cord produce a different nerve deficit than do central nervous system deficits, brachial plexus injuries, or isolated peripheral nerve injuries. The pattern seen with a spinal cord injury is based on segmental innervation; this concept means that the anterior horn cells in the spinal cord are arranged in a pattern from cephalad to caudad. Motor nuclei form longitudinal columns crossing several segmental levels, innervating the peripheral musculature in a predictable manner.

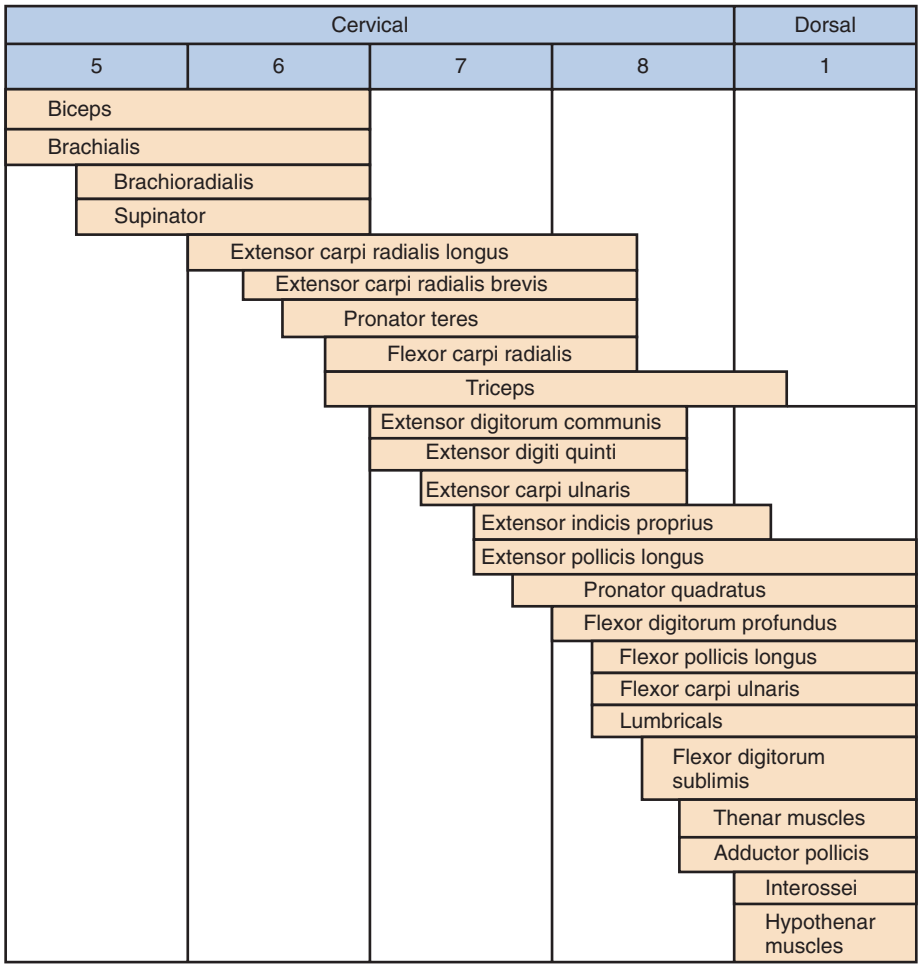

FIGURE 33.2 Segmental innervation of muscles of the elbow, forearm, and hand. Although not shown in this figure, the deltoid and biceps are both innervated from the C5-C6 level. Both the deltoid and the biceps receive their innervation from a higher level on the cervical cord than the triceps. (See Zancolli EA: *Structural and dynamic bases of hand surgery*, ed 2, Philadelphia, 1979, JB Lippincott.)

Figure 33.2 shows the segmental anatomy, based on Zancolli's clinical experience with tetraplegic patients.[96] When a spinal cord injury occurs, the motor nuclei cephalad to the injury will be functional; the motor nuclei at or caudad to the level of the injury will be nonfunctional.

Historical Review

Before the 1960s, the poor prognosis and low survival rate of patients with spinal cord injury precluded the need for upper extremity reconstruction. As the prognosis and medical care of patients with spinal cord injury improved, so did the surgical advancements in tendon transfer surgery. As shown in Table 33.4, advancements in tendon transfer surgery that were initiated by Bunnell were applied to tetraplegic patients by Moberg, Lamb, Zancolli, and Freehafer. Patients and physicians are now enthusiastic about the potential benefits of a well-designed and well-executed surgical plan for upper limb reconstruction in those with tetraplegia.

In addition to hand surgery reconstruction, significant research on and clinical treatment with a neuroprosthesis was performed from the 1980s to the 2000s. The use of electrical current for muscle stimulation in patients with spinal cord injury led Keith and associates at Case Western University to develop a fully implantable functional neuromuscular stimulation neuroprosthetic system.[47,49,75] This technology takes advantage of paralyzed muscles that are no longer under cortical control (due to spinal cord injury) but have intact spinal reflex arcs. The anterior horn cell of the motor units for eligible muscles must be uninjured to preserve the spinal reflex arc; the muscles are generally located below the level of the direct spinal cord injury. These muscles can be stimulated to contract with relatively weak electrical currents. Muscle signals, nerve signals, or volitional movements (above the level of spinal cord injury), typically from the contralateral shoulder or neck, are used to control the device.

The neuroprosthesis is indicated for tetraplegic patients for whom standard surgical procedures or orthotic devices cannot provide useful improved function or who have exhausted these options.[46] Most commonly, the neuroprosthesis is implanted in patients in groups 0, 1, 2, and 3. More than 250 adults and children have received the neuroprosthesis system worldwide.[7,12,18,20-22,41,71,73,76,83] As of 2008, the company that manufactured the device discontinued its production; second-generation 12-channel devices with telemetry and myoelectric control are available under research protocols and have shown promise in achieving independent two-handed use.[48]

Indications and Contraindications for Operative Intervention

The goal of tetraplegic hand reconstructive surgery is to increase the patient's independence; thus, the indication for operative treatment is functional impairment that can be improved through surgical reconstruction. Candidates for surgery include patients whose injury occurred at least 12 months ago, who have a stable upper extremity motor examination, and whose functional impairments can be improved by hand reconstruction. Ideally, the patient is free from contractures, pain, and spasticity; has the ability to comply with the postoperative rehabilitation regimen; has appropriate postoperative support services available; and is highly motivated to improve hand function. It is also critical that the patient be medically stable, including bowel and bladder function, blood pressure control, and no urinary tract infection or decubitus ulcers.

Two factors have had a uniformly adverse effect on the results of surgical treatment: spasticity and psychological problems. Spasticity that cannot be controlled by the patient is a strong contraindication to surgery. Freehafer and colleagues[29] and Moberg[66] stated that some spasticity might be helpful, but judging the degree of spasticity that is compatible with good results is very difficult; in fact, Moberg noted such an error in his poor results group. Psychological impairment, unrealistic expectations, insufficient motivation to complete the operative and postoperative protocols, and inadequate social support mechanisms should be assessed before surgery. Patients who want to have reconstructive surgery and are strongly motivated to improve their functional status are more likely to obtain a better outcome. The surgeon and patient must be able to communicate effectively and share *realistic* expectations of the benefits of surgery. Allowing a prospective patient to visit a

postoperative patient with a similar condition is particularly useful.

CRITICAL POINTS *Indications and Contraindications for Operative Intervention*

Indications

- Cervical spine injury with upper limb partial paralysis
- Stabilized motor recovery (12 months since injury)
- Functional deficits that can be improved with surgery
- Medically stable (blood pressure, bowel and bladder function)
- Infection free (decubitus ulcers, bladder)
- Full passive range of motion
- Realistic goals with good motivation and desire
- Personal and social stability to carry out rehabilitation and staged procedures (if necessary)

Contraindications

- Spasticity
- Contractures
- Chronic pain problems
- Psychological instability

TYPES OF OPERATIONS FOR TETRAPLEGIA

Three types of surgical procedures are most commonly performed: tendon transfer, tenodesis, and arthrodesis.

Tendon Transfer

Provided that the patient has adequate voluntary muscle control and strength of potential donor muscles, tendon transfers are preferred over tenodesis or arthrodesis because these restore active control and strength. However, the primary problem after spinal cord injury is a paucity of adequate donor muscles available for transfer. It is critical to ensure that sacrifice of a potential donor muscle for transfer will not create another functional deficit. The available muscles are prioritized first for wrist extension, then for pinch, then for grasp, and finally for release functions. Tendon transfer principles, including donor availability, donor strength, amplitude of excursion, passive mobility of recipient joints, and condition of the soft tissue bed, must be followed (see Chapter 31). When transfer options are exhausted, remaining hand functions are achieved through tenodesis and/or arthrodesis.

Tenodesis

Tenodesis is defined as the movement of one joint produced by the motion of an adjacent (usually proximal) joint. For instance, with active or passive extension of the wrist, the fingers and thumb spontaneously flex; with wrist flexion, the fingers and thumb extend. Although the finger and thumb muscles are paralyzed, there is sufficient remaining myostatic tension to induce reciprocal action of the digital flexor and extensor tendons that cross the wrist joint. Spinal cord injury patients learn to use the tenodesis effect naturally and commonly have functional but very weak pinch or grasp owing to the tenodesis effect alone. The tenodesis effect can be enhanced surgically without the need to transfer an active muscle. Passive tenodesis procedures anchor the paralyzed tendon proximal to the wrist joint to decrease effective tendon excursion and thus increase digital movement with active wrist movement. Common tenodesis techniques include those for finger flexion and extension, as well as for thumb flexion, extension, and abduction. Tenodesis can also be used to improve function of the intrinsic muscles of the fingers and thumb.

Arthrodesis

Arthrodesis is useful in the thumb to make this multiarticular joint more stable and easier to control. Combinations of tendon transfers and tenodesis procedures can be used at the CMC, metacarpophalangeal (MP), and interphalangeal (IP) joints to provide effective positioning and control of the thumb to produce pinch function. Particularly in the index finger, proximal interphalangeal (PIP) joint fusions can be used to stabilize a digit to provide a post for pinch. The wrist is never fused because the tenodesis effect would be lost. Surgical techniques for arthrodesis are no different in the paralytic hand; when possible, rigid fixation should be chosen to allow some weight bearing and early mobilization for tendon transfer rehabilitation.

Surgical reconstruction is based on the patient's International Classification group (see Table 33.2). Elbow procedures are presented first, followed by procedures used for grasp, pinch, and release.

ELBOW EXTENSION TENDON TRANSFER

For patients lacking active elbow extension, two options exist for reconstruction: deltoid to triceps transfer and biceps to triceps transfer.[87] Active elbow extension assists the patient in reaching objects above the shoulder level, improves driving ability, aids in wheelchair propulsion, permits pressure relief, and facilitates independent transfer.[6,25,81,84] Additionally, active elbow extension provides an antagonist to elbow flexion, which facilitates improved function through tenodesis after hand reconstructions that use the BR as a tendon transfer.[13] Pinch strength has been shown by Brys and Waters[13] to improve from 0.15 to 3.9 pounds in wrist extension in patients after elbow extension tendon transfers that improve elbow extension strength.

The biceps and the deltoid are innervated from the spinal cord at a higher level than the triceps. The posterior deltoid to triceps transfer has been used extensively over the past 30 years, but more recently, the medially routed biceps to triceps transfer has been used more frequently.

Biceps to Triceps Tendon Transfer

The biceps to triceps tendon transfer is my preferred method for establishing elbow extension (Figure 33.3). The biceps is used as the donor muscle. To ensure that function will not be lost with transfer of the tendon, the strength of the brachialis as an elbow flexor and of the supinator as a forearm supinator must be verified before transfer. Manual muscle testing is performed, testing elbow flexion, attempting to isolate the brachialis by supinating the forearm, and allowing relaxation of the biceps. This can be verified by palpating the groove between the more tubular biceps anteriorly and the flatter brachialis posteriorly to differentially test strength. In reviewing the segmental innervations of the upper limb from the spinal cord (see Figure

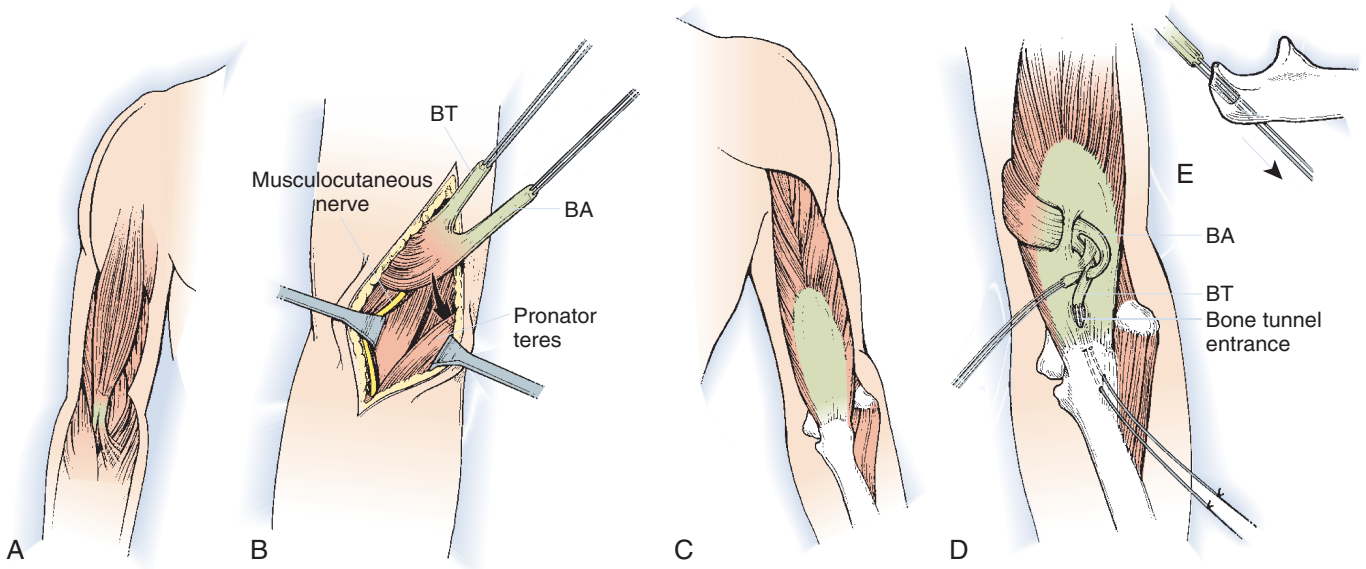

FIGURE 33.3 Biceps to triceps transfer. **A** and **B**, The biceps tendon (BT) and bicipital aponeurosis (BA; lacertus fibrosus) are released, and the muscle belly is mobilized proximally through an anterior incision. **C** and **D,** The biceps is rerouted medially around the arm in the subcutaneous plane and inserted by braiding the tendon "tails" into the triceps tendon. **E**, Direct insertion of the biceps tendon into a bone tunnel in the olecranon, with heavy sutures tied over bone. This provides strong fixation, permitting relatively early mobilization.

33.2), note that the biceps, brachialis, and supinator are all innervated at about the same level (C5-C6). If the patient has strong wrist extension, the spinal cord lesion should be below C6, sparing the biceps, brachialis, supinator, and wrist extensors, but above the innervation of the paralyzed triceps. Such findings on clinical examination verify that transfer of the biceps will not lead to a functional loss. Electromyography is generally not necessary as part of the routine evaluation.

The biceps to triceps tendon transfer can be performed using a medial[52,80] or a lateral[26,34,69] routing technique. The lateral technique was first described by Friedenberg[34] in 1954 and later reported by Zancolli.[95,97] No loss of active elbow flexion was noted, although flexor strength was diminished by 24%. In 1988 Ejeskar[26] reported his results using the lateral routing technique in five patients, including the first complication of radial nerve palsy. Because the radial nerve is the only functioning peripheral nerve in these patients, such a complication is devastating and has subsequently been noted by others using the lateral routing technique. Thus, medial routing is strongly preferred.

The procedure is performed with the patient supine, a roll under the operative shoulder blade, and the limb draped free with a sterile tourniquet high on the arm. The incision extends from the midhumerus on the medial side, transversely across the antecubital crease, and courses distally, centered over the biceps insertion on the radial tuberosity.[52] The lateral antebrachial cutaneous nerve is identified and protected as the biceps tendon is dissected free from its medial and lateral fascial attachments and sharply dissected off its insertion on the bicipital tuberosity. The lacertus fibrosus is freed from the forearm fascia during the dissection and is preserved as a second tail of the biceps tendon for subsequent weaving. The muscle is raised proximally, with care taken to preserve the musculocutaneous nerve running on the surface of the brachialis muscle.

A second (posterior) incision is made over the distal one third of the triceps tendon, passing lateral to the olecranon to avoid subsequent olecranon pressure ulceration and allowing an adequate skin bridge with the medial incision. A subcutaneous tunnel is made medially from the anterior wound to the posterior wound, creating a line of pull that is straight and free for medial rerouting of the biceps. The medial intermuscular septum may need to be partially resected, and care is taken to protect the neighboring ulnar nerve. The biceps tendon is passed from the anterior wound into the posterior wound, superficial to the ulnar nerve. A bone tunnel is created in the tip of the olecranon with a drill bit of 4 to 8 mm to receive the terminal end of the biceps tendon. The biceps length usually allows two or three weaves through the triceps tendon before it is inserted into the olecranon drill hole. A No. 5 nonabsorbable grasping suture is placed into the end of the biceps tendon and passed through the bone tunnel using Keith needles, tying the grasping suture over bone.

The transfer is tensioned to allow 60 to 90 degrees of passive elbow flexion. The lacertus fibrosus is interwoven through the biceps to triceps weaves to further secure the tendon weave. Postoperatively, the elbow is placed in about 30 degrees of flexion in a long-arm cast for 4 weeks. A flexion block splint (hinged elbow orthosis) is then used full time, and 15 degrees of flexion is added each week until full flexion and adequate arm control are achieved. Strengthening exercises are then added.

The strength of the biceps to triceps transfer continues to improve for at least a year, resulting in substantial improvements in performing activities of daily living. Published series have reported functional improvements for overhead, reaching, and driving activities.[26,51,52,96,97] No clinical loss of active flexion has been reported, although flexor strength was diminished by 24% in one series.[97] Mulcahey and coworkers[72] published a randomized prospective comparison of posterior deltoid to biceps transfer versus biceps to triceps with medial routing transfer. These authors reported that at 2 years, seven of eight

arms treated with biceps to triceps transfer had antigravity use of the arm, whereas only one of eight arms treated with posterior deltoid to triceps transfer had antigravity use of the arm.

CRITICAL POINTS *Biceps to Triceps Tendon Transfer*

Indications
- Availability of biceps as donor (adequate brachialis and supinator strength)
- Full passive range of motion or an elbow flexion contracture of less than 30 degrees
- Absent triceps function

Preoperative Evaluation
- Verify brachialis and supinator strength.
- Obtain elbow passive range of motion (splint if necessary).

Pearl
- Medial routing avoids the possible complication of radial nerve palsy.

Technical Points
- Anterior and posterior incisions are used, with an adequate skin bridge.
- Mobilize the biceps tendon, with the lacertus fibrosus included.
- Use No. 5 Ethibond grasping suture in the biceps tendon.
- Ensure a straight line of pull around the *medial* distal one third of the humerus.
- Perform two to three weaves of biceps tendon into triceps tendon.
- Insert the terminal end of the biceps tendon into the bone tunnel at the tip of the olecranon.

Pitfall
- A posterior incision over the olecranon is a potential pressure sore area.

Postoperative Care
- Long-arm cast in 30 degrees of flexion for 4 weeks
- Full-time flexion block splint, increasing 15 degrees per week until full range of motion is achieved
- Strengthening begins at 8 weeks, starting with a powder board to eliminate gravity.

Posterior Deltoid to Triceps Tendon Transfer

The posterior deltoid to triceps transfer uses the posterior third and the posterior half of the middle third of the deltoid muscle as a donor to provide active elbow extension (Figure 33.4). An interposition tendon graft is used, and the triceps tendon serves as the insertion. The posterior deltoid is tested before surgery by supporting the limb in 90 degrees of shoulder abduction and palpating the muscle for bulk and selective control while testing the strength of shoulder extension. Scapular stabilization and control are also necessary to maximize the effectiveness of the transfer.

The procedure is performed with the patient in a lateral decubitus position with the shoulder forequarter draped free. An incision is made from the tip of the posterior corner of the acromion distally to the deltoid tubercle insertion. Dissection is along the posterior border of the deltoid, leading into its insertion onto the deltoid tubercle. The axillary nerve courses about 5 cm distal to the acromion on the deep surface of the deltoid and must be protected as the posterior half of the middle deltoid is dissected with the posterior deltoid and freed from its insertion. A separate incision is made over the distal one third of the humerus to expose the triceps tendon. A subcutaneous tunnel is made, connecting the two incisions for placement of an interposition graft.

Several alternatives exist for the interposition graft. Moberg[66] originally used toe extensors from the second, third, and fourth toes to allow at least three weaves at each attachment site. Alternative graft materials have included fascia lata,[37] tibialis anterior,[53,58] and extensor carpi ulnaris (ECU).[54] Alternatively, Castro-Sierra and Lopez-Pita[15] used the central one third of the triceps. In this method, a 1-cm strip from the central one third of the triceps is harvested from its insertion in a retrograde manner (proximally based), mobilizing it sufficiently to graft back to the distal end of the posterior deltoid. Reflecting the central third of the triceps with a bone block and internally fixing this to a bone block from the deltoid insertion has also been described.[65]

After the interpositional graft has been placed, the transfer is sewn into place and tensioned with the shoulder in 30 to 40 degrees of abduction and no forward flexion, so that the elbow can flex to 60 degrees with moderate tension. Most commonly, a well-padded long-arm cylinder cast is applied to hold the elbow in about 10 degrees of flexion. The wrist can be left free. Forward flexion and shoulder adduction are avoided during the 6 weeks of cast immobilization. Gentle active exercises are performed to slowly gain elbow flexion for the next 3 months with a rate of 5 to 10 degrees of increased flexion per week.

Posterior deltoid to triceps transfers are compromised by the prolonged shoulder and elbow immobilization required postoperatively, as well as tendon graft elongation over time.[23,68,77,78] Elongation of the tendon graft leads to decreased strength over time. Friden and colleagues[30] used intraoperative metal markers at the ends of the tendon grafts and measured an average of 2.3 cm of elongation after 2 years. They changed their postoperative regimen to include longer elbow extension immobilization, and increased shoulder abduction. Follow-up of five patients using this regimen using the same markers averaged 0.8 cm.

PROCEDURES FOR PRODUCING FOREARM PRONATION

Pronation is important to patients who have only active wrist extension (groups 2 and 3). These patients use the automatic or tenodesis effect for grasp, but if the hand cannot be pronated, gravity cannot be used to provide a tenodesis effect for digital extension and release. Those patients using a tenodesis brace need pronation for the same reason.

Zancolli produced pronation by converting the biceps into a forearm pronator. He rerouted the tendon around the radius, converting the biceps from a supinator to a pronator.[94]

Biceps Rerouting Procedure

The biceps is rerouted from a supinator moment arm wrapping counterclockwise around the proximal radius, to a pronator moment arm wrapping clockwise around the proximal radius (Figure 33.5). This procedure can be done in isolation or in combination with one of the hand reconstructive procedures listed below. Indications for surgery are passive mobility of the forearm into pronation, without active pronation, as well as a

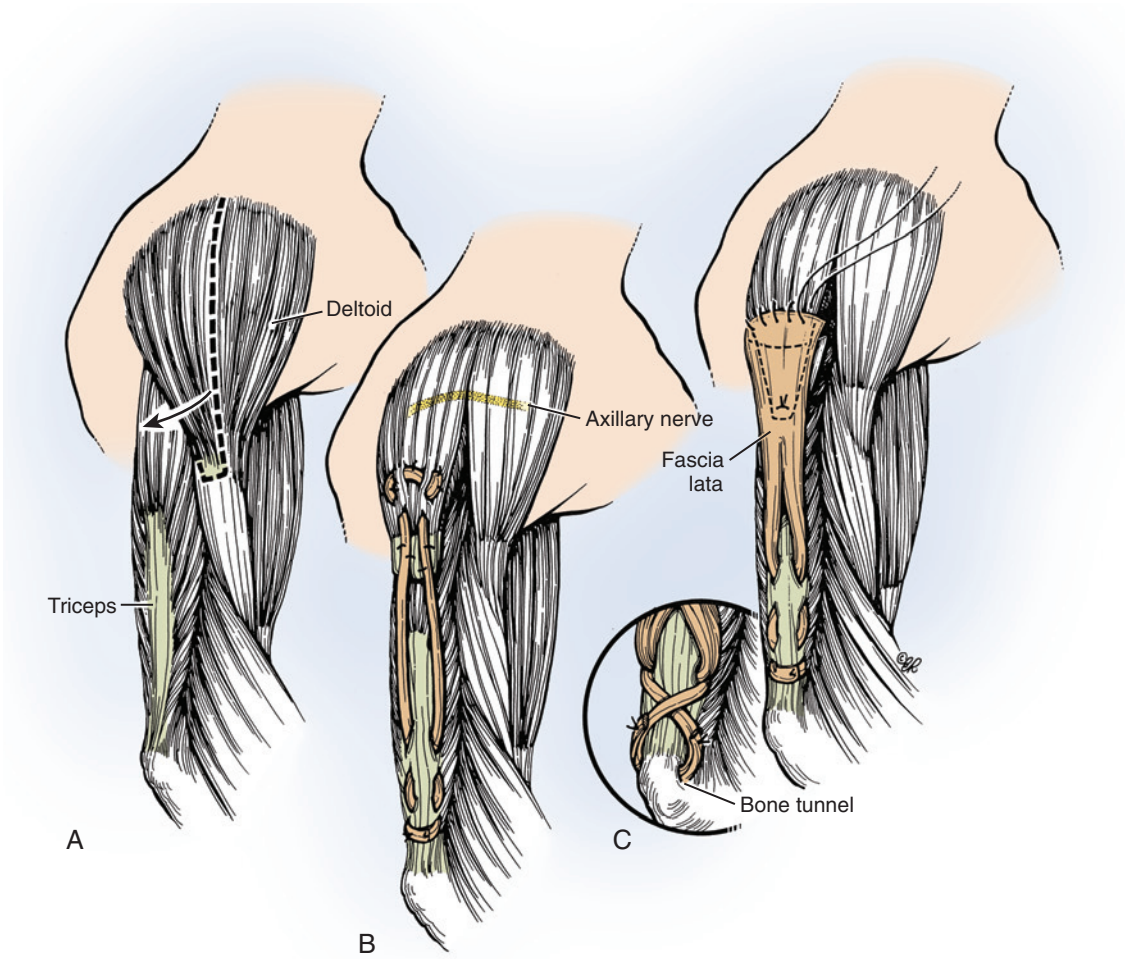

FIGURE 33.4 Deltoid to triceps transfer. **A,** The posterior border of the muscle belly is isolated, preserving as much of the tendinous insertion as possible. **B,** Tendon grafts are laced into the distal end of the deltoid muscle belly and triceps aponeurosis. **C,** Fascia lata is used rather than tendon grafts. Direct insertion into the olecranon through a bone tunnel can be performed with either type of graft. (Copyright © Elizabeth Martin. See also Moberg EA: Surgical treatment for absent single-hand grip and elbow extension in quadriplegia. *J Bone Joint Surg Am* 57:196–206, 1975.)

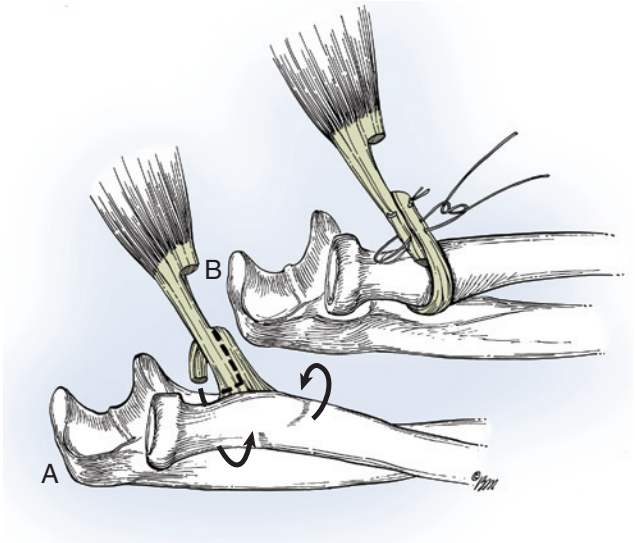

FIGURE 33.5 Zancolli's method for rerouting the insertion of the biceps tendon to provide pronation of the forearm. Half the tendon is passed behind the neck of the radius **(A)** and then sutured into the remaining biceps tendon **(B)**. (Copyright Elizabeth Martin. See also Zancolli EA: *Structural and dynamic bases of hand surgery*, ed 2, Philadelphia, 1979, JB Lippincott.)

biceps tendon of grade 5 strength that is a deforming force as a supinator leading to dysfunctional supination posturing. The biceps needs to be available for transfer, but not for transfer to the triceps to provide elbow extension strength.

A curvilinear incision is made from the proximal ulna, across the elbow crease, to past the radial neck on the radial side of the forearm. Dissection exposing the biceps from its musculotendinous junction to its insertion on the radial tuberosity is performed with coagulation or protection of the multiple venous structures. The biceps tendon is split longitudinally over a segment of 8 to 10 cm, and both ends are tagged. The forearm is placed in full supination, and the distal end of the biceps tendon is passed around the radial side of the radial neck using a long, curved, right-angle clamp, passing the tendon directly next to the bone. The proximal end of the Pulvertaft tendon is woven back into the distal end with two to three Pulvertaft weaves and secured using nonabsorbable 0-0 suture.

OPERATIONS FOR GROUP 0 PATIENTS

By definition, patients in this group have no muscle groups below the elbow with grade 4 strength to provide restoration of

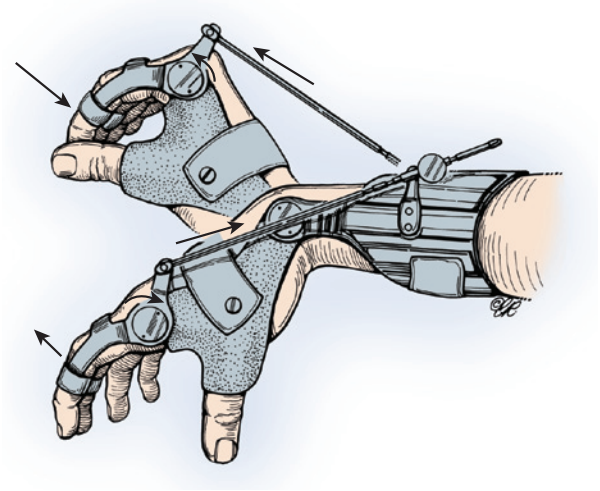

FIGURE 33.6 The wrist-driven flexor hinge splint uses the principle of synergistic action. As the wrist is extended, the fingers are flexed to bring them into contact with the thumb, which is fixed. As the wrist is flexed, the fingers are extended. (Courtesy of T. Engen, MD. Copyright Elizabeth Martin.)

pinch function. Elbow extension transfers should be performed as described earlier. Some group 0 patients may have both a weak BR and a weak ECRL. Assessing the strength of the BR muscle is difficult and requires an experienced examiner. It is best performed by having the patient flex the elbow against resistance while the examiner evaluates BR muscle tension by palpitating and trying to deflect the muscle belly. Transfer of the BR to the radial wrist extensors may provide sufficient strength to extend the wrist against resistance; this tendon transfer technique is described later for group 1 patients. Because the muscle's strength is no better than grade 3, the patient needs good elbow extension to serve as an antagonist to the BR transfer to enhance wrist extension function. If sufficient wrist extensor strength is obtained, a wrist-driven hinged tenodesis splint can be used (Figure 33.6), or a passive pinch tenodesis reconstruction can be considered.

OPERATIONS FOR GROUP 1 PATIENTS

In group 1 patients the BR has grade 4 or greater strength, and all other muscle groups below the elbow have less than grade 4 strength. Because elbow flexion is provided by the biceps and brachialis (innervated above the level of the BR), the BR is available for tendon transfer to provide wrist extension, which is the most necessary basic function. Lateral key pinch can be provided by tenodesis using a wrist-driven tenodesis splint (see Figure 33.6) or by surgical reconstruction. If a tenodesis splint is not used, two procedures are necessary for group 1 patients, and both can be done simultaneously: BR to ECRB transfer for active wrist extension, and passive key pinch reconstruction.

Brachioradialis to Extensor Carpi Radialis Brevis Tendon Transfer

Freehafer and Mast[28,29] describe a "utilitarian" incision on the radial side of the forearm near the junction of the proximal and middle thirds; its length is variable, depending on the exposure needed. The BR is on the radial aspect of the forearm, the ECRL is dorsal and parallel to it, and the ECRB is on the ulnar side of the ECRL. The tendons are exposed by opening their sheaths.

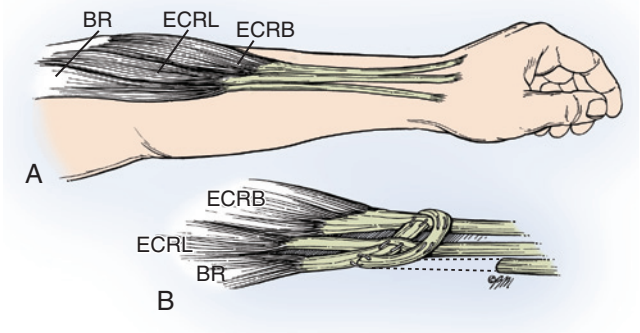

FIGURE 33.7 Brachioradialis (BR) transfer to extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB). An important technical detail is that the BR muscle belly must be mobilized completely to the elbow, taking care to protect its nerve supply from the radial nerve. I prefer to weave the BR three times into the wrist extensor (ECRB). Usually the ECRL is not included in the juncture (see text).

The BR tendon is dissected off its insertion and mobilized toward the elbow sufficiently to increase its excursion to 3 cm or more.[50] Special care is required to protect the superficial radial nerve, which courses beneath the BR muscle and becomes superficial between the BR and ECRL tendons (Figure 33.7). The BR tendon is passed through into the ECRB tendon, and secured with two to three Pulvertaft weaves. The BR tendon is usually woven through and sutured only to the ECRB tendon so as not to induce a radial deviation posture of the wrist, which would occur with transfer to the ECRL tendon. The tension should be set with the elbow at 45 degrees of flexion, with tension sufficient to hold the wrist in neutral. With the elbow flexed, the wrist should passively flex, and with the elbow extended, the transfer should tighten. Postoperatively, a long-arm cast is applied in the operating room to hold the elbow in 90 degrees of flexion and the wrist in 45 degrees of extension. The cast is removed at 4 weeks, and active range of motion is started; a removable splint is used for an additional 4 weeks to support the wrist when the patient is not exercising. Strengthening and functional use are then advanced, with night splinting only if necessary. Transfer of the BR to a weak or nonfunctioning radial wrist extensor should provide adequate strength for the use of a hinged tenodesis splint or surgical reconstruction of a passive pinch function.

Passive Key Pinch Reconstruction

To say that reconstruction of the paralyzed thumb for pinch function is a difficult proposition is an understatement at best. In activities of daily living, lateral key pinch is most useful. Although pulp-to-pulp pinch was described by Bunnell[14] in 1944 and referred to by Curtis[19] as an "opponodesis," this procedure has largely been abandoned because opposition pinch is beyond the scope of restoration in high-level injuries.[3,90] Skeletal control of three segmental joints (CMC, MP, and IP) must be combined with tenodesis vectors that appropriately position the thumb for effective pinch and release.

Because no additional muscles are available in this group (after BR to ECRB transfer), tenodesis of the FPL is used to produce a weak pinch, motored by active wrist extension (from the BR to ECRB transfer). Tenodesis of the EPL is used for release of pinch, activated through passive wrist flexion. Alternatives to passive key pinch tenodesis reconstruction include a

CRITICAL POINTS *Brachioradialis to Extensor Carpi Radialis Brevis Tendon Transfer*

Indications
- Group 1 patients with at least grade 4 BR strength and less than grade 4 strength of wrist extension
- Group 0 patients with grade 3 BR strength and less than grade 4 strength wrist extension

Preoperative Evaluation
- Strength testing (br, ecrl, ecrb)
- general indications and contraindications (spasticity, contractures, chronic pain, psychological or medical instability)

Pearl
- Full mobilization of the BR is needed to achieve excursion of 3 cm or more.

Technical Points
- A "utilitarian" radial-side incision extends proximally to fully mobilize the BR from its fascial attachments.
- Perform BR to ECRB tendon transfer with two to three tendon weaves sewn in place.
- Adjust tension so that with 45 degrees of elbow flexion, the wrist rests at neutral. With elbow extension, the wrist extends; with elbow flexion, the wrist flexes (not too tight and not too loose).

Pitfalls
- Inadequate BR excursion
- Inadequate tendon weaves
- Protect superficial branch of radial nerve

Postoperative Care
- From 0 to 4 weeks: long-arm cast
- From 4 to 8 weeks: active range of motion with protective wrist cock-up splint
- After 8 weeks: strengthening and functional use; optional night splint

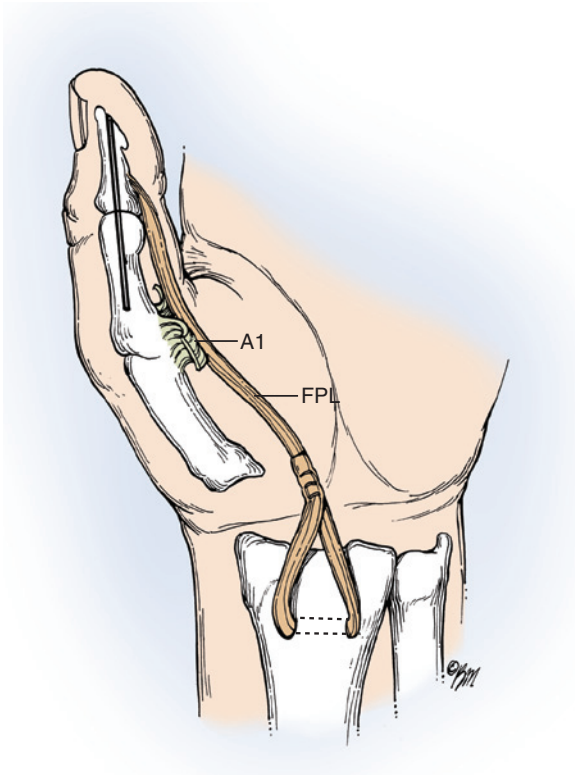

FIGURE 33.8 The classic Moberg passive key pinch reconstruction includes flexor pollicis longus (FPL) tenodesis to the radius at the proximal edge of the pronator quadratus and Kirschner wire fixation of the interphalangeal (IP) joint to prevent premature flexion (Froment sign). Additional optional steps include A1 pulley release to increase FPL torque at the metacarpophalangeal (MP) joint and fixation of the extensor pollicis brevis to the dorsal first metacarpal to avoid MP hyperflexion. This classic combination is seldom used because it has undergone many modifications, as described in the text. (Copyright Elizabeth Martin.)

tenodesis splint (see Figure 33.6) or functional electrical stimulation (see later).

As described by Bunnell[14] and popularized by Moberg,[66] the following combination has been recommended for passive key pinch reconstruction:

- FPL tenodesis to the radius at the proximal edge of the pronator quadratus
- Kirschner wire fixation of the IP joint to prevent premature and excessive flexion (Froment sign)

Additional optional steps include:

- A1 pulley release to increase FPL flexion axis at the MP joint
- Tenodesis of the extensor pollicis brevis (EPB) to the dorsal first metacarpal to avoid MP hyperflexion

This combination is classically referred to as the Moberg tenodesis pinch reconstruction (Figure 33.8).

Moberg's procedure has been modified to change the technique of FPL tenodesis so that it is divided high in the forearm, delivered into a volar wound over the MP joint through the flexor sheath proximal to the A1 pulley, and rerouted across the palm, deep to the flexor tendons and neurovascular bundles. The FPL tendon is passed proximally via the Guyon canal and is anchored onto the volar aspect of the radius. This change in pull provides a greater adduction moment arm, in addition to flexion. This modification, termed the Brand-Moberg tenodesis, was reviewed by Hentz and associates[38,39] and found to provide less pinch power than the original Moberg tenodesis.

Alternative techniques for the FPL tenodesis include fixation of the FPL tendon around the distal ulna as a "winch procedure," as described by Brummer.[11] Forearm supination helps activate the tenodesis as it "winds up" the ulna, which pulls the thumb into lateral pinch. This is generally not acceptable, because most functional activities are not carried out with simultaneous supination, wrist extension, and thumb pinch; however, for very high level involvement, the tenodesis strength of wrist extension is augmented by the strength of forearm supination.

Moberg stressed the importance of key pinch and described techniques for creating it,[66,68] and Hentz[39] modified Moberg's original tenodesis as follows:

- Stabilization of the thumb IP joint by pin fixation, fusion, or split FPL transfer (see the section on intrinsic reconstruction)
- FPL tenodesis to the distal radius to obtain the correct tension for lateral pinch
- Stabilization of the MP joint: if more than 45 degrees of flexion is present, use EPB and EPL tenodesis to the dorsal first metacarpal with a bone anchor suture; if more than 10 degrees of passive hyperextension is present, use a volar capsulodesis or an MP arthrodesis

Results of this procedure are superior for groups 2 and 3; group 1 patients fare less well because fewer muscles are available. Ejeskar and Dahllof[27] reported a typical series with an average final pinch strength of 0.7 kg. However, pinch *power* may be less important than thumb positioning.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Because of the common supination posturing of the thumb after a modified Moberg-type reconstruction, I prefer to add a CMC arthrodesis as described by House and colleagues[38] to better control thumb position in the active one-stage key pinch reconstruction (Table 33.5). For group 1 patients, the Hentz modification of the Moberg procedure, as described earlier, remains the procedure of choice.

OPERATIONS FOR PATIENTS IN GROUPS 2 AND 3

By definition, patients in groups 2 and 3 have a functional BR and wrist extension strength. It is difficult to determine the differential strength of the ECRL (group 2) and ECRB (group 3). If the patient has grade 4 or greater strength of the ECRL and grade 0 strength of the ECRB, the wrist will posture in radial deviation; however, such a large difference between ECRL and ECRB strength is uncommon. More commonly, both the ECRL and ECRB show active function, making it difficult to clearly differentiate group 2 (grade 4 or greater ECRL) from group 3 (grade 4 or greater ECRL and ECRB). If the ECRB has less than grade 4 strength and the ECRL is transferred, the result is devastating, with functional loss of wrist extension.

Methods have been described to test ECRL versus ECRB strength. Mohammed and coworkers[70] described the Bean sign: a groove between the ECRL and ECRB if both are firing at grade 4 or greater strength. Moberg[67] stated that the only way to measure differential ECRB and ECRL strength is with surgical exploration: With the use of local anesthesia, a needle is passed through the ECRB tendon and hooked up to a 5-kg weight. If the ECRB can lift at least 5 kg, the ECRL can be used without risk of loss of wrist extension function. Allieu[2] stated that if PT function is present, the two radial wrist extensor strengths can be assumed to be intact. Hentz and LeClerq[39] stated that in 25 years they had only one patient who was treated as a group 3 patient with transfer of the ECRL but was actually group 2, with resultant loss of wrist extension function. They recommended transfer of the ECRL only if the ECRB has grade 5 (not grade 4) strength. Most surgeons recommend using the ECRL for transfer and leaving the ECRB in place, because its insertion is central and the ECU is paralyzed.[38,60,96]

Review of the literature shows a variety of options for groups 2 and 3 patients. The BR is always available for transfer and has been used in a variety of ways. Street and Stambaugh[86] recognized the value of side pinch or "key grip" in 1959 and, in an attempt to increase the strength of pinch, transferred the BR to the FPL. Moberg[66] reported four patients with BR to FPL transfer and found the FPL tenodesis to be stronger than the transfer. In most cases, House and coworkers[37,42] transferred the BR to the FPL for a one-stage active key pinch reconstruction, and House's group and Zancolli[94] preferred to fuse the thumb CMC joint in 30 degrees of abduction to improve positioning.

Moberg used the BR to improve the release phase of the grasp-release sequence. He placed traction on the EPL, EPB, and abductor pollicis longus (APL) tendons at surgery to determine which gave the best abduction and then transferred the BR to that tendon. He did this operation as a second-stage procedure, following construction of a simple key grip (lateral pinch). He reported that the additional abduction was not as useful for the patient as he had anticipated.[66]

For group 3 patients, Zancolli[96] recommended a two-stage reconstruction. The first stage consists of (1) extensor tenodesis of the thumb and fingers, (2) intrinsic tenodesis using the "lasso" procedure to reduce clawing, and (3) thumb IP joint fusion. The second stage includes (1) ECRL to FDP tendon

transfer, (2) BR to FPL tendon transfer, (3) a volar thumb MP capsulodesis if the thumb MP joint is hyperextended, and (4) a volar tenodesis of the EPB tendon if the thumb is in excessive extension.

Zancolli's Staged Reconstruction for Group 3 Patients

Stage 1: Extensor Tenodesis

An 8- to 10-cm longitudinal incision is made on the radial side of the forearm to expose the dorsum of the radius proximal to the extensor retinaculum. A window large enough to accept the distal stumps of the common extensor tendons (which have been divided just distal to the musculotendinous junction) is made on the dorsum of the radius. Suturing the distal stumps together before severing the tendons preserves tendon balance. Stout nonabsorbable or wire sutures are passed through the tendon ends and brought through two drill holes made proximal to the window. Tension on the sutures draws the tendon stumps snugly into the bone window, and the sutures are tied to each other. The tension is set so that the finger MP joints are extended to 0 degrees with the wrist in slight palmar flexion. Next, a strip of the APL tendon is freed through the original radial longitudinal incision and is kept small enough to pass it proximally through the tunnel of the EPL, around the Lister tubercle, and into the window on the dorsum of the radius, where it and the tendon of the EPL are sutured to the bone with wire. This tenodesis produces thumb extension. Arthrodesis of the thumb IP joint is done in slight flexion to prevent hyperflexion of the joint and to facilitate side pinch. Additionally, a lasso is performed, as described later in the intrinsic rebalancing section.

Stage 2: Extensor Carpi Radialis Longus to Flexor Digitorum Profundus Transfer

When scar resolution is complete and the tenodesis is functional, the second-stage operation is done. The same radial lateral incision used in stage 1 is reopened to expose the ECRL and FDP tendons at their musculotendinous junction in the wrist crease. The ECRL is detached as distal as possible, delivered proximal to the retinaculum, and dissected proximally to improve its excursion and create a straight line of pull for its new insertion. The ECRL tendon is passed into the volar forearm, woven through each of the profundus tendons in an end-to-side fashion, and sutured with care to produce balance among all the fingers. Three Pulvertaft weaves are desired, and 2-0 nonabsorbable suture is used. Preliminary tension on the fingers should be observed during passive wrist flexion and extension with the elbow in varying degrees of flexion. Final tension should be set so that the fingers and thumb come together in a lateral pinch with the wrist in approximately 20 degrees of dorsiflexion and the elbow at 90 degrees. The tension is set loosely enough to allow easy release of the fingers during passive wrist flexion and so that the digital tips touch the palm with the wrist in full passive extension.

Next, the BR is detached from its insertion (leaving a short stump) and dissected well proximally so that maximal excursion can be obtained. The BR is sutured to the FPL with tension set to achieve lateral pinch with the wrist in approximately 20 degrees of extension and the elbow at 90 degrees (the same as in the ECRL transfer). If the thumb MP joint is hyperextended, a volar capsulodesis is recommended. The flexor tendon sheath is exposed through a transverse incision just proximal to the thumb MP joint flexion crease. The sheath is opened, and the FPL is retracted away from the volar plate. Care should be taken to protect the digital nerves. A longitudinal incision is made in the volar plate to expose and roughen the surface of the neck of the metacarpal. Two holes are drilled in the bone to receive a nonabsorbable suture. Alternatively, mini-suture anchors can be used. The volar plate is pulled proximally and sutured against the bone. Tension is set with the MP joint in 10 degrees of flexion.

Zancolli also constructs a volar tenodesis of the EPB tendon if the thumb is in excessive extension and lateral pinch is impaired. Through the radial incision, the EPB tendon is divided as far proximally as possible. The tendon is passed through the FCR tunnel and sutured into the short distal stump of the BR, which was left in place when it was divided for transfer previously. Tension is set to hold the thumb in complete abduction with the wrist in moderate extension.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

To avoid the loss of wrist extensor strength, my preference is to treat patients in groups 2 and 3 identically—not transferring either the ECRL or the ECRB. For groups 2 and 3 patients, I prefer House's one-stage active key pinch reconstruction[37] consisting of CMC fusion, BR to FPL tendon transfer, EPL tenodesis, split FPL transfer for stabilization of the thumb IP joint, and, if the index finger does not flex sufficiently to be a post for key pinch, a lasso procedure (see Table 33.5). Because most patients in groups 2 and 3 have adequate natural tenodesis and balance of the paralyzed fingers, reconstructive efforts are focused on the thumb.

House's One-Stage Key Pinch Reconstruction for Patients in Groups 2 and 3[42,43]

Carpometacarpal Fusion

A 3- to 4-cm incision is made, centered over the CMC joint in the interval between the APL and abductor pollicis brevis (APB). After exposure of the joint, a Kirschner wire is placed from the thumb metacarpal to the index metacarpal to preposition the thumb in the desired key pinch position: about 20 degrees of extension, 30 to 40 degrees of palmar abduction, and 10 degrees of pronation. The pulp of the thumb should be able to pinch against the radial side of the index finger at the PIP level. A thin slice of articular cartilage is resected from the base of the thumb metacarpal and the distal trapezium, using a small oscillating saw and taking care to minimize bone stock loss. The Kirschner wire is withdrawn from the index metacarpal, the joint surfaces are firmly opposed, and the Kirschner wire is advanced back into the index metacarpal, securing the thumb position before final internal fixation. After appropriate positioning adjustments are made, final fixation is secured with a mini–fragment blade plate (Figure 33.9).

Brachioradialis to Flexor Pollicis Longus Tendon Transfer

The BR tendon is exposed through the same radial-side utilitarian incision. The tendon is divided at its insertion and freed from its investing fascia to the proximal third of the forearm, taking care to protect the superficial radial nerve lying directly

FIGURE 33.9 Miniblade plate carpometacarpal (CMC) fusion. CMC fusion is best achieved using stable internal fixation; this allows mobilization of the hand when the tendon transfers are ready for active motion at 4 weeks after surgery.

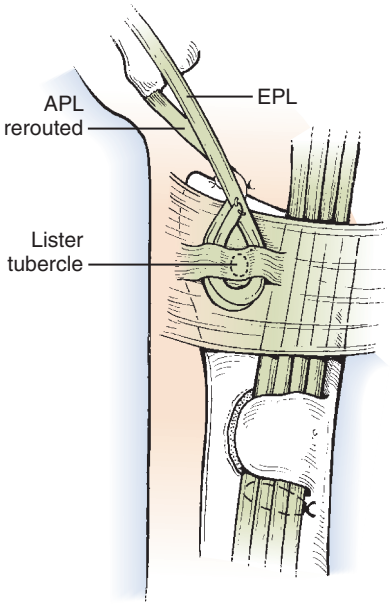

FIGURE 33.10 Extensor pollicis longus (EPL) tenodesis is woven through the extensor retinaculum, around the Lister tubercle, and back onto itself. This loop can be augmented by a bone anchor suture at the Lister tubercle if necessary. *APL,* Abductor pollicis longus.

underneath. This extensive mobilization of the BR is required to produce at least 3 cm of excursion. Through the radial incision, the FCR, flexor digitorum superficialis (FDS) tendons, and median nerve are gently retracted ulnarly to expose the FPL tendon. The BR is transferred under (dorsal to) the radial artery and woven into the FPL tendon with two to three Pulvertaft weaves and secured using 2-0 braided nonabsorbable suture, beginning the first weave at the musculotendinous junction. Tension is adjusted so that when the elbow is in about 45 degrees of flexion and the wrist is in neutral, the thumb is in neutral. With 20 degrees of wrist extension, the thumb should come into a key pinch position.

Extensor Pollicis Longus Tenodesis

Through the same incision, the proximal portion of the EPL tendon is exposed after identifying and protecting the superficial radial nerve. The tendon is divided at the level of the musculotendinous junction. The EPL is left in the third dorsal compartment, and the proximal portion of the tendon is woven through the extensor retinaculum just radial to the Lister tubercle and woven back into itself distal to the retinaculum. This creates an EPL loop around the Lister tubercle (Figure 33.10); fixation can be augmented with a bone anchor into the Lister tubercle if necessary. The APL tendon can undergo tenodesis with the EPL if greater thumb abduction, in addition to extension, is desired.

Split Flexor Pollicis Longus Transfer

The split FPL transfer is used to correct hyperflexion of the thumb IP joint due to intrinsic loss (Froment sign), which can prevent proper placement of the pulp onto the index finger for key pinch. In this procedure, half the FPL tendon is rerouted to the terminal extensor tendon to balance the IP joint.

In Sinclair's method of split FPL distal tenodesis (Figure 33.11),[70] the FPL is split through a longitudinal volar incision over the proximal phalanx. The radial half is detached and transferred subcutaneously to the dorsum, where it is sutured to the EPL, thus equalizing the pull on the volar and dorsal sides of the IP joint. I prefer a zigzag palmar incision to provide access for splitting the FPL from the divided A1 pulley to its terminal insertion on the distal phalanx. The oblique pulley is left intact. The radial half of the FPL is mobilized proximal to the oblique pulley and rerouted around the radial border to a longitudinal dorsal incision. The radial half of the FPL is woven into the EPL. The tendon is usually set so that the IP joint rests in about 30 degrees of flexion and contacts the side of the index finger in an appropriate key pinch position. The IP joint may be pinned for 4 weeks in slight flexion.

If the index finger does not flex into a key pinch position as part of the hand's natural tenodesis, index finger MP joint flexion can be enhanced through use of a lasso tenodesis (described later).

OPERATIONS FOR PATIENTS IN GROUPS 4 AND 5

By definition, patients in these groups have BR and wrist extension (ECRL and ECRB), grade 4 or greater strength in the PT (group 4) and FCR (group 5), and less than grade 4 strength in all other muscle groups below the elbow.

In patients in group 4, the PT should be considered for transfer; however, because the PT provides strong action for manual wheelchair propulsion, its use should be avoided if this is important to the patient. Zancolli[96] transferred the PT to the FCR to further enhance the strength of the wrist-activated

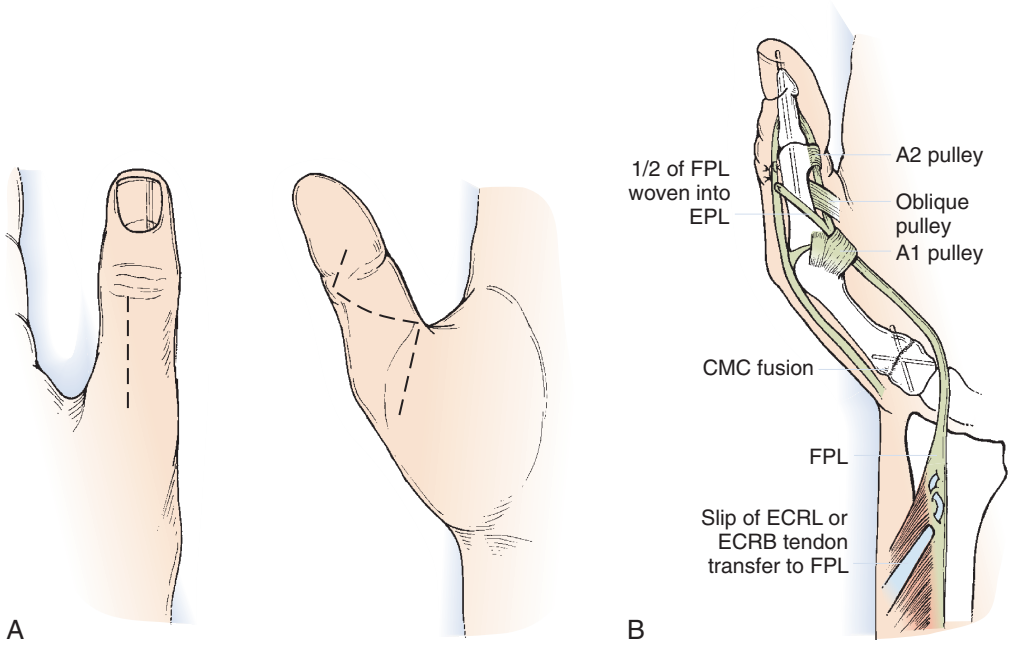

FIGURE 33.11 Split flexor pollicis longus (FPL) distal tenodesis. **A,** Dorsal and palmar incisions. **B,** Transfer of the radial half of the FPL to the extensor pollicis longus (EPL) improves thumb intrinsic balance by stabilizing the metacarpophalangeal and interphalangeal joints, providing more effective lateral pinch. *CMC,* Carpometacarpal; *ECRB,* extensor carpi radialis brevis; *ECRL,* extensor carpi radialis longus. (See Mohammed KD, Rothwell AG, Sinclair SW, et al: Upper limb surgery for tetraplegia. *J Bone Joint Surg Br* 74:873–879, 1992.)

CRITICAL POINTS *Split Flexor Pollicis Longus Tendon Transfer*

Indication
- All patients undergoing transfer to the FPL tendon with IP joint flexion greater than 60 degrees or the Froment sign, which precludes effective key pinch positioning of the thumb pulp onto the side of the index finger

Preoperative Evaluation
- Joint stability assessment of thumb CMC, MP, and IP range of motion
- Intraoperative assessment of the effect of FPL pull on the thumb pulp in "hitting" the side of index finger as the FPL is tensioned

Pearl
- Many patients benefit from this procedure as a part of an overall reconstruction.

Technical Points
- Tension can be set to allow some IP joint flexion with FPL activation, but as the dorsal tenodesis of the split FPL into the EPL tightens, no further flexion will occur.
- The tendon weave can occur over the dorsal proximal phalanx as needed.

Pitfall
- Incorrect tension of the FPL tendon weave

Postoperative Care
- From 0 to 4 weeks: cast or Kirschner wire–cast immobilization of the thumb IP joint
- From 4 to 8 weeks: thumb spica splint
- After 8 weeks: strengthening and active functional use with nighttime bracing if needed

tenodesis of digital extension. House and Walsh[40] described transferring the PT to the FPL as part of a two-stage reconstruction; House[40] does not believe that transferring the PT produces a significant loss of pronation.

The wrist flexion strength of patients in group 5 improves antagonist power for the wrist extension–driven tenodesis function of the fingers. Lipscomb and colleagues[60] in 1958 and Lamb and Landry[55] in 1971 reported transfer of the FCR in group 5 patients, but House[41] prefers to leave the FCR in place to preserve maximal wrist control.

In groups 4 and 5, the BR, ECRL, and PT muscles are available for transfer. The ECRB and the FCR are generally preserved to retain good wrist control. Because there are more muscles available in patients in groups 4 and 5, the surgeon most commonly chooses a two-stage reconstruction of grasp (flexor phase) and release (extensor phase), using the method described by either House or Zancolli. At the first stage (extensor phase), the thumb is positioned and tenodesis of the extensor tendons is performed. At the second stage (flexor phase), the thumb and finger flexor tendons are activated for grasp and the finger intrinsics are activated for balance. Other options include a simple lateral pinch reconstruction or a single-stage reconstruction that prioritizes grasp.[45]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

I prefer the House two-stage reconstruction using a thumb CMC arthrodesis to stabilize the thumb in an optimal position (see Table 33.5). However, when bilateral reconstruction is performed, one thumb is arthrodesed and the second thumb undergoes adduction-opponensplasty transfer to maximize mobility (Figure 33.12).[39,44] One of the available motors (usually

CRITICAL POINTS *House's One-Stage Key Pinch Procedure*

Indications
- Group 1 patients using FPL for passive tenodesis
- Groups 2 and 3 patients with greater than grade 4 wrist extensor strength using BR to FPL for active pinch

Preoperative Evaluation
- Verify BR and wrist extensor strength
- Evaluate thumb position and index finger position in their "natural tenodesis" pattern to verify that this combination of FPL tenodesis, EPL tenodesis, and CMC fusion will obtain the desired thumb position.

Pearl
- The thumb is tensioned so that it "hits" the lateral aspect of the PIP joint of the index finger with 20 degrees of wrist extension and opens with wrist flexion, providing adequate clearance for release.

Technical Points
- CMC fusion: Stable minifragment fixation after parallel CMC joint surfaces are prepared, positioning the thumb in 40 degrees of abduction, 25 degrees of extension, and 10 degrees of pronation, so the thumb "hits" the lateral aspect of the PIP joint of the index finger.
- EPL tenodesis: Tenodesis of the EPL is performed around the Lister tubercle and woven through the extensor retinaculum and back through itself, tightly enough to allow full thumb opening with passive wrist flexion and full passive thumb flexion with passive wrist extension.
- BR to FPL transfer (groups 2 and 3): full mobilization of the BR tendon and Pulvertaft weave to the FPL
- Split FPL transfer for IP stabilization
- If the fingers do not pull into enough flexion to allow a stable base for key pinch reconstruction, a lasso procedure may be necessary (see later).

Pitfall
- Check thumb position based on both elbow flexion-extension and wrist flexion-extension, because the BR crosses both joints. Tension is adjusted so that when the elbow is in about 45 degrees of flexion and the wrist is in neutral, the thumb is in neutral. With 20 degrees of wrist extension, the thumb should come into a key pinch position. With 20 degrees of wrist flexion, tenodesis should cause the thumb to be positioned in extension.

Postoperative Care
- From 0 to 4 weeks: short-arm thumb spica cast in neutral to protect from active flexion-extension of the thumb
- From 4 to 8 weeks: active range of motion with protective forearm-based thumb splint
- After 8 weeks: strengthening and functional use with night splint if necessary

the BR) is lengthened with a tendon graft (taken from the paralyzed FDS)[9,38] to motor the opponensplasty.

House's Two-Stage Grasp, Pinch, and Release Procedure

Stage 1: Extensor Phase

A CMC fusion is performed using the previously described technique, and an EPL tenodesis is performed using House's technique (see earlier). House prefers a different EDC technique than that described by Zancolli.[45]

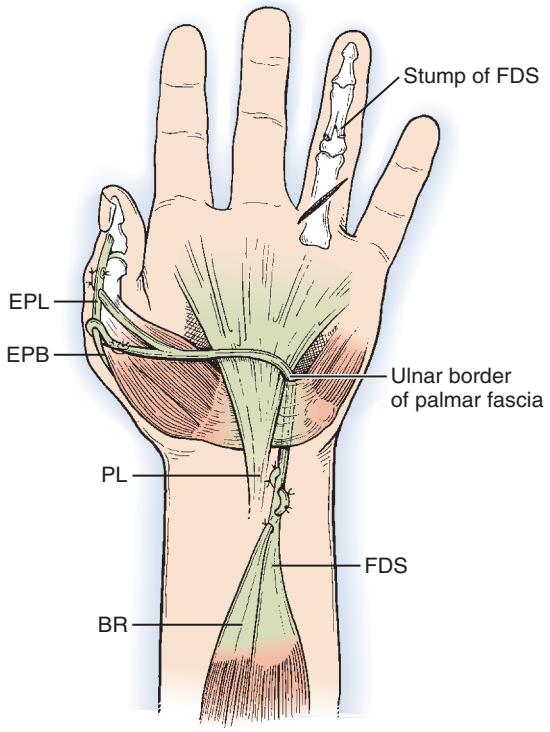

FIGURE 33.12 Adduction-opponensplasty. A motor is transferred to the paralyzed flexor superficialis as an "in situ tendon graft." It is rerouted around a palmar fascial "pulley" to a dual insertion that controls thumb rotation and stabilizes the metacarpophalangeal and interphalangeal joints, for more effective lateral pinch. The brachioradialis (BR) is usually used as the motor in group 5, and the flexor carpi ulnaris is used in group 7 or 8. *FDS,* Flexor digitorum superficialis; *EPB,* extensor pollicis brevis; *EPL,* extensor pollicis longus; *PL,* palmaris longus. (See House JH, Shannon MA: Restoration of strong grasp and lateral pinch in tetraplegia: a comparison of two methods of thumb control in each patient. *J Hand Surg [Am]* 10:22–29, 1985.)

Extensor Digitorum Communis Tenodesis. Finger extension is produced by tenodesis of the common extensors to the distal radius (Figure 33.13). The antebrachial fascia is opened from the proximal edge of the extensor retinaculum to the musculotendinous junction of the extensor digitorum tendons through the radial incision. Retracting the extensor indicis proprius (EIP) and the common extensors ulnarward exposes the floor of the fourth dorsal compartment. A 2- by 2-cm flap of periosteum of the distal radius is elevated on the metaphysis of the radius, leaving it attached on its ulnar side. A 2-cm bone window is created. Next, the common extensor tendons are sutured together with the fingers in balance using 2-0 nonabsorbable suture, transected proximal to the suture, and inserted into the bone window. The periosteal flap is sewn over the extensor tendons using a 2-0 braided, nonabsorbable suture. The tension is adjusted so that when the wrist is passively flexed to 30 degrees, the MP joints extend to 0 degrees; full finger passive flexion is possible with full wrist extension.

Intrinsic Tenodesis. Intrinsic tenodesis can also be performed in this stage to correct inadequate digital PIP extension. A free tendon graft is routed through the lumbrical canals, volar to the deep transverse metacarpal ligament and around the second metacarpal (as shown in Figure 33.13, *A*), and braided and sutured into the lateral bands and central slips of adjacent fingers. The same technique is used for the ring and little fingers

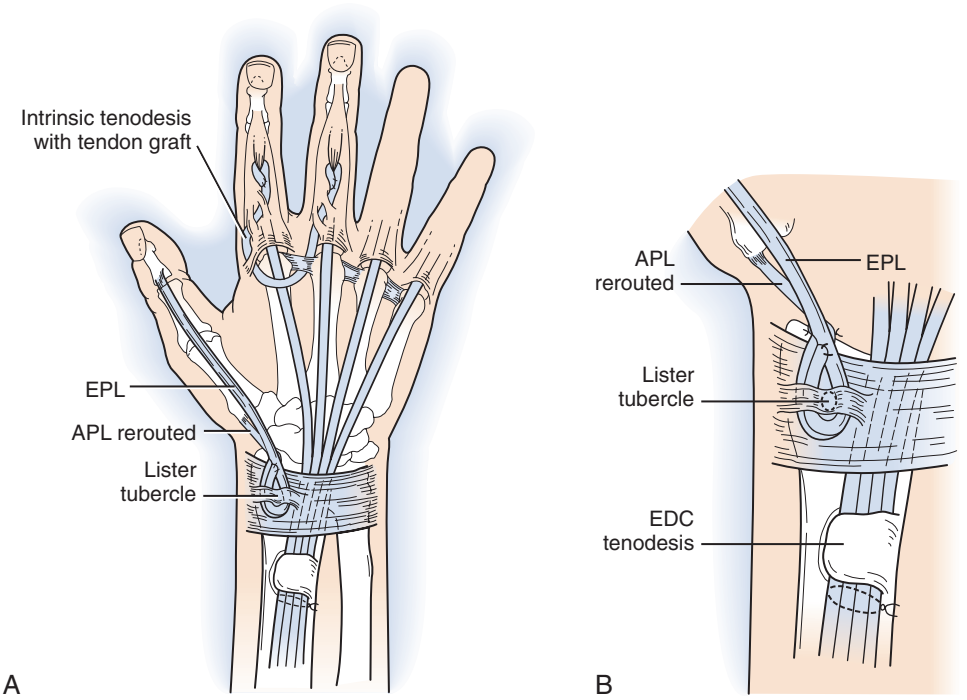

FIGURE 33.13 Stage 1 (extensor phase) of House's two-stage reconstruction for patients in group 5. **A,** Intrinsic tenodesis may be performed for inadequate interphalangeal extension. A free tendon graft is routed through the lumbrical canals, volar to the deep transverse metacarpal ligament and around the second metacarpal, and braided and sutured into the lateral bands and central slips of adjacent digits. The same technique can be used for the ring and little fingers (around the fourth metacarpal). **B,** Tenodesis of the extensor digitorum communis (EDC) is accomplished by fixation of the tendons into a "horseshoe window" in the distal radius with a heavy suture that also balances the relative tension of all four fingers. The extensor pollicis longus (EPL) and abductor pollicis longus (APL) (rerouted through the third dorsal compartment) are usually passed around the Lister tubercle and braided together to provide balanced thumb abduction and extension and sutured in a loop around the extensor retinaculum. (Copyright Elizabeth Martin. See also House JH, Shannon MA: Restoration of strong grasp and lateral pinch in tetraplegia: a comparison of two methods of thumb control in each patient. *J Hand Surg [Am]* 10:22–29, 1985.)

(around the fourth metacarpal) when IP joint extension is inadequate in those digits.[39]

Postoperative Casting and Rehabilitation. The patient is placed in a short-arm cast for 4 weeks of immobilization, with the fingers included in a position of MP extension and the PIP joints in full extension (if intrinsic reconstruction was performed concurrently). A thumb spica component is used to hold the CMC in the fused position. After 4 weeks, the same position is held with a volar forearm-based resting splint. Active range of motion with light activities of daily living is initiated. After 8 weeks the splint is worn only at night, and strengthening exercises are added. The second stage is usually planned 3 months after the extensor phase surgery.

Stage 2: Flexor Phase

The ECRL is transferred to the FDP tendons, using the technique described earlier. If the BR was not used in the extensor phase, it is transferred to the FPL. If the BR was used, the pronator is transferred to the FPL for pinch (Figure 33.14). Although several options exist, my preference is CMC fusion, EDC tenodesis, and EPL tenodesis (extensor phase), followed by ECRL to FDP and BR to FPL transfers (flexor phase). With bilateral procedures, I perform a BR adduction-opponensplasty instead of a CMC arthrodesis (in the flexor phase) and transfer the pronator to the FPL for pinch. Alternatively, the BR can be transferred to the EDC and EPL instead of tenodesis in the extensor phase, followed by ECRL to FDP and PT to FPL transfers (flexor phase). I find the extensor tenodesis more reliable than the BR transfer for digital extension in groups 4 and 5.

Pronator Teres to Flexor Pollicis Longus Tendon Transfer. The PT is harvested from its radial insertion through the radial incision. The tendon length can be augmented by elevating the attached radial periosteum distally for 4 to 5 cm. The muscle should be lifted and dissected proximally to increase its excursion, and the tendon-periosteal extension is transferred to the FPL. Tension should be set so that the thumb comes into contact with the lateral side of the index finger when the wrist is passively extended to 20 degrees.

Opponensplasty. The adduction-opponensplasty is produced by transferring a motor to the paralyzed flexor superficialis as an "in situ tendon graft." It is rerouted around a palmar fascial "pulley" to a dual insertion that controls thumb rotation and stabilizes the MP and IP joints for more effective lateral pinch. The BR is usually used as the motor in group 5 (see Figure 33.12). As described later for groups 7 and 8, the flexor carpi ulnaris (FCU) can be used as the motor.[39]

Postoperative Casting and Rehabilitation

The patient is placed in a long-arm dorsal extension block cast with the fingers included for 4 weeks of immobilization; MP extension is blocked at 30 degrees, PIP joints are blocked at 30 degrees of extension, and thumb extension is blocked at the MP

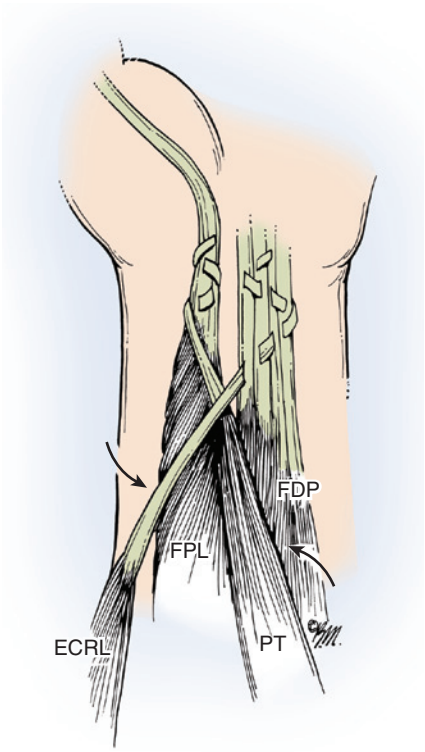

FIGURE 33.14 Stage 2 (flexor phase) of House's reconstruction includes both extensor carpi radialis longus (ECRL) to flexor digitorum profundus (FDP) tendon transfer and pronator teres (PT) to flexor pollicis longus (FPL) tendon transfer. Another option would be ECRL to FDP and brachioradialis to FPL tendon transfers. (Copyright Elizabeth Martin. See also House JH, Shannon MA: Restoration of strong grasp and lateral pinch in tetraplegia: a comparison of two methods of thumb control in each patient. *J Hand Surg [Am]* 10:22–29, 1985.)

and IP joints. After 4 weeks the same position is held with a dorsal forearm-based resting splint. Active range of motion with light activities of daily living is initiated. After 4 additional weeks the splint is worn only at night, and strengthening exercises are added.

Alternative Techniques for Patients in Groups 4 and 5

Alternative techniques for reconstruction of groups 4 and 5 have recently been described by Friden and colleagues.[33] They have used a single-stage grip, pinch, and release advanced balanced combined digital extensor flexor grip (ABCDEFG) procedure, or "alphabet reconstruction." They also describe using this technique for group 3 patients with verified grade 5 strength of both the ECRL and ECRB. If used for higher-level patients (those in group 5 or above), not all seven elements of the reconstruction would be necessary.

ABCDEFG Procedure (Alphabet Reconstruction)

This procedure has seven components, all of which may be used for each patient or some of which can be chosen based on the specific passive mobility or tenodesis pattern.[33] The seven elements of the reconstruction include:

1. BR to FPL tendon transfer to provide pinch
2. ECRL to FDP tendon transfer to provide grasp
3. EPL tenodesis for passive thumb extension
4. ECU tenodesis to provide balanced wrist extension (without excessive radial deviation)
5. Split FPL transfer to prevent the Froment sign
6. Thumb CMC fusion to pre-position the thumb in key pinch position
7. Intrinsic tenodesis to provide passive PIP extension

The technique for each of the elements of this procedure is described in this chapter, except for the ECU tenodesis, which is not described as part of other reconstructive plans.

CRITICAL POINTS *House's Two-Stage Grasp, Pinch, and Release Procedure*

Indications
- Group 4 patients with BR, ECRL, ECRB, and PT strength grade 4 or 5 or greater
- Group 5 patients with BR, ECRL, ECRB, PT, and FCR strength grade 4 or 5 or greater

Preoperative Evaluation
- Verify muscle strength testing.
- General indications and contraindications (spasticity, contracture, chronic pain, psychological or medical instability)

Pearl
- Use of at least three tendon weaves increases strength at the tendon weave junctions.

Technical Points

Extensor Phase
- CMC fusion for stable thumb, positioning the thumb in 40 degrees of abduction, 25 degrees of extension, and 10 degrees of pronation, so that the thumb "hits" the lateral aspect of the PIP joint of the index finger
- EDC and EPL tenodesis for passive finger and thumb extension
- Option: BR to EDC and EPL tendon transfers for active finger and thumb extension

Flexor Phase
- ECRL to FDP tendon transfer for active finger flexion
- BR to FPL tendon transfer for active thumb pinch
- Option: PT to FPL tendon transfer for active thumb pinch (if BR was used in extensor phase)
- Option: thumb adduction-opponensplasty using BR and FDS tendon graft, performed in bilateral reconstructions instead of CMC fusion on one side

Pitfall
- Inappropriate tension: not too tight and not too loose

Postoperative Care
- From 0 to 4 weeks
- Extensor phase: short-arm thumb spica cast with thumb IP extension and finger MP extension
- Flexor phase: long-arm cast with dorsal extension block with the fingers and thumb included, with MP extension blocked at 30 degrees, PIP extension blocked at 30 degrees, and thumb extension blocked at the MP and IP joints
- From 4 to 8 weeks: active range of motion with protective forearm-based thumb splint
- After 8 weeks: strengthening and functional use with night splint if necessary

Extensor Carpi Ulnaris Tenodesis

As part of the tetraplegic hand reconstruction, excessive radial deviation can be corrected by the ECU tenodesis procedure.[79] A curved incision is made at the wrist over the sixth compartment. The extensor retinaculum is opened over the ECU tendon, which is elevated with a tendon hook. The tendon is shortened approximately 2 cm by folding the tendon and securing it with two size 2-0 double mattress nonabsorbable sutures, and then sutured onto the joint capsule of the ulnar head with two 4-0 absorbable sutures. Passive position of the wrist decreases radial deviation but maintains flexion and extension.

Reinholdt and associates[79] present 18 patients treated with a tetraplegia hand reconstruction that included ECU tenodesis and compared this with a historical control group of 33 patients treated without ECU tenodesis. The ECU tenodesis group had less radial deviation deformity and had 6.1 kg of grip strength compared with 2.1 kg of grip strength in the control group. No differences in pinch strength were noted.

Other differences between the alphabet reconstruction and the techniques described in this chapter are the intraoperative tendon transfer technique and the postoperative rehabilitation.

Tendon Transfer Technique

In this tendon transfer technique,[10,32] the BR to FPL tendon transfer and the ECRL to FDP tendon transfer are sewn with a side-to-side tendon to tendon attachment that allows more aggressive and active postoperative rehabilitation. A 5-cm overlap between the tendon donor and tendon recipient is made. A single slit is made in the recipient tendon and the donor tendon is passed through and overlapped for a 5-cm segment. Running 3-0 nonabsorbable sutures are placed along both sides of the overlapping tendons as shown in Figure 33.15. One double-loop suture secures each free end of each tendon using 3-0 nonabsorbable suture.

Postoperative Rehabilitation. Active range of motion begins on the first postoperative day and is allowed in a protective manner for the first 4 weeks following operation. During this time, full flexion of the digits is not allowed (at least 2 cm of the fingertip to palm distance is required to protect the intrinsic tenodesis). Resting splints are used for protection, maintaining the wrist in neutral position and the MP joints in 60 degrees of flexion. A protective splint for the CMC and IP joints of the thumb is also used. Between 4 and 8 weeks following the operation, the patient continues to wear the protective splints, but the patient removes them for functional activity training. All restrictions and splints are removed by 12 weeks after surgery.

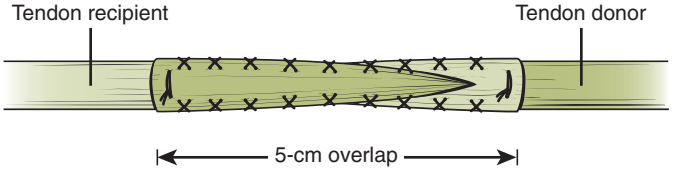

FIGURE 33.15 Side-to-side weave consists of the donor tendon inserting through one incision in the recipient tendon with cross-stitch running 3-0 nonabsorbable sutures back and forth down both sides and one double-loop 3-0 nonabsorbable suture at each tendon free end.

Reinholdt and colleagues[33] reported on 14 patients with 16 hands treated with the alphabet reconstruction and rehabilitation, and compared this group with a historical control group of 15 patients with 18 hands treated with two-stage reconstruction. All patients were in ICS group 4. In the alphabet group, grip strength was 6.5 kg, compared with 1.6 kg in the control group. Pinch strength was similar in the two groups. The opening of the first web space was 5.5 cm in the alphabet group, compared with 3 cm in the control group. Complications included one tenolysis, one ruptured intrinsic tenodesis that required another repair, and one subsequent tendon transfer for digital opening. Four patients could not make a full fist with a 1- to 2-cm gap between fingertip and distal palmar crease.

OPERATIONS FOR PATIENTS IN GROUPS 6 AND 7

Patients in group 6 have at least grade 4 strength of the group 5 muscles (BR, ECRL, ECRB, PT, FCR) as well as the EDC. Patients in group 7 have at least grade 4 strength of the EPL in addition to the functioning muscles of group 6. In these two groups a separate extensor phase is not required, and reconstruction involves a flexor phase consisting of an ECRL to FDP transfer and a BR to FPL transfer. An intrinsic reconstruction is added as needed.

Because these patients have active unopposed digital extension, they often present with a characteristic "flat hand" appearance.[39] Their digital function is not significantly greater than that of patients in groups 4 and 5, because they lack active grasp and release. Of note, patients with this lower level of spinal cord injury also have stronger shoulder and elbow control, so their ability to position the hand in space is usually excellent. These patients benefit greatly from grasp and pinch reconstructive surgery. Results after surgery in groups 6 and 7 patients are much better than in those with higher-level injuries; their improved shoulder control and normal extensor function give them more precise control.

For group 6 patients, the finger extensors are strong but EPL function is either absent or too weak to extend the thumb adequately. The EPL can undergo tenodesis or transfer into the digital extensors to improve thumb extension. This can be done in conjunction with the flexor transfers or staged, based on the surgeon's preference.

For group 7 patients, both finger and thumb extensors are strong, so the flexor phase alone is performed. Thumb control can be achieved through either CMC fusion or opponensplasty, depending on the thumb's stability and position as well as the patient's preference. Many patients prefer opponensplasty for one thumb and fusion for the other.[37] Intrinsic reconstruction can also be done to augment digital grasp in patients with severe clawing.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

The ECRL is transferred to the FDP for active finger flexion as described earlier, and the BR or PT is transferred to the FPL for active pinch. My preference is to transfer the BR to the FPL for active pinch, preserving the PT for wheelchair propulsion (see Table 33.5). In addition, the following thumb control and intrinsic reconstructions can be added.

Extensor Pollicis Longus to Extensor Digitorum Communis Transfer (Group 6 Patients)

A half-thickness slip of the EPL tendon is braided through the index EDC. This transfer is performed such that the length-tension relationship of the EPL is unchanged, ensuring that relative tension will be maintained between the EDC and EPL tendons. The tendons are firmly sutured together with three or four horizontal mattress sutures of 2-0 nonabsorbable, braided polyester. If the common extensor tendon to the index finger is small, additional common extensor tendons can be included to produce a strong union.

Thumb Control Options

Examination for joint instability is essential. The CMC joint can be fused to provide key pinch positioning, as described earlier. If the MP is hyperextensile, it can be stabilized by advancing the volar plate proximally and anchoring it to the metacarpal neck with sutures or a suture anchor. Zancolli[96] has also described a volar capsulodesis technique employing sesamoid fusion. The radial or ulnar sesamoids are lifted in continuity with the attached volar plate, decorticated, and fixed with sutures or Kirschner wires to a denuded area on the volar metacarpal neck.

A hyperflexed IP joint can be stabilized using the split FPL technique described earlier (see Figure 33.11). Additional power and positioning control can be provided by performing an opponensplasty using the BR or PT as a motor, as described earlier. My preference is to perform a CMC fusion on one side and an opponensplasty on the other side to provide different types of thumb functions for the patient.[37]

Intrinsic Reconstruction: The Lasso Procedure

These patients have excellent selective digital control because their digital extensors are intact, but they may benefit from an active lasso procedure to compensate for the loss of intrinsic function. Palsy of the intrinsics in patients with functioning extrinsic extensors and flexors leads to digital "roll-up," which makes effective grasp difficult. Digital roll-up occurs when the distal interphalangeal (DIP) joint flexes before the PIP, and the MP joint fails to flex. Such hand positioning makes it difficult to grasp large objects.

The Zancolli lasso procedure helps initiate MP flexion as the first stage of digital grasp, followed by PIP and finally DIP flexion, to enable grasping of large or cylindrical objects. Because the FDS is nonfunctional, transfer of the BR or PT to the FDS provides a motor to power the lasso procedure.

Postoperative Casting and Rehabilitation

The patient is placed in a long-arm dorsal extension block cast with the fingers included for 4 weeks of immobilization; MP extension is blocked at 30 degrees, the PIP joints are blocked at 30 degrees of extension, and thumb extension is blocked at the MP and IP joints. If an extensor tenodesis is included, the PIP joints are held in full extension. After 4 weeks the same position is held with a dorsal forearm-based resting splint, with removal of the splint three to five times a day for initiation of active range of motion and light activities of daily living. After 8 weeks the splint is worn only at night, and strengthening exercises are added.

OPERATIONS FOR GROUP 8 PATIENTS

Group 8 patients have grade 4 strength of all the group 7 muscles (BR, ECRL, ECRB, PT, FCR, EDC, EPL) as well as an intact FCU and partial finger flexion (FDP). Usually, the long flexors to the ulnar digits (ring and small fingers) are stronger than those to the thumb, index, and long fingers. Patients in group 8 also lack intrinsic function.

Flexion of the index and long fingers can be strengthened by suturing the FDP of all four digits to one another in the distal forearm. To augment thumb IP flexion, the BR can be transferred to the FPL. Finally, intrinsic balance must be assessed and addressed surgically.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

My preferred technique is Zancolli's two-stage reconstruction.

Stage 1: Extrinsic Transfers

Flexor Digitorum Profundus Side-to-Side Transfer. The four profundus tendons are exposed through a longitudinal approach along the FCU tendon. The ulnar neurovascular bundle is retracted to the ulnar side, and the profundus tendons are easily exposed by gentle radial retraction of the median nerve and FDS tendons. A site in the distal forearm is selected for side-to-side suture of the four profundus tendons. The peritenon is scraped away from the tendons for a distance of 3 cm, and the tendons are sutured together with horizontal mattress sutures using 2-0 nonabsorbable suture. Half the FDP of the index finger is woven transversely across the other FDP tendons to ensure proper relative tension among the four tendons.[40] The fingers should be evenly balanced during the connection.

Brachioradialis to Flexor Pollicis Longus Transfer. As described earlier, the BR is transferred directly to the FPL and connected by braiding the tendon of the BR into the tendon of the FPL with the wrist in neutral and the thumb just touching the side of the index finger, with mild tension on the BR.

Stage 2: Intrinsic Reconstruction

Opponensplasty. The opponens transfer can be motored by the FCU, and the palmaris longus (PL) can be used as a free tendon graft (if the PL is not present, a toe extensor or the plantaris tendon can be used) to extend the tendon of the FCU to its insertion into the ulnar side of the base of the proximal phalanx of the thumb. The FCU is exposed through an "L"-shaped incision over its insertion, with the transverse arm of the "L" in the wrist crease. The FCU tendon is split in half for a distance of 3 to 4 cm proximal to its insertion, and half the tendon is divided, leaving the hemitendon segment attached distally on the pisiform. The cut end of this segment is sutured to itself at the insertion to create a loop. The other half is detached from the pisiform and attached to the proximal end of the free tendon graft using a braiding technique. A subcutaneous tunnel is created from the loop to the MP joint of the thumb. The tendon graft is passed through the loop at the pisiform and through the subcutaneous tunnel and attached to the tendon of the APB at the base of the proximal phalanx. Tension is adjusted so that with the wrist in neutral, the thumb pulp just touches the radial side of the index finger. With wrist extension, the thumb is positioned in wide abduction.

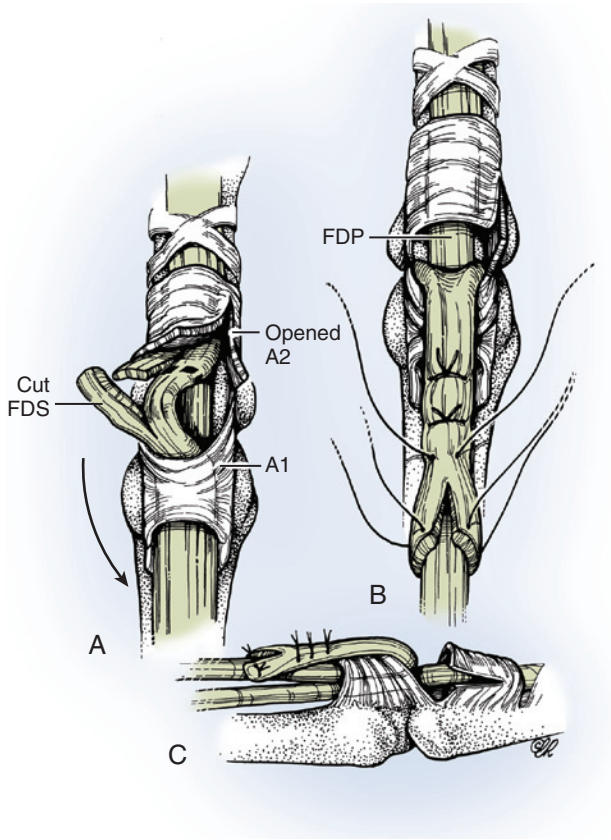

FIGURE 33.16 **A** to **C,** Zancolli's lasso operation is an intrinsic balancing operation that can be used to improve metacarpophalangeal joint flexion and lessen interphalangeal joint flexion deformities with early digital "roll-up." *FDP,* Flexor digitorum profundus; *FDS,* flexor digitorum superficialis. (Copyright Elizabeth Martin. See also Zancolli EA: *Structural and dynamic bases of hand surgery*, ed 2, Philadelphia, 1979, JB Lippincott.)

Intrinsic Tenodesis. Intrinsic balance in the hand can be improved by preventing MP hyperextension (clawing) with a lasso procedure, or by improving PIP flexion posturing with an intrinsic tenodesis procedure. The intrinsic tenodesis uses a free tendon graft (as described below) to improve PIP extension, which enhances digital opening. Use of intrinsic tenodesis as part of the reconstruction has been shown to improve grip strength.[61]

Zancolli's Lasso Procedure. Because the FDS lacks grade 4 strength, Zancolli[96] recommended transfer of the ECRL to the FDS to produce active control of the lasso intrinsic reconstruction. After the lasso procedure has been completed (Figure 33.16), tension on the ECRL transfer is set so that with the wrist in neutral, the MP joints of the fingers are at 0 degrees. With the wrist in extension, the MP joints should be flexed 30 to 40 degrees.

OPERATIONS FOR GROUP 9 PATIENTS

Patients in group 9 have functioning FDS muscles, as well as all the other extrinsic finger and thumb flexors and extensors, but they do not have intrinsic muscle innervation. This is the least common group of patients with tetraplegia,[39] and, in many ways, they can be treated much like patients with combined low median and ulnar peripheral nerve palsy. These patients benefit most from opponensplasty and intrinsic reconstructions, tailored to the intrinsic imbalance present. The Zancolli lasso operation is generally more effective because the superficialis muscles are under voluntary control in group 9 patients.

INTRINSIC RECONSTRUCTION

Intrinsic reconstruction procedures are adjuncts to extrinsic tendon reconstructions and thus refine and improve their results. Intrinsic reconstructive procedures are tendon transfers or tenodesis procedures that improve intrinsic balance in the fingers or thumb, or both. Extrinsic reconstructive procedures done in conjunction with intrinsic reconstructions result in greater final grip strength than those done without intrinsic reconstructions.[2] Intrinsic reconstruction can be done at the same time as the extrinsic reconstruction or as a separate staged procedure, and it must be tailored to the particular intrinsic imbalance present. In patients with little digital imbalance, intrinsic reconstruction is not necessary.

Patient evaluation includes an assessment of digital balance. Evaluation of passive motion of the joints is necessary, as is assessment of dynamic deformity and position of the fingers with wrist tenodesis. At the MP joint, lack of intrinsics leads to MP hyperextension deformity (clawing). At the PIP joint, spasticity of the FDS muscles or central slip deficits (stretched or incompetent) can lead to PIP joint flexion deformities and early digital "roll-up" during grasp. The Zancolli lasso procedure helps initiate MP flexion as the first stage of digital flexion, followed sequentially by PIP and DIP flexion, making the patient's grasp of large cylindrical objects more natural and effective.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

The most common intrinsic imbalances and their recommended treatments include the following:

- Hyperflexion of the thumb IP joint (Froment sign): treated with split FPL transfer
- Clawing of the digits with MP hyperextension of the fingers and PIP flexion with early digital "roll-up": treated with Zancolli passive or active lasso procedure
- PIP flexion deformity due to central slip deficiency: treated with intrinsic tenodesis

Digital Clawing

The goal of the lasso procedure is to prevent MP joint hyperextension or clawing of the fingers during finger extension.[61] The lasso procedure uses the FDS to flex the MP joints. For patients with a PIP flexion deformity associated with FDS spasticity, the lasso procedure has the added benefit of removing the FDS as a spastic deforming force at the PIP joint and transferring it to a more useful position as an MP flexor. The lasso procedure is recommended during the flexor phase for patients in groups 3 to 8 with excessive clawing deformity of their digits. It can be performed with a paralyzed FDS tendon as a passive tenodesis when appropriate motors are not available, or it can be augmented with a tendon transfer to create an active transfer.

Lasso Procedure. A single transverse incision, or separate Bruner incisions, is made across the MP flexion creases; the A1 and A2 pulleys are exposed, protecting the neurovascular bundles. The proximal and distal limits of the A1 pulley are

identified at the base of each digit. Tension is applied to each A1 pulley using forceps to be certain that a transfer around the A1 pulley will pull the MP joint into flexion; if it does not, the proximal portion of the A2 pulley should be included in the transfer attachment. Once the surgeon is sure that MP flexion will occur, the sheath is opened transversely at that point. Both slips of the FDS are divided distal to the A2 pulley, near the middle phalanx insertion, leaving a small tail to prevent recurvatum. The FDS tendon is delivered into the palmar wound through the transverse opening in the pulley sheath, looped back over the transverse pulley, and sutured with an interweave technique into the FDS tendon itself using 4-0 nonabsorbable suture (see Figure 33.16). After the first suture is inserted, appropriate tension is confirmed by observing MP joint motion in response to passive tenodesis wrist motion. With the wrist extended, the MP joints should flex in a uniform cascade. As the wrist is passively flexed, all MP joints should extend fully but not hyperextend. The same procedure is repeated in each finger. If the FDS to the small finger is vestigial, the ring finger FDS can be split into two tails and delivered to both the ring and small fingers.

The patient is placed in a short-arm dorsal extension block cast with the fingers included for 4 weeks of immobilization; the wrist is slightly flexed, the MP joints are blocked at 30 degrees of flexion, and the PIP joints are free. After 4 weeks the same position is held with a dorsal forearm-based resting splint. Active range of motion with light activities of daily living is initiated. After 4 weeks, the splint is worn only at night, and strengthening exercises are added.

Proximal Interphalangeal Central Slip Deficiency

In patients with significant PIP joint flexion deformities due to central slip deficiency, an intrinsic tenodesis with a free tendon graft can be included in the extensor phase to increase the effect of intrinsic balancing.[61] A free tendon graft is passed volar to the axis of rotation of the MP joint (using the intermetacarpal ligaments as the proximal anchor) and dorsal to the axis of rotation of the PIP joint; it is then inserted into the central slip of the extensor tendon. Thus, extension of the MP joint by the extrinsic muscles provides PIP joint extension through a tenodesis effect.

Intrinsic Tenodesis. Any fixed PIP contractures should be released in a staged procedure to ensure full PIP mobility before considering intrinsic tenodesis. The intrinsic tenodesis is performed in the extensor phase of reconstruction after tenodesis of the extrinsic finger extensors (Figure 33.17). The EIP, extensor digiti minimi, PL, or toe extensor tendons can be harvested for use as a free tendon graft. For grafting the index and long fingers, a curvilinear incision is made over the dorsal radial aspect of the index metacarpal neck. The extensor mechanism is exposed over the index metacarpal. The EIP tendon graft is divided just proximal to the sagittal band and retrieved through a counterincision proximal to the retinaculum. A curvilinear incision is made from the radial midlateral line over the proximal phalanx, continuing dorsally over the PIP joint. Subcutaneous dissection is performed to follow the lateral band from the lumbrical canal to the central slip. A tendon passer is gently passed in retrograde fashion from the midlateral incision through the lumbrical canal (*palmar* to the intermetacarpal ligament) and out of the index metacarpal incision. The tendon graft is threaded through this path, palmar to the intermetacarpal ligament. A similar incision is made on the midlateral aspect of the proximal phalanx of the long finger, and the tendon passer is similarly passed through the lumbrical canal, palmar to the intermetacarpal ligament and ulnar to the index metacarpal neck. The proximal end of the tendon graft is passed dorsal to the index extensor tendon over the index metacarpal neck and retrieved with the tendon passer. The free graft is woven and sewn to the index finger central slip using 4-0 absorbable suture; it is then tensioned by suturing to the middle finger central slip so that the PIP joints are in nearly full extension when the MP joints are in full extension. When the wrist is in extension and the MP joints are in flexion, passive flexion of the PIP joints should be possible without undue tension. The same procedure can be performed for the ring and small digits by harvesting the extensor digiti minimi tendon and using it as a free graft.[40]

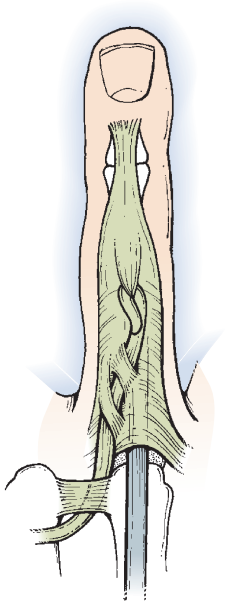

FIGURE 33.17 Intrinsic tenodesis technique. Close-up view illustrates weaving of the free graft from under the deep transverse metacarpal ligament, in line with the lateral band, and into the central slip. This simulates intrinsic function with the graft volar to the axis of the MP joint for MP flexion and dorsal to the axis of the PIP joint for PIP extension (see also Figure 33.13, *A*).

The patient is placed in a short-arm cast with the fingers included for 4 weeks of immobilization; the MP joints are held at 30 degrees of flexion, and the PIP joints are held at full extension. After 4 weeks the same position is held with a volar forearm-based resting splint. Active range of motion with light activities of daily living is initiated. After 4 additional weeks the splint is worn only at night, and strengthening exercises are added.

FURTHER AREAS OF RESEARCH

The ultimate goal of spinal cord injury research would be repair of the spinal cord and return of neurologic function. Although this goal has not been achieved, other work has been done to try to improve the return of neurologic function. Another area of research has been the use of nerve transfers in tetraplegia. In

reports of transfer to the axillar nerve branches to the triceps, and supinator motor branches to the posterior interosseous nerve, the outcomes have not been beneficial enough to warrant routine use. Risk of loss of existing nerve function must be weighed in these experimental procedures.[4,5,31,60]

OUTCOMES

Measurement of outcomes in surgery for tetraplegia has traditionally focused on range of motion, pinch, and grip strength. The World Health Organization has provided a framework for evaluating the consequences of disease through the *International Classification of Functioning, Disability, and Health*.[92] This framework has been evaluated for patients with spinal cord injury.[82] The classification measures not only impairment but also activity limitation and restrictions. Impairment is measured by objective physician-determined parameters such as range of motion and grip pinch strength. Quality of life is further assessed by outcome questionnaires such as the Quadriplegia Index of Function[35] and the Tetraplegia Hand Activity Questionnaire.[56] This broader view of outcome assessment incorporates not only traditional measurements of physical impairment but also quality-of-life issues.

CONCLUSION

Hand and upper extremity reconstruction is only one facet of the medical care and support services necessary for rehabilitation after spinal cord injury. The most useful evaluation of the tetraplegic patient involves the creation of a working list of what the patient *has* (grade 4 strength or higher) and what the patient *needs* (grade 1 strength or lower). The surgeon must determine which muscles are available for transfer and which muscles best match the patient's needs. The success of tendon transfer depends on a working understanding of the principles of work capacity, amplitude, and direction of pull. Reconstruction combines tendon transfers with appropriate combinations of arthrodesis and tenodesis. Assessment of outcomes for tetraplegic upper extremity reconstruction continues to improve and allows the comparison of interventions.[1,8,36,37,57,70,85,88,91]

CASE STUDY 33.1 Upper Extremity Reconstruction in Persons With Tetraplegia

Kara C was a 15-year-old girl who was injured in August of 2000 as a result of diving into a 3-foot-deep pool. She was treated with a halo brace for 13 weeks and had inpatient acute rehabilitation for 5 months. In September of 2001, Kara C was admitted to the Shriners Hospital for evaluation:

- American Spine Injury Association C5-C6
- On bladder and bowel program
- Mobility by means of a power wheelchair
- Bilateral FDS spasticity

Right	Muscle	Left
5/5	Biceps and brachialis	4/5
5/5	Brachioradialis	5/5
0/5	Triceps	0/5
5/5	Supinator	5/5
1/5	Pronator	2/5
1/5	FCR	2+/5
0/5	FCU	0/5
0/5	Palmaris	0/5
4/5	ECRL	5/5
4/5	ECRB	5/5
0/5	ECU	0/5
0/5	FDP	0/5
0/5	FDS	0/5
0/5	EDC	1/5

ICSHT Classification:

- Right 3
- Left 3

Treatment, May 16, 2002, Left:

- Split FPL transfer
- BR to FPL transfer
- ECRL to FDP transfer (Video 33.1)
- Biceps to triceps (Video 33.2)
- FDS fractional lengthening

Treatment, May 22, 2003, Right:

- Split FPL transfer
- BR to FPL transfer
- Biceps to triceps
- FDS lengthening of index through small fingers

Outcome:

Oucome after treatment is shown in Videos 33.3 and 33.4.

Videos 33.5 and 33.6 show Kara C's outcome after several years.

Traumatic Brachial Plexus Injury

Robert J. Spinner, Alexander Y. Shin, Bassem T. Elhassan, and Allen T. Bishop

Acknowledgments: The authors wish to acknowledge the contributions of Professors Rod Hentz and Kazuteru Doi, who wrote an earlier rendition of this chapter on brachial plexus injury in adults, and those of Marie-Noëlle Hébert-Blouin, who assisted with the previous chapter.

In the early 19th century, well before microsurgical equipment and techniques were developed, surgeons published encouraging results of brachial plexus reconstruction.[107] Subsequently, others reported poor results and high complication rates.[25] Little else was published on reconstruction of the brachial plexus until the 1970s and 1980s, when surgeons began to apply the fascicular nerve grafting techniques described by Millesi to birth and traumatic injuries of the brachial plexus. These pioneers established indications and techniques for plexus reconstruction and reported better recovery in operated patients than in those observed without surgical reconstruction.*

In the late 1980s and early 1990s, advances occurred in diagnostic and surgical techniques. New surgical procedures and experimental nonoperative treatments were introduced. In the late 1990s, very aggressive reconstructions using extraplexal sources for reinnervation of vascularized muscle transfers were reported. In the past 10 years, the role of nerve transfers has expanded. The introduction of novel distal nerve transfers has changed the way in which brachial plexus surgery is being performed. Although full recovery of function after brachial plexus reconstruction still remains unachievable, the exciting developments of the past several years have considerably improved surgical outcomes, and future directions for research are promising.

SURGICAL ANATOMY

The brachial plexus is formed from five cervical nerves, typically C5, C6, C7, C8, and T1 (Figure 34.1), and is generally divided into five anatomic sections, nerves, trunks, divisions, cords, and terminal branches. The spinal nerves are formed by coalescence of the ventral and dorsal nerve rootlets as they pass through the spinal foramen (Figure 34.2). The dorsal root ganglion holds the cell bodies of the sensory nerves and lies within the confines of the spinal canal and foramen. Each spinal nerve sends a small dorsal ramus to the paraspinal musculature. The remaining large ventral rami of the lower four cervical (C5-C8) and T1 spinal nerves emerge from the foramina as the first section of the brachial plexus.

The C5 and C6 and the C8 and T1 nerves merge and form the upper and lower trunks, respectively. C7 continues distally as the middle trunk, with no clear demarcation point for this change in nomenclature. The point of convergence of the C5 and C6 nerves, known as the Erb point, marks the spot at which the suprascapular nerve emerges. Nerves and trunks are located above the clavicle and collectively form the *supraclavicular plexus*. Each trunk then divides beneath (dorsal to) the clavicle into anterior and posterior divisions (the *retroclavicular plexus*). The posterior divisions from all trunks merge to become the posterior cord, and the anterior divisions of the upper and middle trunks merge to form the lateral cord. The anterior division from the lower trunk continues distal to the clavicle as the medial cord. The lateral cord splits into two terminal branches, the musculocutaneous nerve and the lateral cord contribution to the median nerve. The posterior cord forms the axillary nerve and the radial nerve, and the medial cord gives off the medial cord contribution to the median nerve, as well as the ulnar nerve. The cords and terminal branches arising from them collectively make up the *infraclavicular plexus*.

Additional branches of clinical importance at the proximal nerve level include a C5 contribution to the phrenic nerve, the dorsal scapular nerve (C5), and formation of the long thoracic nerve from C5, C6, and C7. The only trunk branches are the suprascapular nerve and the nerve to the subclavius muscle, both from the upper trunk. There are no muscular branches from the retroclavicular plexus. The lateral pectoral nerve arises at the division level in the retroclavicular plexus. Infraclavicularly, the posterior cord gives off the lateral pectoral nerve. The posterior cord gives off branches (proximal to distal) that include the upper subscapular nerve, the thoracodorsal nerve, and the lower subscapular nerve. The medial cord gives off the medial pectoral nerve, the medial antebrachial cutaneous nerve, and the medial brachial cutaneous nerve.

CLASSIFICATION OF NERVE INJURIES

Nerve injuries are generally classified according to the Seddon[178] and Sunderland[196] classifications. Both classifications overlap; Seddon classified nerve injuries into three different categories: neurapraxia, axonotmesis, and neurotmesis; Sunderland expanded Seddon's axonotmetic category, for a total of five degrees of nerve injury: first-degree (neurapraxia), second- to fourth-degree (axonotmesis), and fifth-degree (neurotmesis) injuries. Basic knowledge of the different degrees of nerve injury is necessary to understand the need for observation in some patients and for surgical intervention in others.

*See references 4, 32, 83, 98, 140, 141, 157, 158, 179, and 204.

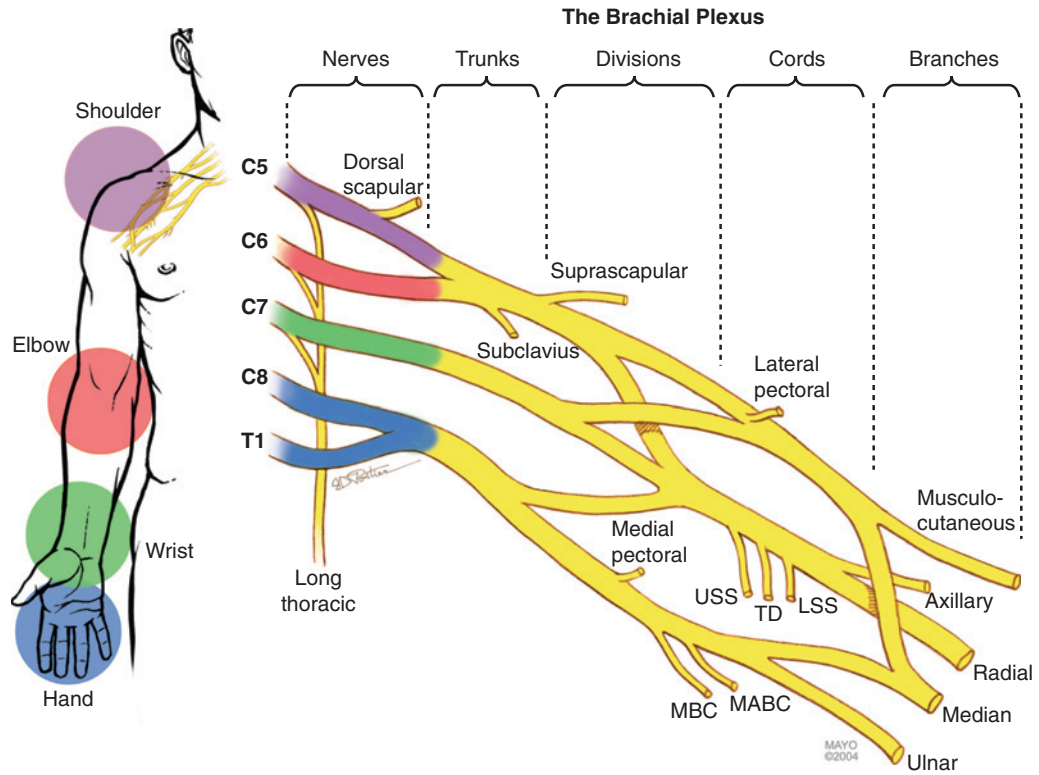

FIGURE 34.1 Anatomy of the brachial plexus. Localization of brachial plexus lesions is dependent on detailed understanding of brachial plexus anatomy. This illustration is reviewed with patients at the time of their initial evaluation. *LSS*, Lower subscapular nerve; *MABC*, medial antebrachial cutaneous nerve; *MBC*, medial brachial cutaneous nerve; *TD*, thoracodorsal nerve; *USS*, upper subscapular nerve. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

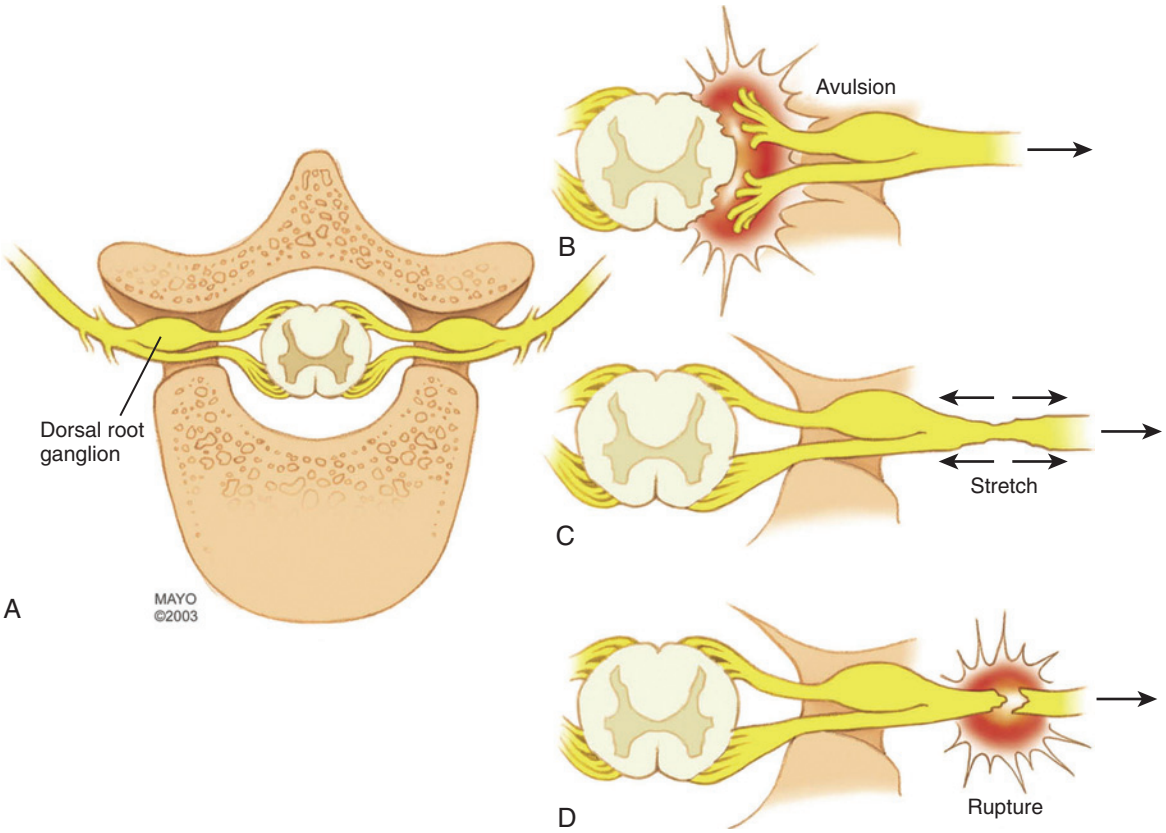

FIGURE 34.2 **A** to **D,** Traction injury to the brachial plexus may cause nerve injuries of varying severity in the same patient. Such injuries include avulsion (preganglionic injury) of nerve roots from the spinal cord (for practical purposes, cannot be repaired), stretch (postganglionic injury) of different magnitudes (sometimes spontaneous recovery possible), and extraforaminal rupture of the nerve or trunk (can be repaired with surgery). (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

In neurapraxia (first-degree injury), there is a focal conduction block at the site of injury. Wallerian degeneration does not occur, and as the conduction block resolves, neurologic function returns. These injuries do not require surgical intervention, and recovery occurs within hours to weeks. In axonotmesis (second- to fourth-degree injury), the axons are disrupted and wallerian degeneration occurs distal to the injury. However, the nerve remains in gross continuity. Stretch injury is the most common mechanism. Depending on the severity of the injury, regeneration may occur (at a rate of 1 mm/day or 1 inch/month) or not. To better describe axonotmetic lesions, Sunderland further classified them into second-degree injury (axon disrupted, but intact endoneurium, perineurium, and epineurium), third-degree injury (axon and endoneurium disrupted, but intact perineurium and epineurium), and fourth-degree injury (axon, endoneurium, and perineurium disrupted, but intact epineurium). In second-degree injury, regeneration and neurologic recovery are expected but will require several months or even years. In very proximal injuries with distal targets (such as the proximal ulnar nerve or lower trunk lesions), muscle atrophy or motor end-plate degeneration may occur before regeneration is completed and prevent functional recovery. In third- and fourth-degree injury, regeneration may occur to a variable degree or may not occur at all, and these lesions may require surgical intervention. Finally, in neurotmesis (fifth-degree injury), the nerve is completely disrupted and there is no continuity. These lesions cannot spontaneously recover and surgical intervention is necessary. In brachial plexus injuries, neurotmetic lesions include postganglionic ruptures and preganglionic avulsions.

MECHANISMS OF TRAUMATIC BRACHIAL PLEXUS INJURY

Traction Injury

Most traumatic injuries of the brachial plexus are due to traction or stretch injury.[50,108] These brachial plexus injuries are caused by varying amounts of energy imparted to the plexus that may result in different injuries ranging from mild stretch to rupture or avulsion (see Figure 34.2).[117] Low-energy traction trauma, not severe enough to cause rupture or avulsion, typically causes injuries with a potential for spontaneous regeneration, such as neurapraxia (Sunderland type I) or lower degrees of axonotmesis (Sunderland types II and III). Experimental evidence also suggests that low-energy injuries may interfere with brachial plexus microcirculation and cause ischemic injury.[109] High-energy injuries are associated with more significant damage to the plexus that may include rupture of plexal elements (Sunderland type V) or avulsion of nerve roots from the spinal cord. When a combination of incomplete rupture and avulsions occurs, some spontaneous recovery may take place, but early microneurosurgical reconstruction generally improves the functional outcome. If the shoulder-neck angle is forcibly widened by downward traction on the arm, damage is imparted first to the upper nerves (C5 and C6)/upper trunk and/or C7/middle trunk (Figure 34.3); if the scapulohumeral angle is forcibly widened, damage is imparted first to the lower nerves (C8 and T1) and the lower trunk. If the impact is extreme, all levels can sustain damage.[50] Anatomic studies have determined that the supporting tissue anchoring the upper nerves (C5 and C6)

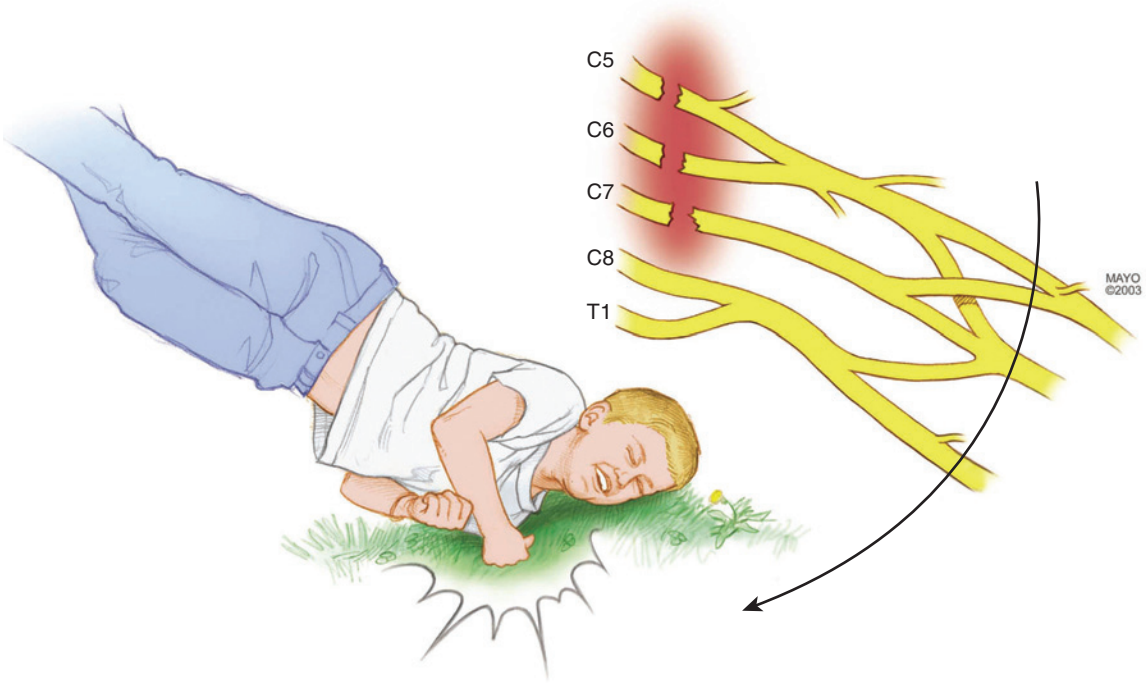

FIGURE 34.3 Patterns of injury can often be predicted. Upper brachial plexus injuries occur when the shoulder is forced downward and the head is forced to the opposite side. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

to the vertebral foramina is significantly stronger than the supporting tissue of the lower nerves (C8 and T1). This anatomic arrangement predicts that the more caudal structures of the brachial plexus (i.e., the C8-T1 nerves) are more likely to be avulsed from the spinal cord,[98] whereas the more cranial structures of the brachial plexus are more likely to stretch or rupture after exiting the neural foramina (i.e., the C5-C6 nerves). In approximately two thirds of traction injuries involving the brachial plexus, the injury is located in the supraclavicular region; in the other third, the injury is retroclavicular or infraclavicular and involves the divisions, cords, or terminal nerves.[108] In some patients, a double-level (supraclavicular and infraclavicular) injury can occur and should be considered. The principal factors determining the extent of injury are the energy imparted by the blow and, to a lesser degree, the direction and the relationship of the arm to the neck during the injury.

An individual patient may have different degrees of injury at different nerve levels; for example, the C8 and T1 roots may be avulsed, the C7 nerve or middle trunk may be ruptured (Sunderland type V), and the upper trunk may remain intact but with varying degrees of internal damage (Sunderland types I to IV). Within an individual brachial plexus element, individual axons and fascicles may also suffer various degree of injury. This variability in the degree of injury affecting each plexal element explains why spontaneous recovery may occur in some plexal elements but not in others. Extensive longitudinal injury is also common and at times results in injury to the retroclavicular and infraclavicular plexus (divisions and cords or terminal branches, respectively), as well as the roots, nerves, and trunks cephalad to the clavicle.

The same high-energy traction injury that damages the brachial plexus may also cause other injuries. Approximately 75% of traumatic brachial plexus injuries are associated with head injury, thoracic trauma, and fractures or dislocations (or both) of the cervical spine or ipsilateral upper extremity; 20% of patients have associated vascular trauma.[207] These associated injuries, such as fractures, dislocations, and vascular injuries (from either an associated hematoma, pseudoaneurysm, or arteriovenous fistula), can further damage the brachial plexus.

Gunshot Injury

Most commonly, the plexal elements are in continuity following a gunshot injury, but in a small proportion of patients, some elements may be transected. The injury will depend on the caliber, velocity, and angle of incidence of the missile. Low-velocity missiles usually damage nerve elements by direct impact; high-velocity missiles can injure nerves by direct impact (which transects the nerves) or, more commonly, by shock wave and cavitation effects (which contuse or stretch the nerves).[108] Because the injury is often in continuity, some patients will have spontaneous recovery. Others do not recover, however, and will require surgical exploration; high-velocity injuries are more likely to cause extensive damage and to fail to recover spontaneously. Gunshot wounds may cause associated vascular injuries that may require emergency or delayed repair; the latter may occur over time as a result of the formation of a pseudoaneurysm, which can compress the plexus, produce progressive loss of function, and require an intervention on the vessel(s) or nerves, or both.

Penetrating Trauma

The brachial plexus is occasionally injured by sharp (caused by knives or glass) or blunt (caused by fan and motor blades, chainsaws, or animal bites) penetrating trauma.[108] Iatrogenic injuries have also been reported from various surgical procedures. As expected, most patients have brachial plexus elements in discontinuity (i.e., transected); however, despite the mechanism of injury, some patients have a lesion with a degree of continuity. Because of the high suspicion of transection of one or more nerves, these patients require nerve exploration. A third of these patients require vascular surgery, which is often performed concomitantly.[108] In these patients, as in patients with gunshot wounds or traction injuries, an associated hematoma, pseudoaneurysm, or arteriovenous fistula may compress the plexus and require intervention because of progressive neurologic deterioration.

COMMON PATTERNS OF BRACHIAL PLEXUS INJURY

In brachial plexus injuries, any combination of stretch, rupture, and avulsion can occur. However, certain patterns are more frequent, such as supraclavicular injuries (upper brachial plexus, including the nerves and trunks, often described by the pattern of root involvement; i.e., C5-C6, C5-C7, C8-T1, or pan-plexus), retroclavicular injuries (divisions), and infraclavicular injuries (cords and terminal branches).

C5-C6 Injury

Approximately 15% of patients[108] have injury to the C5 and C6 nerves or to the junction where they form the upper trunk (Erb point). These patients have deficits in shoulder stability, abduction, and external and internal rotation (supraspinatus and infraspinatus, deltoid, subscapularis), as well as in elbow flexion (biceps, brachialis, and brachioradialis) and forearm supination (biceps, supinator). Sensory deficit will be present in the C5 and C6 distributions. Elbow extension is normal, as is wrist and hand function. This pattern of injury is commonly referred to eponymously as Erb or Erb-Duchenne palsy in recognition of the early work of Wilhelm Heinrich Erb and Guillaume Duchenne on peripheral nerve injury.

C5-C7 Injury

In approximately 20% to 35% of patients,[108] weakness of muscles innervated by C5 and C6, as described earlier, will be accompanied by a partial or complete C7 or middle trunk injury. In these patients, there will be variable weakness of the elbow, wrist, and sometimes finger extensors. The C7 contribution to wrist and finger extension and even to the flexor digitorum profundus muscles varies between patients and leads to different degrees of weakness. Sensory disturbances in the proximal part of the arm, as well in the thumb and index and middle fingers, may be present. This at times is referred to as an Erb-plus pattern.

C8-T1 Injury

Approximately 10% of patients[108] (even less in our experience) have supraclavicular lesions isolated to the C8 and T1 nerves. These patients will have weakness of the hand intrinsics, as well

as variable weakness of the hand extrinsics and finger extensors, depending on the C7 contribution to these territories. Sensory loss in the ulnar digits, medial aspect of the forearm, and distal part of the arm may be present. Involvement of the lower roots can result in Horner syndrome, which is noted on examination by meiosis (constricted pupil), ptosis of the upper eyelid, anhidrosis, and enophthalmos (see the section Physical Examination). This rare pattern of injury is often referred to as Klumpke or Dejerine-Klumpke palsy.

Pan-Plexus (C5-T1) Injury

Traumatic injury to the entire brachial plexus (C5-T1) occurs in 50% to 75% of patients with supraclavicular brachial plexus injuries.[108] These patients most commonly have a completely flail arm and insensate hand. Occasionally, certain elements may be partially injured. Even with complete pan-plexus injuries, postganglionic injury (particularly of C5) is often present, with preganglionic lesions affecting other nerves.

Infraclavicular and Terminal Branch Injury

Retroclavicular or infraclavicular brachial plexus injuries may involve injuries at the division or cord level. Clavicular fracture is often present in these cases. A few patterns are more commonly seen, including injuries to the posterior cord (radial and axillary nerve distributions), as well as isolated axillary or suprascapular nerve injuries.

PREOPERATIVE EVALUATION

A comprehensive preoperative evaluation that includes a detailed history, physical examination, imaging, and electrodiagnostic evaluation is essential to determine the location and severity of the brachial plexus injury and appropriate management. The goal is first to determine whether there is potential for spontaneous and functionally significant recovery, which warrants further observation. If no recovery is seen within the first 2 to 3 months, surgery is indicated. In cases in which surgery is indicated, determining whether the injury is preganglionic or postganglionic will also help in planning the surgical approach and possible reconstructive options. In preganglionic injuries, the nerve root is nonfunctional (avulsed from the spinal cord) and, for practical purposes, cannot be repaired or grafted. The presence of a preganglionic injury at one or more levels indicates a more severe injury with a lower probability of spontaneous recovery; thus, earlier surgical intervention may be warranted. No single finding or evaluation can tell the surgeon whether the injured plexus requires a surgical intervention. All the information must be analyzed and each patient requires an individualized approach.

Patients at our institution are evaluated in a multidisciplinary clinic, first by a neurologist and then by a team of surgeons skilled in primary and secondary reconstruction. A physiatrist and physical/occupational therapist are also involved in the care of each patient. They teach and emphasize the importance and timing of passive and active range-of-motion exercises before and after any operation. Decisions regarding management are discussed and planned collectively. We believe that this type of team approach best addresses the short- and long-term needs of these patients with complex injuries.

History

A good history of the injury mechanism is helpful in determining its severity. High-energy traction injuries, such as motor vehicle or motorcycle injuries, will probably be more severe, with less potential for spontaneous recovery, than low-energy traction injuries, such as falls. Still, some falls, especially those associated with musculoskeletal injuries, may result in severe nerve lesions that do not recover spontaneously. Nerve deficits from lacerations, either sharp or blunt, will not recover spontaneously (except in the rare case in which the nerve elements were not transected) and should be explored acutely or subacutely (see the section on Timing of Surgery). On the contrary, the majority of gunshot wounds associated with brachial plexus injury should be observed because most lesions are in continuity and have the potential for spontaneous recovery.

When a patient with brachial plexus injury is evaluated acutely in the emergency room; the airway, breathing, and circulation should be evaluated and stabilized; and the standard trauma evaluation guidelines should be followed. If the patient sustained high-energy trauma, a thorough search for associated life- and limb-threatening injuries should be conducted. In patients with head or spinal cord injuries,[88] brachial plexus injury is often underdiagnosed; the opposite may also occur if the surgeon focuses on the upper extremity and fails to diagnose an associated head or incomplete spinal cord injury. Every patient should therefore be asked about loss of consciousness and paresthesias or weakness affecting the other extremities.

The presence of associated injuries (especially vascular injury, ipsilateral upper extremity musculoskeletal injury, scapulothoracic dissociation, rib fractures, pneumothorax and hemothorax, lung contusion, spine fracture and spinal cord injury, and traumatic brain injury) should be considered and documented. Associated injuries may indicate a more severe injury with less potential for spontaneous recovery and may influence the available reconstructive options. Severe pain in an anesthetic extremity may be due to deafferentation, as seen in patients with root avulsion injuries. When evaluated weeks to months after the injury, the patient should be questioned about any improvement in function or pain since the injury.

Physical Examination

The examination of patients with brachial plexus injury must be carried out in a standardized and detailed manner. The objective is to establish the location of the nerve injury (preganglionic [i.e., root] or postganglionic [i.e., nerve, trunk, division, cord, or branches]) and the severity of the lesion (i.e., partial or complete for each element of the brachial plexus) (see Figures 34.1 and 34.2). Careful systematic motor and sensory examination of the entire limb should be performed and recorded (Figure 34.4). Serial examinations over the first few months after injury may help determine the presence or absence of ongoing nerve regeneration and the prognosis for functional recovery.

The motor and sensory innervation of the upper extremity is well known and assists the surgeon in predicting the location of nerve lesions. Terminal branches can be assessed by examination of the fingers and wrist (median, ulnar, and radial nerves), elbow (musculocutaneous and high radial nerves), and shoulder (suprascapular or axillary nerves). Involvement of the

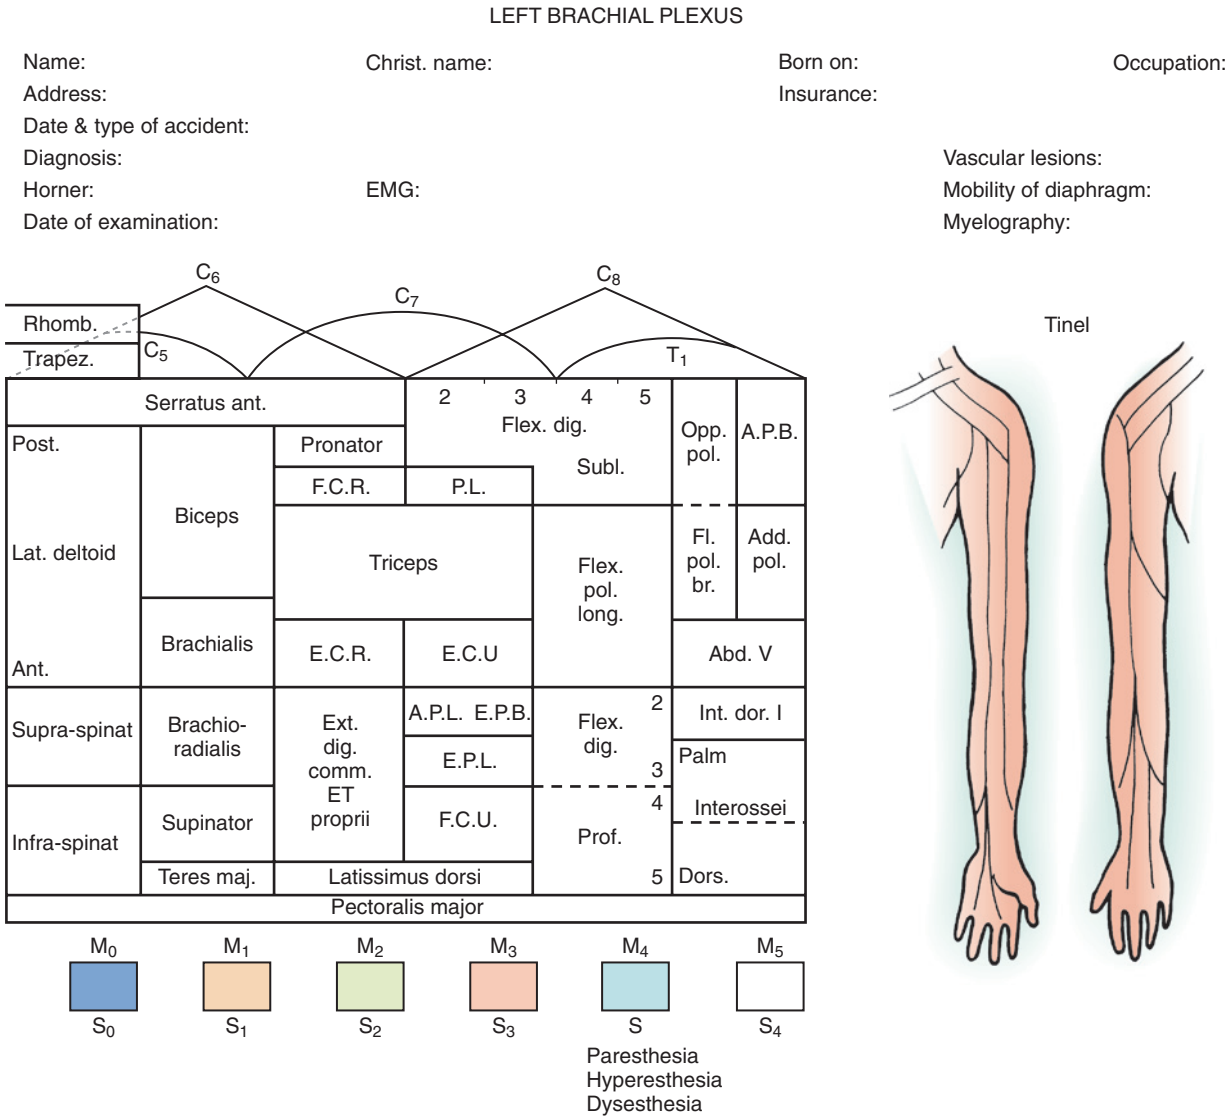

FIGURE 34.4 Motor and sensory findings must be accurately documented preoperatively and postoperatively. Most brachial plexus surgeons use some variation of this format introduced by Merle d'Aubigne to record the data.

latissimus dorsi (thoracodorsal nerve), sternal head of the pectoralis major (medial pectoral nerve), and clavicular head of the pectoralis major (lateral pectoral nerve) implies a lesion at least at the posterior, medial, and lateral cord levels, respectively. Involvement of the suprascapular nerve (supraspinatus and infraspinatus for shoulder abduction and external rotation, respectively) indicates a lesion at this terminal branch or at the upper trunk level. Finally, loss of function of the rhomboid (dorsal scapular nerve derived from C5) and serratus anterior (long thoracic nerve from C5 to C7) is an important indicator of a proximal lesion or preganglionic injury.

There is some variability in plexus anatomy and root contribution to individual muscle innervation. For example, a prefixed plexus receives significant innervation from the C4 nerve and a postfixed plexus receives innervation from the T2 nerve; these variations are reported commonly by anatomists.[134] The dorsal scapular nerve may on occasion receive innervation from the C4 nerve root, such that rhomboid activity may be identified by electrical studies in the presence of a C5 avulsion injury. Unusual motor and sensory impairment that is not distributed in the proper territory of the cervical and peripheral nerves may indicate incomplete nerve injury and some recovery.

Certain findings on physical examination suggest preganglionic injury of the brachial plexus; if present, these findings imply a lower probability of spontaneous recovery and a higher probability of finding an avulsed root at exploration. As stated earlier, injury to the rhomboid and serratus anterior indicates a proximal nerve injury and suggests a preganglionic injury of the upper neural elements, whereas the presence of Horner syndrome (Figure 34.5) on the affected side strongly correlates with avulsion of the lower elements (i.e., the C8 or T1 roots, or both).[98] Because the T1 sympathetic ganglion is close to the T1 root, an avulsion injury may interrupt sympathetic outflow and be manifested as Horner syndrome. Absence of a Tinel sign or of tenderness to percussion in the neck also suggests a preganglionic injury. Finally, muscular atrophy of the paraspinal muscles, which is associated with root avulsion, may be associated with shifting of the head away from the injured side.

Physical examination findings suggesting a postganglionic or more distal injury include the presence of tenderness to percussion in the supraclavicular or infraclavicular region, absence of sweating in the distribution of the injured nerve (sympathetic interruption), and minimal preservation of movement (partial injury). An advancing Tinel sign is suggestive of a recovering lesion.

The examination should also include testing of the distal spinal accessory nerve (cranial nerve XI), which supplies the trapezius muscle. It is frequently used for reconstruction options as a nerve transfer but can occasionally be injured concomitantly at the time of traumatic brachial plexus injury. In all patients, stability and active and passive range of motion of the joints should be assessed preoperatively. To rule out a concomitant spinal cord injury, a lower extremity neurologic examination (that includes reflexes) should be performed. The vascular system of the affected upper extremity should be assessed by palpation or Doppler examination of distal vascular flow, as well as for thrills or bruits in the infraclavicular and supraclavicular fossae.

Imaging Evaluation

Radiographs of the cervical spine, chest, shoulder girdle, and humerus should be obtained in patients with high-energy traumatic brachial plexus palsy to rule out associated upper limb fractures and dislocations. Chest radiographs should include anteroposterior inspiration and expiration views and should be examined for the presence of rib fractures and for activity of the diaphragm. A paralyzed (i.e., elevated) diaphragm indicates a proximal (probably preganglionic) brachial plexus injury because it is supplied by the phrenic nerve, which originates from the proximal C3-C5 nerves. The presence of cervical transverse process fractures is also associated with brachial plexus avulsion injuries. First or second rib fractures are associated with brachial plexus injuries. Rib fractures may be important if the intercostal nerves are to be considered for nerve transfers (≈10% of the intercostal nerves will be damaged by rib fractures in our experience).

FIGURE 34.5 The presence of Horner syndrome (i.e., ptosis, miosis, anhidrosis, and enophthalmos caused by paralysis of the sympathetic nerves), as seen in the left eye, is associated with avulsion of the C8 and T1 nerve roots. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Myelography[152] and computed tomographic (CT) myelography,[150,202] although invasive, have been considered the most reliable methods for detecting root avulsions (Figure 34.6). Myelographic findings have been classified by Nagano and colleagues' modified scheme[152] into six categories, from normal roots, to ventral or dorsal root avulsions (or both), to the presence of traumatic pseudomeningoceles. Myelography or CT myelography is typically performed at least 3 to 4 weeks after the injury; such a delay will allow a potential blood clot in the area of the root avulsion to dissolve and the pseudomeningocele to form and be visualized on imaging.

More recently, magnetic resonance imaging (MRI) has been used increasingly[41,155] to evaluate patients with traumatic brachial plexus injury; in some centers it has supplanted CT myelography. MRI can reveal traumatic pseudomeningoceles, large neuromas, rootlet abnormalities, associated inflammation and edema, and mass lesions. Newer techniques have improved the detection of nerve root avulsions by MRI.[7,65]

Finally, the vasculature to the injured upper extremity should be assessed, especially when a functioning free muscle transfer (FFMT) is being considered. In the authors' experience, a normal peripheral pulse on examination does not preclude a vascular injury affecting the major vessels. We generally evaluate the vasculature with magnetic resonance angiography; special attention is given to our preferred source of arterial

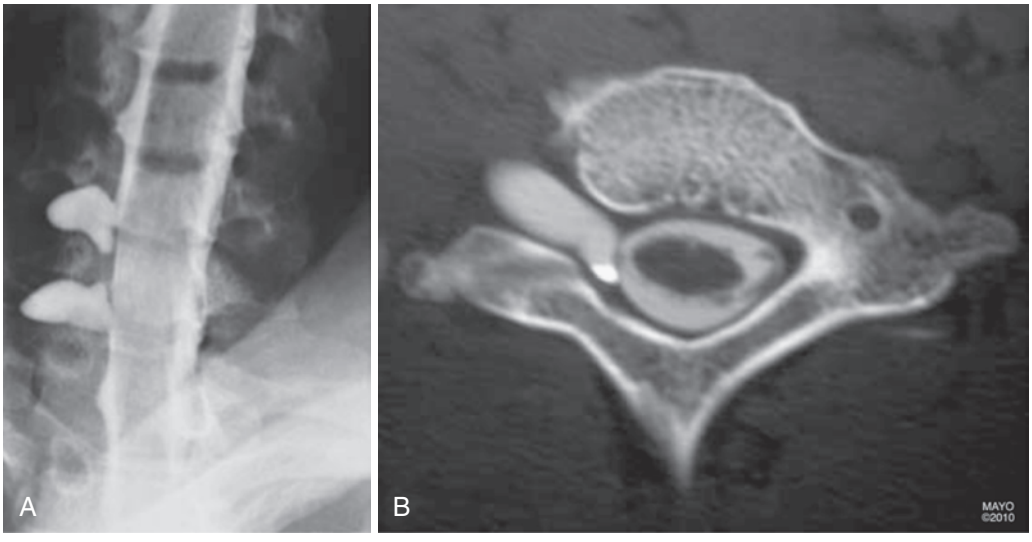

FIGURE 34.6 Myelography shows two right-sided cervical pseudomeningoceles **(A)**, one of which is seen on the axial computed tomographic myelogram **(B)**. The left side is normal. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

supply for FFMT, the thoracoacromial trunk. Other adequate options to formally evaluate the vasculature include CT angiography and conventional angiography.

Pulmonary Function Tests

Patients with a history of chest wall trauma (e.g., rib fractures, pneumothorax, hemothorax) and those found to have phrenic nerve dysfunction should have pulmonary function tests performed to better characterize their pulmonary function. These evaluations, with assessment by a pulmonologist if necessary, will help determine whether the patient will tolerate intercostal nerve transfers. Unless the preoperative pulmonary function test results are very low (i.e., <40% of expected, but no definitive criteria exist), a patient can generally tolerate up to four or five intercostal nerve transfers even if concomitant phrenic nerve dysfunction is present.

Electrodiagnostic Evaluation

Electrodiagnostic studies are an integral component of the evaluation of traumatic brachial plexus injury. These studies can confirm the diagnosis, localize and characterize (i.e., partial vs. complete) the nerve lesion, and assess for subclinical evidence of recovery. A baseline examination should be done 3 to 4 weeks after the traumatic injury, when wallerian degeneration has occurred, to ensure that the electrodiagnostic study reflects the degree of nerve injury. Serial electrodiagnostic studies complement the physical examination when assessing for recovery and reinnervation. The electrodiagnostic evaluation should include electromyography (EMG) and nerve conduction studies (NCSs). EMG evaluates and records the electrical activity of muscles both at rest and with activity. Changes reflective of a denervation injury include the presence of fibrillation potentials at rest and absent (complete injury) or reduced (partial injury) motor unit potentials with voluntary effort. Over time, nascent motor unit potentials (low in amplitude, polyphasic in configuration, and of variable duration) may appear and suggest reinnervation. Several muscles, difficult to test clinically, can be evaluated by EMG to help localize the lesion. For example, the rhomboids, serratus anterior, and cervical paraspinal muscles, if affected and abnormal on EMG, may suggest a very proximal or preganglionic injury. The trapezius muscle should be evaluated, especially if the spinal accessory nerve is being considered as a potential donor for nerve transfer. NCSs, especially sensory nerve action potentials (SNAPs), are also helpful to evaluate the level of the nerve injury. With preganglionic injuries, the dorsal root ganglion, where the sensory neuron cell body is located, is intact. The distal axons do not undergo wallerian degeneration, because they remain connected to the cell body; thus, the SNAP is preserved. However, the patient is insensate because the sensory neurons are not connected to the central nervous system (i.e., spinal cord and brain). The finding of intact SNAPs in the presence of dermatomal anesthesia is pathognomonic of a root avulsion injury. In postganglionic injuries, the sensory axons will degenerate and the SNAP will be lost. On occasion, a segmental or longitudinal injury will cause both preganglionic and postganglionic lesions, and the SNAP will be absent in the presence of a root avulsion injury. On the contrary, motor conduction will be absent with both preganglionic and postganglionic injuries because the motor axons will have undergone wallerian degeneration (i.e., because their cell body is located in the anterior horn of the spinal cord).

Whenever possible, a follow-up electrodiagnostic study is performed 6 to 12 weeks after the initial study to assess for recovery. Although an advancing Tinel sign and the presence of nascent units are encouraging findings, they need to be taken into consideration along with improvement in clinical function; these findings do not necessarily eliminate the need for surgery.

INDICATIONS FOR SURGERY

Multiple studies on the exploration and reconstruction of brachial plexus traction injuries suggest the value of surgical intervention in many of these patients. Surgery is indicated in patients with no hope for spontaneous recovery or for further recovery. This principle applies to patients with traumatic brachial plexus injuries from any mechanism. All patients with laceration injuries in proximity to the brachial plexus should undergo exploration because in the vast majority of these injuries (sharp or blunt), there is no possibility of spontaneous improvement and surgery is clearly indicated. In patients with gunshot injuries, an initial potential for spontaneous recovery exists because the nerves are usually in continuity. The same applies to patients with traction injuries. However, after a period of observation (see Timing of Surgery), surgery is indicated if there is no clinical or electrophysiologic evidence of recovery. Signs of electrophysiologic recovery that do not translate to clinical recovery within a short period of observation should not be viewed as meaningful recovery, and such patients should be considered for a surgical intervention. If it were possible to clearly identify patients with complete nerve root avulsion or nerve rupture, a surgical intervention could be performed without the observation period because these injuries cannot recover spontaneously. However, at present, no definitive study or sign is sufficiently reliable; the decision should be made after analyzing the different evaluations (history, physical examination, imaging studies, electrodiagnostic studies) in the context of time.

CONTRAINDICATIONS TO SURGERY

Absolute contraindications to surgery for the reconstruction of brachial plexus injury are few. Stiffness and contractures, age, medical comorbidity, associated traumatic brain injury, and associated spinal cord injury should be considered in the decision process and may need to be addressed, but they are not generally contraindications. The main contraindication is unrealistic goals or unwillingness of the patient to undergo the procedure. Before a decision to operate is reached, it is therefore crucial to inform the patient about the possible surgical options, risk-benefit ratio, postoperative rehabilitation program, success rate, long recovery time, and possibility of additional surgery. This discussion should be individualized to each patient according to that patient's specific injury, needs and expectations, and goals and priorities (set by the treating team and patient). Surgery is also not usually indicated for patients with spontaneous ongoing recovery in all involved elements because outcomes will generally be better without surgery in such patients. We believe that the rare patient with a C8-T1 lesion has a relative contraindication to primary nerve repair or grafting because

of the limited ability for successful regeneration to reach the hand. Forearm nerve transfers or secondary reconstruction with tendon transfer may yield more predictable results. Finally, if more than a year has passed since the injury, primary plexus reconstruction is generally contraindicated, except perhaps in a young patient. In select cases, distal nerve transfers may be considered up to 18 months after the injury.

TIMING OF SURGERY

Timing of brachial plexus reconstructive surgery is based on three principles: (1) Better functional outcomes occur in patients with spontaneous recovery who do not require a surgical intervention; (2) surgical intervention is indicated for patients with no hope for spontaneous recovery or for further recovery; and (3) most series demonstrate that the surgical outcome is inversely proportional to the time interval from injury to surgery (i.e., outcomes are better if surgery is performed earlier). Based on these principles, primary nerve reconstruction may ideally be initiated immediately (within days) after injury or in a delayed fashion (within months). Timing of secondary reconstructive procedures is discussed separately.

Primary (Nerve) Reconstruction

Immediate Surgery

In patients with plexus deficits and a sharp open injury, immediate exploration plus repair is indicated. Immediate surgery allows direct repair of the lacerated elements. In patients with blunt laceration injury to the plexus, surgical intervention is also clearly necessary, but the timing of the surgery is controversial and less definite. A subacute (within 3 to 4 weeks) surgical intervention may be preferable; time will allow better definition of the zone of nerve injury. Occasionally, a reconstructive brachial plexus surgeon gets the opportunity to assess the degree of damage to the plexus at the time of injury when emergency vascular reconstruction of an injured subclavian or axillary artery is performed by the vascular surgeons. This may occur with sharp or blunt laceration injuries and with traction injuries. The supraclavicular and infraclavicular regions may be explored, the damage to the plexus mapped, and the plexus reconstruction planned. If the nerves are sharply divided, they can be repaired immediately; if they are bluntly transected or ruptured, they may be tagged with radiopaque vascular clips (to allow identification) and loosely coapted to prevent retraction. The injury can then be reexplored 3 to 4 weeks later to allow the zone of damage to be better demarcated. If the nerves are avulsed, reconstruction can be performed immediately or at a second setting, depending on the situation and condition of the patient; finally, if the nerves are stretched but in continuity, a period of observation will be necessary.[140,156]

Delayed Surgery

Surgery is delayed in patients who have a potential for spontaneous recovery or for injuries that require time to become better defined. In patients with closed traction injuries or gunshot injuries (because most are in continuity), surgery is performed after a period of observation if there is no evidence of spontaneous clinical or electrophysiologic recovery. Even though outcomes are better if surgery is performed earlier, a balance must be reached such that patients demonstrating early spontaneous recovery (i.e., who will probably fare well) do not undergo surgery. The timing of surgery needs to be individualized based on multiple factors, including the mechanism of injury, findings on physical examination and imaging, and the surgeon's preference. Patients with a low probability of spontaneous recovery may undergo surgery earlier, and patients with a high probability of spontaneous recovery may be observed longer. However, there are no universal guidelines and different opinions exist in the literature. Our preference is to explore and perform primary nerve reconstruction early in patients in whom there is a high suspicion of root avulsion based on the history/mechanism, physical examination, electrophysiologic studies, or imaging studies. At our institution we are not performing surgery extremely early, as is advocated by some.[23] We operate on patients with pan-plexal lesions 2 to 3 months after injury if they have no evidence of recovery but have imaging evidence of avulsions. In patients without this high suspicion of root avulsion and no adequate signs of recovery, we perform exploration 3 to 6 months after the injury. We may wait longer (5 to 6 months) for patients with a higher chance of spontaneous recovery, such as those with incomplete brachial plexus palsy or complete brachial plexus palsy without evidence of root avulsion. An early intervention may not allow sufficient time for spontaneous recovery; however, we believe that routine use of intraoperative monitoring (such as nerve action potentials [NAPs]) will help determine whether there is early subclinical evidence of recovery at the time of exploration. We seldom wait for more than 6 months because long delays diminish the outcomes of the reconstructive procedure.

Secondary Reconstruction

For adult patients initially seen late (i.e., >12 months after the injury), primary nerve reconstructive procedures are associated with significantly poorer results. In select cases, distal nerve transfers can still be considered even later (i.e., <18 months). However, secondary reconstructive procedures, such as tendon transfer, FFMT (gracilis muscle), and bony or soft tissue procedures, may be indicated and can be done at any time.

OPERATIVE CONSIDERATIONS

Informed Consent

The possible surgical options, risk-benefit ratio, postoperative rehabilitation program, expected outcome with or without surgery, and long reinnervation period should be discussed in detail with the patient and his or her family. The patient should have realistic expectations and a clear understanding of the goals and priorities of the planned surgery. The surgical approach should be individualized according to the patient's comfort level (acceptable risks and set of goals).

Preparation and Positioning

The surgical procedure, in particular its indeterminate duration and the need to perform intraoperative stimulation and recordings, should be discussed with the anesthesiologist. Long-acting paralytic agents, muscle relaxants, and agents depressing cortical responses should be avoided. Adequate vascular access should be obtained and an indwelling urinary catheter should be inserted. After induction of anesthesia and intubation, the

patient is positioned in the supine position. The head is turned to the contralateral side, the upper part of the body is elevated, and a small pillow is placed beneath the ipsilateral scapula to bring the shoulder forward. Proper padding and positioning to protect bony prominences are necessary because brachial plexus reconstructive procedures are lengthy. Surgical preparation and draping should include the ipsilateral neck, mandible, hemithorax, axilla, entire upper extremity, and both lower extremities (for possible nerve grafts). Some surgeons use tourniquets placed on the upper part of the thighs that can be inflated just before sural nerve graft harvesting. The arm is prepared and draped freely; this will permit the response to nerve stimulation to be observed and appropriate changes in arm positioning to be made during the procedure if needed. Tight circumferential elastic drapes are avoided on the extremities because of the long duration of surgery and possible swelling. If planning is being done to use the contralateral C7 nerve for transfer, the contralateral neck and hemithorax should be included in the surgical field. The surgeon should be prepared to expose both the supraclavicular and infraclavicular portions of the brachial plexus, harvest nerve grafts (sural nerve, superficial radial nerve, or vascularized ulnar nerve), or perform nerve transfers if required.

Electrodes required for intraoperative electrophysiologic monitoring (such as motor evoked potentials [MEPs] and somatosensory evoked potentials [SSEPs]) are placed. A bipolar microcoagulator, nerve stimulator, magnifying loupes, and operative microscope should be available for the surgical procedure.

Surgical Approaches to the Brachial Plexus

The elements of the brachial plexus are exposed through a supraclavicular approach (i.e., nerves, trunks, suprascapular nerve) or an infraclavicular approach (i.e., cords, terminal branches). Depending on the pattern of injury, a combined approach may be necessary. The divisions, which are retroclavicular, can be accessed through one or both approaches. With introduction of the newer nerve transfers, some surgeons do not routinely explore the brachial plexus in all patients, even if a proximal nerve would be available for grafting, believing that nerve transfers provide a more reliable option. We recommend routinely exploring the proximal brachial plexus, except in specific patients who are initially seen late and have a more reliable, distal nerve transfer option. When a pan-plexus injury is present, less than 20% of patients are reported to have avulsions of all five roots of the plexus[98]; we therefore believe that exploration is warranted because a proximal nerve can often be found for grafting.

The variability in surgical approaches to the brachial plexus is mainly in the incisions used to expose the supraclavicular or infraclavicular brachial plexus and in the reconstructive approach used. Traditionally, a zigzag skin incision (Figure 34.7) was used: the supraclavicular incision begins at the angle of the jaw and follows the posterior border of the sternocleidomastoid to the midclavicular area; the infraclavicular incision begins at the clavicular insertion of the sternocleidomastoid (connecting with the supraclavicular incision), courses laterally toward the coracoid process, and extends laterally to the deltopectoral groove and into the arm. These incisions are connected to achieve a wide exposure. However, connecting these incisions increases the risk for scar hypertrophy, and some surgeons prefer to use separate transverse skin incisions. An alternative is to expose the supraclavicular plexus with a transverse incision, parallel to the clavicle, and the infraclavicular plexus with an incision over the deltopectoral groove. These two incisions can be connected if required. Some surgeons use a transverse cervical skin incision between the posterior tubercle of the C5 transverse process and the anterior tubercle of the C6 transverse process to expose the C5 and C6 nerves and an incision that runs transversely over the clavicle to expose the C7, C8, and T1 nerves. Our preference, for exposure of the supraclavicular plexus, is to use a single transverse 5- to 6-cm cervical incision, off midline, parallel to and approximately two to three fingerbreadths above the clavicle (Figure 34.8). With this approach

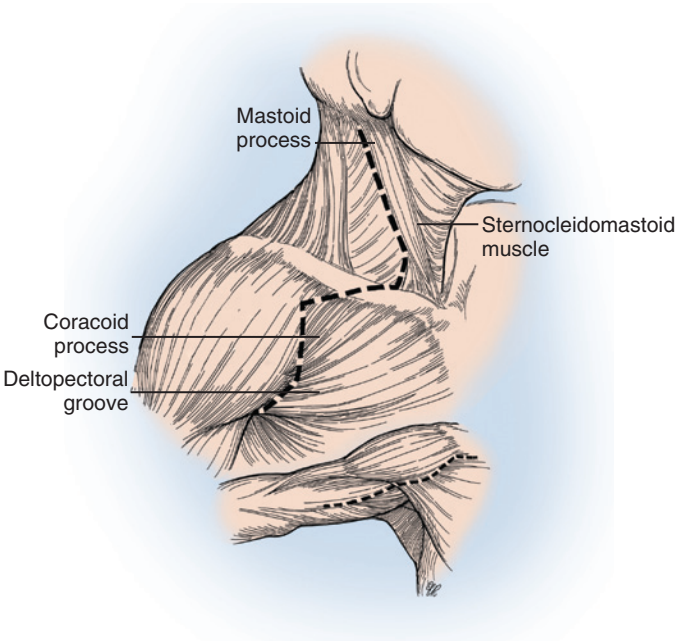

FIGURE 34.7 Classic zigzag skin incision used for exploration of the brachial plexus from the vertebral foramen to the terminal branch level in patients with traumatic brachial plexus injuries. The distal limb of the incision can be extended into the arm as needed. (Copyright © Elizabeth Martin.)

FIGURE 34.8 Our preferred skin incisions for surgical exploration of the brachial plexus. A transverse neck incision allows exposure of the supraclavicular brachial plexus and spinal accessory nerve. A deltopectoral skin incision allows exposure of the infraclavicular portion of the brachial plexus. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

we can expose the C5 through T1 nerves. We expose the infraclavicular plexus with a second incision overlying the deltopectoral interval. The skin incision may be infiltrated with a vasopressor agent to decrease bleeding.

Supraclavicular Exploration

After the skin incision, the platysma is incised and the cutaneous branches of the cervical plexus are identified and protected. Skin flaps that include the platysma are carefully raised both superiorly and inferiorly. We generally do not encounter the spinal accessory nerve in the proximal portion of this exposure where it exits beneath the sternocleidomastoid muscle; however, we can easily identify it more distally near the medial border of the trapezius muscle if necessary (see the section on Nerve Transfer). The external jugular vein on the surface of the sternocleidomastoid muscle is dissected and retracted. Dissection proceeds along the posterolateral margin of the sternocleidomastoid muscle, which is retracted medially. The superficial layer of the deep cervical fascia and cervical fat pad are opened and retracted. The dissection is extended to the superior border of the clavicle. The omohyoid muscle and transverse cervical vessels are identified, divided, and retracted medially and laterally. The first brachial plexus element to be visualized is usually the upper trunk. Medially, the phrenic nerve is found on the anterior surface of the anterior scalene muscle (Figures 34.9 and 34.10). Contraction of the diaphragm after electrical nerve stimulation can confirm identification of this nerve except in patients with phrenic nerve dysfunction (e.g., very proximal or preganglionic C5 nerve injury). The phrenic nerve should be mobilized with care. The anterior scalene muscle can then be resected safely to expose the proximal cervical nerves. When traced proximally, the C5 phrenic contribution will be visualized, thereby confirming identification of the C5 nerve. Careful dissection medial to the phrenic nerve may be necessary in patients with proximal C5 injury; iatrogenic injury to vital neck structures should be avoided. The upper trunk is exposed proximally and its C5 and C6 nerve origin identified. The C5 nerve is usually smaller, superior, lateral, and more vertical than the C6 nerve. The upper trunk is dissected distally to its anterior and posterior divisions, as well as to the origin of the suprascapular nerve. The C7 nerve and middle trunk can be isolated between the anterior and middle scalene muscles, more medial, posterior, and horizontal than the C6 nerve. Even more inferior and posterior are the C8 and T1 nerves (forming the lower trunk), which are closely associated with the subclavian artery. Mobilization of the clavicle may help improve exposure. Osteotomy of the clavicle in our experience is only seldom performed in treating posttraumatic brachial plexopathies. The clavicular head of the sternocleidomastoid muscle may also be detached from the clavicle to improve exposure. In most cases, however, the C8 and T1 nerves are not specifically exposed, because their repair is rarely, if ever, indicated in our opinion, given the poor outcome after reconstruction of these lower nerve injuries in adults.

If the upper roots are avulsed, the rootlets and swollen dorsal root ganglia may be found twisted and lying either behind the clavicle or slightly above it in the region of the C8 nerve. If the upper plexus nerves or the upper trunk or middle trunk (or both) is ruptured, the distal ends typically lie behind the

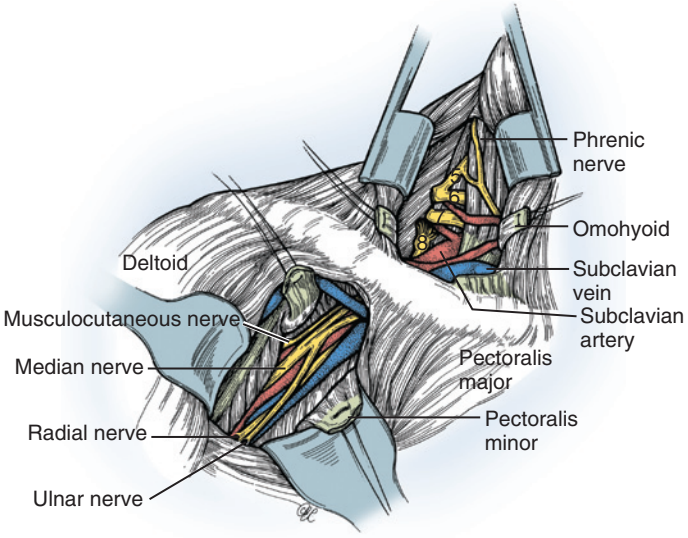

FIGURE 34.9 Key anatomic landmarks include the omohyoid muscle and the pectoralis minor muscle. The supraclavicular portion of the brachial plexus lies deep to the omohyoid and the infraclavicular portion lies deep to the pectoralis minor. These muscles are divided between ligatures for later approximation. With dissection of the deltopectoral groove, the lateral cord is the most superficial structure. In this example, the upper trunk and the C7 nerve are ruptured and the C8 nerve is avulsed (note the rootlets attached to the swollen dorsal root ganglion). (Copyright © Elizabeth Martin.)

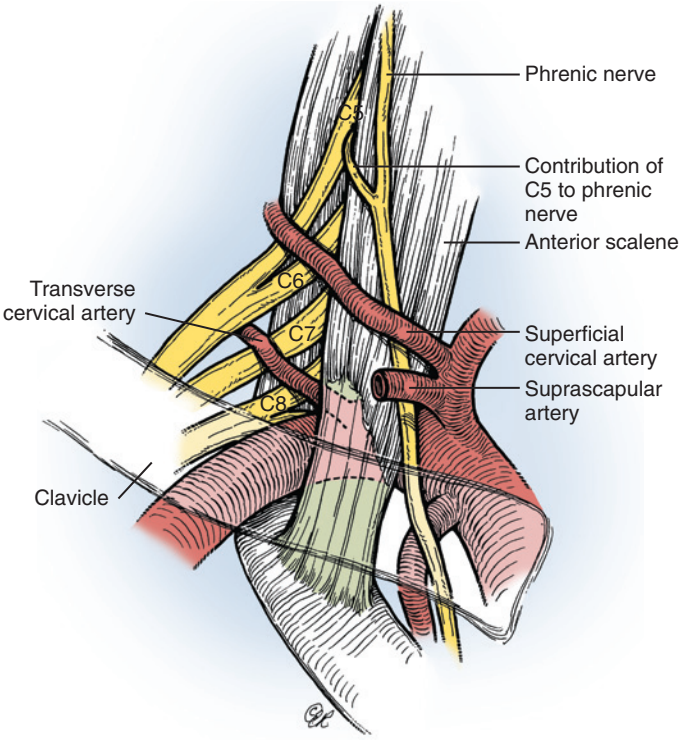

FIGURE 34.10 Exposure of the supraclavicular brachial plexus. Additional landmarks helpful in identifying the various nerves include the phrenic nerve contribution from the C5 nerve and the transverse cervical (scapular) artery, which frequently crosses over the C7 nerve. The C8 nerve is located just above and posterior to the subclavian artery, whereas the T1 nerve is almost directly posterior to the artery. Division and resection of a portion of the anterior scalene muscle are necessary to obtain proximal exposure of the spinal nerves. (Copyright © Elizabeth Martin.)

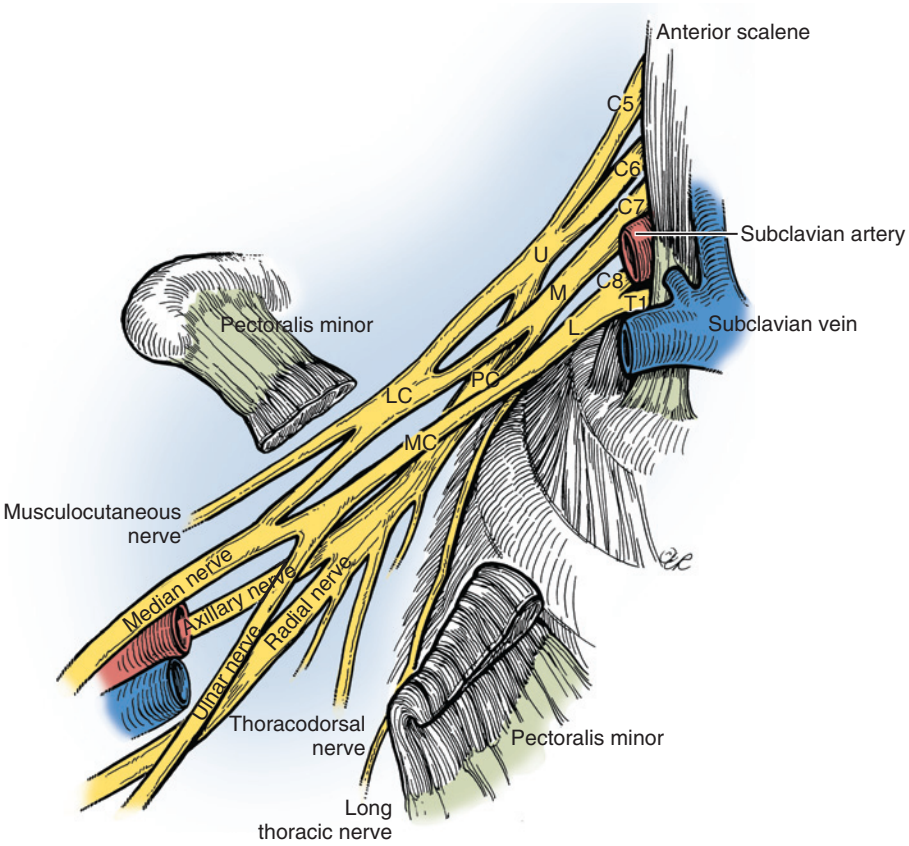

FIGURE 34.11 Exposure of the infraclavicular brachial plexus is often done in conjunction with exploration of the supraclavicular brachial plexus. *L*, Lower trunk; *LC*, lateral cord; *M*, middle trunk; *MC*, medial cord; *PC*, posterior cord; *U*, upper trunk. (Copyright © Elizabeth Martin.)

clavicle. The avulsed (often) or ruptured (infrequently) C8 and T1 structures are usually found much closer to their respective foramina than is the case with C5 or C6.

Infraclavicular Exploration

When indicated, the infraclavicular approach to the brachial plexus will expose the cords and branches (Figure 34.11). After the skin incision, the deltopectoral interval is developed to expose the cephalic vein, which is preserved and retracted laterally. The pectoralis major may be taken down from its humeral insertion and retracted as needed for exposure. A portion of its tendon is left on the humerus for reattachment, and the tendinous footprint is tagged with sutures for ease of closure. The infraclavicular plexus is explored by detaching the tendinous origin of the pectoralis minor from the coracoid process and tagging and retracting it. The clavipectoral fascia, which envelops the pectoralis minor, is incised to expose the lateral cord, which is superficial and lateral to the axillary artery. The thoracoacromial artery and its accompanying veins are identified and tagged if an FFMT or vascularized nerve graft is planned. The posterior cord is slightly lateral and deep to the artery, and the medial cord is medial and deep to the axillary artery. Care should be taken to preserve the medial and lateral pectoral nerves arising at this level. Electric stimulation can be helpful for identifying these nerves, which often consist of multiple branches. The lateral cord is identified by following the median nerve from distal to proximal. At this point the musculocutaneous nerve can be seen branching laterally and piercing the coracobrachialis muscle. The median nerve can also be followed proximally to identify the medial cord, which is then followed distally to the ulnar, medial brachial cutaneous, and medial antebrachial cutaneous nerves. Medial and deep to the axillary artery and vein and coursing laterally is the radial nerve. It is followed proximally to the posterior cord; the axillary nerve can be seen branching from the posterior cord. Once the supraclavicular and infraclavicular brachial plexuses are exposed, the retroclavicular area can be addressed. A tunnel is made under the clavicle from the neck to the deltopectoral area with a gloved finger. The most lateral part of the clavicular attachment of the pectoralis major muscle is detached; the subclavius muscle is divided. Crossing vessels, including the suprascapular vessels, should be ligated. By elevating the clavicle with a retractor or heavy tape, the divisions of the brachial plexus are exposed. If and when clavicular osteotomy is needed, predrilling of the screws for plate fixation should be done before the clavicle is divided. Patients with a history of clavicular fracture require special attention; in these cases, blunt dissection underneath the clavicle can be difficult. The risk for major vascular and pleural damage must be considered, especially if the lower brachial plexus elements are exposed medially.

If extensive scarring is present, especially fibrosis related to previous vascular injury or reconstruction, identification of major neurovascular structures in "normal" tissue planes is the rule before proceeding toward the zone of pathology. Release of

the insertion of the pectoralis major and in some cases the conjoined tendon may improve the exposure and facilitate safe dissection. Use of a Doppler device allows mapping of an arterial bypass graft.

INTRAOPERATIVE CONCERNS

Intraoperative Assessment

Direct inspection or palpation (or both) of the brachial plexus in our experience has not proved to be a reliable means of predicting preganglionic versus postganglionic injury or of assessing (postganglionic) neuromas-in-continuity. For example, in some cases of preganglionic injury, there is little scarring of the brachial plexus, which might suggest a minor injury but in fact reflects a more proximal injury (i.e., at the root–spinal cord interface). In other cases, a large neuroma-in-continuity may be recovering but may not have yet reached the distal musculature.

For these reasons, intraoperative electrodiagnostic assessment can be performed; we recommend and routinely use it. Surgical strategies are tailored to the intraoperative findings. Our intraoperative assessment includes the use of SSEPs, MEPs, and NAPs. Spinal evoked potentials[151] can replace SSEPs. Biochemical evaluation by determining choline acetyltransferase (ChAT) activity[77,214] is also used by some groups. If a nerve root or trunk is divided surgically in preparation for nerve grafting, frozen-section histologic analysis of the transected portion can be performed quickly for assessment of relative fascicular preservation and intraneural scarring.[129,211]

Somatosensory and Motor Evoked Potentials

SSEPs and MEPs help determine whether the spinal nerves are in continuity with the spinal cord; they evaluate the integrity of the intraforaminal and intraspinal sensory and motor pathways. SSEPs are based on the principle that it is possible to record very low amplitude potentials on the scalp (over the parietal cortex) after stimulating a contralateral peripheral nerve in the upper or lower limb. MEPs are motor compound action potentials recorded from surgically exposed spinal nerves after central stimulation. Both SSEPs and MEPs have been used to identify root avulsion during brachial plexus surgery.[195,205]

For SSEPs and MEPs, an electrode (which can act either as a stimulator or as a recorder) is placed on the available proximal cervical nerves and stimulations are performed. We rely partly on this examination to confirm the integrity of a proximal nerve that is being considered for grafting.

An important limitation is the fact that the sensory (posterior) roots and motor (anterior) roots may be differentially injured. When an SSEP is present, it does not signify that the motor roots are intact, and vice versa. Another limitation is that SSEPs are easily affected by the depth of anesthesia and technical difficulties; simultaneous recording of SSEPs after peripheral nerve stimulation in the unaffected upper limb is therefore recommended. MEP recording and interpretation are also sometimes challenging and require a team experienced with the technique.

Nerve Action Potentials

NAPs evaluate the presence of functioning axons, both sensory and motor, over a segment of nerve. Although they can be used to assess preganglionic injury, we routinely use SSEPs and MEPs instead for this purpose. We do use NAPs to assess all postganglionic neuromas-in-continuity. Stimulating and recording electrodes are placed directly on the nerve, proximal and distal to a neuroma-in-continuity (Figure 34.12). At least 4 cm of separation is required to record reliable NAPs. If a good NAP is present across a neuroma-in-continuity, the likelihood of significant functional recovery over time is high and the lesion should undergo neurolysis but not resection. We do not routinely use compound muscle action potential recordings in assessing incomplete lesions. Based on a large basic science and clinical experience, Kline and colleagues have shown that when no NAP is obtained across a neuroma-in-continuity, this lesion has minimal potential for spontaneous recovery and should be resected and grafted.[110,111,167]

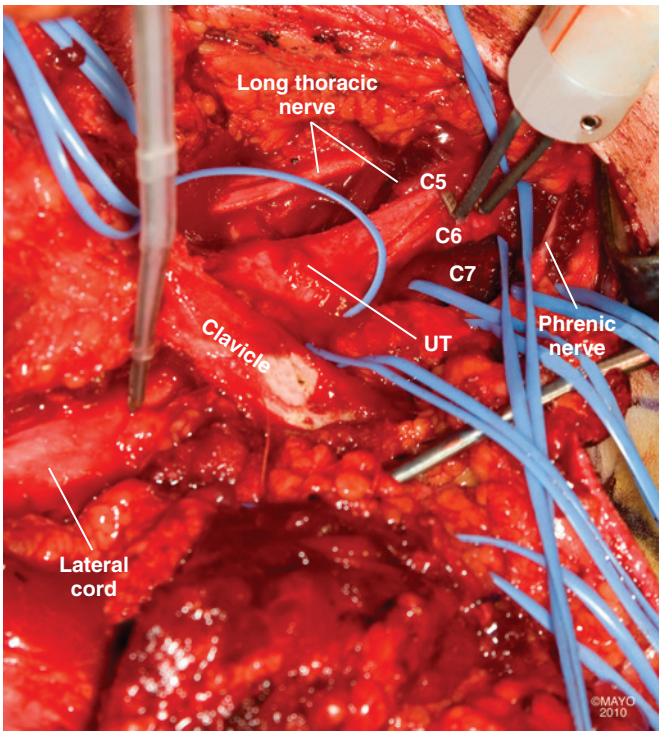

FIGURE 34.12 Intraoperative nerve action potentials are being performed across an upper trunk (UT) neuroma-in-continuity. Stimulation of C6 and recording from the lateral cord are shown. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

While performing intraoperative electrodiagnostic testing, we also observe the effects of direct nerve stimulation on muscle contraction. The phrenic or other functioning proximal nerves can serve as a normal positive control.

Choline Acetyltransferase Activity

ChAT activity has been used clinically to differentiate between motor and sensory fascicles intraoperatively during nerve grafting procedures[77,214] and also to determine the availability of the proximal nerve stump as a donor motor nerve during brachial plexus surgery. ChAT is an enzyme of acetylcholine synthesized in the nerve cell body and transported by axonal flow to the nerve terminals. Its activity is higher in motor fascicles than in sensory fascicles, and this differential expression can be used to identify motor fascicles of good quality (ChAT activity

> 2000 cpm[95,96]). Recent investigations have demonstrated that ChAT may not be as reliable as previously reported.[208] This fact, in addition to the prolonged time of testing, makes the use of this test difficult in the clinical situation.

Intraoperative Decisions and Priorities of Repair

Primary brachial plexus nerve reconstruction is based on functional priorities, depends on intraoperative assessment of the nerve damage and available motor axon donors, and is individualized intraoperatively. When only some elements of the brachial plexus are injured or the nerve gaps are short, we prefer to reestablish continuity to all injured parts by using every available donor nerve. When all brachial plexus elements are injured or the nerve gaps are long, this approach becomes impossible; autologous donor nerve tissue is not available to restore continuity to all parts of the brachial plexus, and priorities for reconstruction should be set. The priorities for reconstruction are based on three factors: (1) the functional significance, (2) the likelihood of regaining function after nerve reconstruction (proximal muscles are reinnervated more successfully than distal muscles), and (3) the degree of difficulty in restoring function by secondary reconstructive surgery.

C5-C6 Injury

For a patient with an injury limited to the upper plexus nerves (C5 and C6), the priorities are regaining elbow flexion and shoulder stability, abduction, and external rotation. Elbow flexion is generally achieved by reinnervation of the biceps and brachialis muscles (via the anterior division of the upper trunk, the musculocutaneous nerve proper, or the motor branches to the biceps and brachialis). Shoulder stability, abduction, and external rotation are usually obtained with reinnervation of the deltoid (via the posterior division of the upper trunk, the axillary nerve proper, or the anterior division of the axillary nerve) and supraspinatus and infraspinatus muscles (via the suprascapular nerve).

❖ AUTHORS' PREFERRED TREATMENT OF C5-C6 INJURY

In the majority of patients with C5-C6 loss of function, we explore the brachial plexus and perform intraoperative recordings. In a patient with a nonrecovering postganglionic injury (i.e., a postganglionic neuroma-in-continuity with a negative NAP or a postganglionic nerve rupture), we typically reinnervate the shoulder by using interpositional grafts between the C5 nerve stump and the posterior division of the upper trunk and suprascapular nerve. Another option that we may use for shoulder reinnervation is an interpositional graft between the C5 nerve stump and the posterior division of the upper trunk combined with transfer of the spinal accessory nerve to the suprascapular nerve. In patients in whom a functional C5 nerve stump is not identified or in those explored late (>6 to 9 months after injury), we perform double-nerve transfers (to axillary and suprascapular nerves) for shoulder reinnervation. Our preferred technique includes a spinal accessory nerve transfer to the suprascapular nerve and a triceps motor branch transfer to the anterior motor branch of the axillary nerve. Consistent with recent literature authored by others,[22,80,183] for elbow reinnervation, we typically perform fascicular nerve transfer(s) preferentially over C6 nerve grafting. Our preferred combination is transfer of an ulnar nerve fascicle to the biceps motor branch, sometimes combined with a second nerve transfer of a median nerve fascicle to the brachialis motor branch. Recent reports have demonstrated that the addition of the second transfer has not statistically improved outcomes.[35,135]

C5-C7 Injury

Patients with C5-C7 injuries have deficits in shoulder motion and elbow flexion (as do patients with C5-C6 injury), as well as variable deficits in elbow extension (triceps) and wrist extension. The priorities for primary nerve reconstruction are similar to those in patients with C5-C6 injury: regaining elbow flexion and shoulder stability, abduction, and external rotation. In addition, if elbow extension (uncommon) or wrist extension is severely affected, these problems should be addressed. The approach for nerve reconstruction differs because of the variable degree of weakness and the available donor motor axons. Generally, a combination of nerve grafts (if proximal nerves are available) and nerve transfers (spinal accessory, intercostals, pectoralis, thoracodorsal, ulnar and median nerve fascicles) is performed.

C8-T1 Injury

Patients with this pattern of injury have weakness in the extrinsic and intrinsic muscles of the hand and more variable wrist weakness. The indications, timing, and approach to reconstruction are controversial. As stated previously, nerve grafting is not appropriate for these rare injuries, because of the long reinnervation distances. Some surgeons are performing distal nerve transfers in patients with C8-T1 lesions when seen early.[21,30,31,92,164] Because patient numbers are small, the results of such procedures have yet to be firmly determined. One can certainly perform early or delayed tendon transfers for an isolated C8-T1 injury.[19] An individualized approach is required, with careful assessment of the strength of potential available donors. Reconstruction of thumb flexion, finger flexion, opposition, and intrinsic-minus claw deformity, as well as finger and thumb extension, will be necessary. If C7 is also affected and tendon transfer options are limited, the use of FFMT may also be appropriate.

Pan-Plexal Injury

In patients with complete pan-plexal injuries, our priorities of repair, in order of importance, include the following:

1. Elbow flexion by reinnervation of the biceps/brachialis muscle
2. Shoulder stabilization, abduction, and external rotation by reinnervation of the suprascapular and axillary nerves
3. Hand sensation by reinnervation of the lateral cord (C6-C7 distribution)
4. Wrist and finger flexion. (When hand reconstruction is performed, the triceps muscle should also be considered for reinnervation because it is a useful antagonist of elbow flexion; as such, it potentiates the strength of an FFMT that crosses the elbow joint.)
5. Wrist and finger extension
6. Intrinsic hand muscle function

In patients with complete root avulsions of the brachial plexus, no functioning nerves are available proximally to restore function to the extremity. In these situations, there are no

local musculotendinous transfers available for restoration of extremity function. Intact extraplexal nerves (spinal accessory, intercostal, C3 and C4 roots) can be transferred and coapted to the distal peripheral nerve of the brachial plexus as a method for reinnervation of critical sensory or motor nerves.

❖ AUTHORS' PREFERRED TREATMENT OF PAN-PLEXUS INJURY

Conventional goals in patients with pan-plexus injury include a stable shoulder and elbow flexion with or without some hand sensation. Advances in microsurgical techniques, as well as novel application of FFMTs in the acute setting (<6 months after injury), have enabled us to achieve rudimentary prehension in select patients. In all patients, we explore the supraclavicular brachial plexus in the hope of finding some viable and usable nerves from the proximal stumps; even in cases with evidence of multiple avulsions based on preoperative testing, exploration may occasionally reveal a viable nerve stump. In our experience, only rarely do we find more than one proximal nerve stump that can be used for nerve grafting in severe brachial plexus injuries. If available, we use this stump to reinnervate shoulder targets (axillary and suprascapular nerves). Our highest priority for nerve reconstruction in patients with complete injury is elbow flexion. For this reason, we have chosen to doubly reinnervate elbow flexion when possible, often using intercostal nerve transfers to the biceps motor branch in addition to a gracilis FFMT neurotized by the intercostals as well. Shoulder abduction, stability, and especially external rotation are provided either by using spinal accessory nerve transfer to the suprascapular nerve (when no available nerves are present) or by leaving the spinal accessory nerve intact and performing a delayed lower trapezius tendon transfer for external rotation. Other options remain for later shoulder reconstruction if these measures prove unsuccessful. When additional nerve resources are available (i.e., more than one viable nerve), we will also target the serratus anterior or pectoralis major.

If hand reinnervation is attempted, a single-stage gracilis FFMT is used for both elbow flexion and finger flexion. The shoulder is stabilized with nerve grafts to either the suprascapular nerve or axillary nerve, or both, from an available cervical nerve stump or with a planned secondary trapezius tendon transfer. The spinal accessory nerve is transferred to a triceps branch with an intervening nerve graft for reinnervation of elbow extension. Sensation in the median nerve distribution of the hand is provided by the transfer of sensory branches of the intercostal nerves to the lateral cord contribution of the median nerve. Secondary surgeries to provide stability to the hand and assist in rudimentary grasp are performed between 4 and 6 months after the index brachial plexus reconstruction. These secondary surgeries include both selected fusions and soft tissue balancing. The fusions include wrist arthrodesis, thumb carpometacarpal arthrodesis (to place the thumb in palmar abduction and pronation), and thumb interphalangeal joint arthrodesis. The soft tissue balancing is primarily achieved with passive flexor digitorum superficialis lasso procedures to create a metacarpophalangeal joint contracture for prevention of a claw deformity. Other options for hand reanimation have also been proposed, including a two-stage FFMT[64] and contralateral C7 (entire or half [hemi]) transfer to the median nerve,[186] as well as extended phrenic nerve transfers to the median nerve.[213]

Infraclavicular and Terminal Branch Injuries

Variable findings are due to different injury patterns in isolation or combination. Intraoperative NAP recordings are used in each case, and nerve grafting is commonly performed when NAPs are absent, when the zone of injury is relatively short, and provided good proximal and distal nerve architecture is maintained. Concomitant or staged tendon transfers may be considered for denervated muscles with long reinnervation distances. Nerve transfers, if available donors exist, may be preferable in patients initially seen 6 to 12 months after injury. For example, in cases of posterior cord injury, we would typically excise the neuroma and perform nerve grafting to the axillary nerve and to triceps nerve branches, and standard tendon transfers would be used for wrist, finger, and thumb extension.

PRIMARY NERVE RECONSTRUCTION

Neurolysis

The indication for neurolysis after traumatic brachial plexus injury is the intraoperative finding of a postganglionic neuroma-in-continuity and a positive (present) NAP. In most of these cases, the integrity of the proximal nerves is confirmed with intraoperative SSEPs and MEPs; however, in patients with a clearly isolated infraclavicular injury, testing of evoked potentials may not be necessary.

Microsurgical neurolysis consists of liberating the nerve from adhesions to neighboring tissue at the epineurial level (external neurolysis). Occasionally, internal neurolysis is indicated and performed under the microscope. This consists of longitudinal incisions made in the fibrotic layers of the epineurium and the epifascicular epineurium; all fascicles are completely separated to remove the surrounding scar tissue.

Direct Nerve Repair

Direct nerve repair is preferable to nerve grafts if it can be performed without excessive tension. However, neurorrhaphy is rarely possible after traumatic brachial plexus injury, except in cases of sharp transection that are explored early. Mobilization of the nerve stumps may make direct repair possible in some situations. In rare cases, direct repair of individual nerves or nerve branches with focal neuromas that are resected may be possible, provided that the nerve ends can be mobilized sufficiently.

Nerve Grafting

Indications

Nerve grafting is indicated in patients with postganglionic nerve ruptures or with postganglionic neuromas that do not conduct a NAP. In these cases, the nerve is in continuity with the spinal cord and has maintained viable motor axons that can be grafted to specific targets. When nerve transfer options exist, some surgeons prefer them to nerve grafting. Our preference, unless the surgery is performed late, the muscle targets are very distal, or the graft length is long (>10 cm), is to use nerve grafting when proximal nerves are available and in good condition.

Operative Procedure

Nerve grafting consists of the coaptation of interpositional grafts (e.g., cable grafts of the sural or other cutaneous nerves)

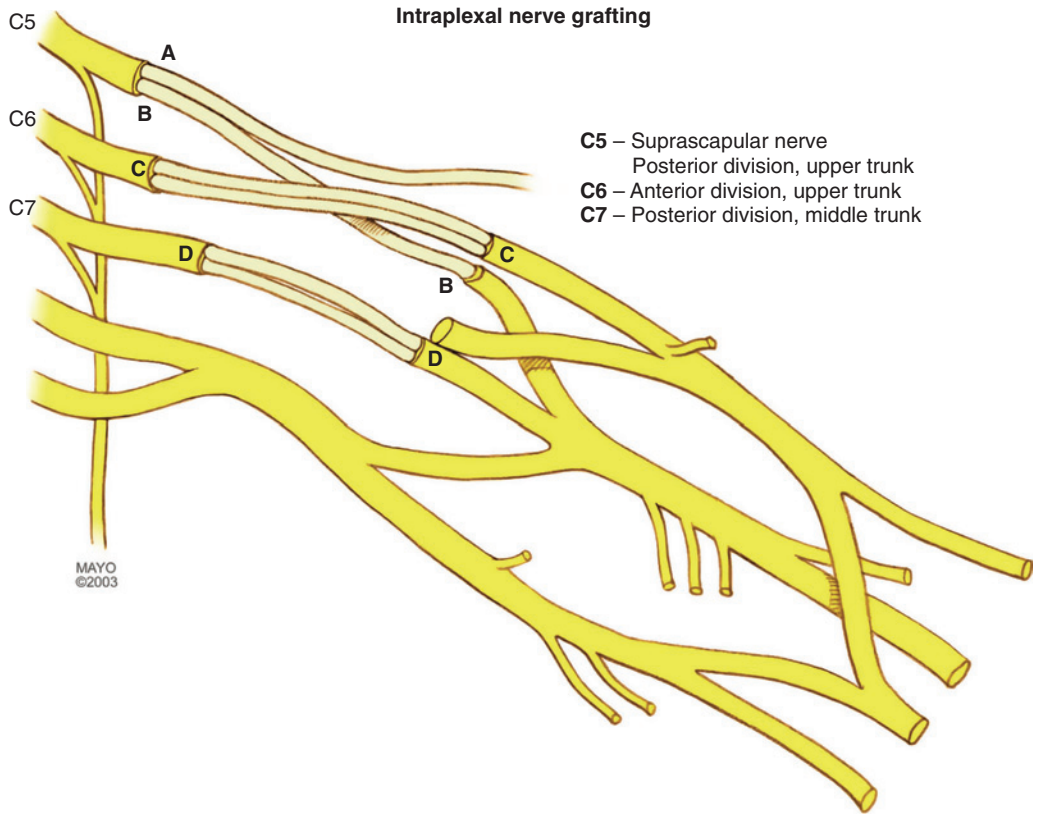

FIGURE 34.13 Anatomic reconstruction of the brachial plexus is done whenever possible with intraplexal nerve grafts: C5 to shoulder targets, C6 to elbow flexors, and C7 to extensor muscles. *A,* Suprascapular nerve; *B,* posterior division, upper trunk; *C,* anterior division, upper trunk; *D,* posterior division, middle trunk. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

between the desired nerve stumps. Generally, the C5 nerve is used to target shoulder stability, abduction, and external rotation (suprascapular nerve, axillary nerve, or posterior division of the upper trunk), the C6 nerve to target elbow flexion (anterior division of the upper trunk or musculocutaneous nerve), and the C7 nerve to target elbow extension (posterior division of the middle trunk or radial nerve) (Figure 34.13).

Conventional Nerve Grafting With the Sural Nerve

The most commonly used donor nerve for brachial plexus injury is the sural nerve, a purely sensory nerve that innervates a small area on the dorsolateral region of the foot (Figure 34.14). If harvested from the popliteal fossa to the lateral aspect of the ankle, up to 35 to 40 cm of donor nerve can be obtained from each leg. The sural nerve can be harvested in the supine position by placing a pad beneath the donor-side buttock to internally rotate the leg because this nerve is located posteriorly in the calf. The sural nerve can be dissected and mobilized with the leg in extension or with the knee flexed. Alternatively, an assistant can hold the leg elevated during harvest. The use of a tourniquet at the upper thigh level is optional; however, if used, surgeons must make certain that the limb tourniquets are deflated and disconnected or removed after harvesting the nerve grafts. Different techniques can be used, including multiple transverse or vertical incisions, a single incision along the course of the nerve (which is our preference), and even the use of an endoscope. The nerve is first identified between the lateral malleolus and Achilles tendon in the subcutaneous tissues

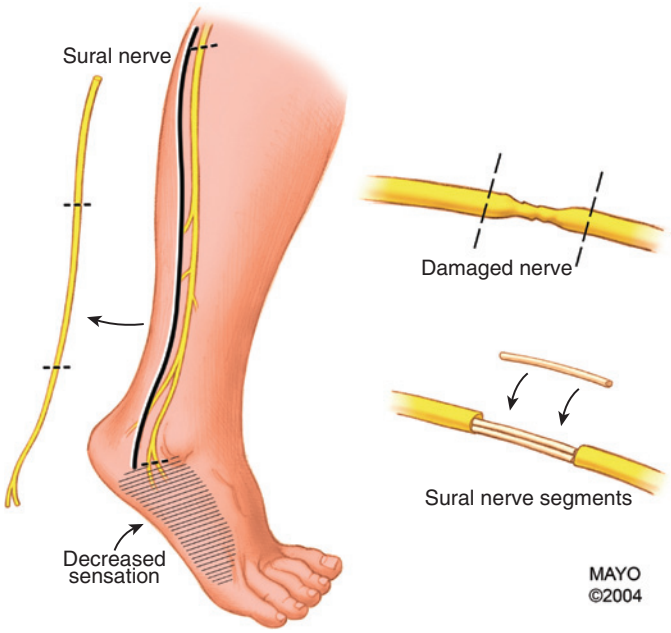

FIGURE 34.14 The sural nerve is a commonly used donor for interpositional nerve grafting of postganglionic lesions. This illustration is reviewed with patients to discuss the incision, technique, and morbidity (expected sensory loss and potential for neuropathic pain in the dorsolateral aspect of the foot). (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

adjacent to the lesser saphenous vein. Gentle traction is applied, and the remaining portion is harvested up to the popliteal fossa; dissection of the nerve graft should be as atraumatic as possible. The nerve is transected as far distally and proximally as possible. The skin wound is closed in layers, and the legs are wrapped in elastic bandages.

Other Nerve Graft Options

If needed, other cutaneous nerves may be used as interpositional grafts, including the superficial radial, medial brachial or antebrachial cutaneous, lateral antebrachial cutaneous, and dorsal ulnar cutaneous nerves. For long defects or when a large-diameter graft is required, some recommend vascularized nerve grafts (pedicled or free). The most common vascularized nerve graft is the ulnar nerve (when it is nonfunctional), as described later with contralateral C7 transfer, but the radial nerve (if nonfunctional) and even the sural nerve[63] may also be used as vascularized nerve grafts.[24]

Coaptation

Coaptations should be performed without tension, and the grafts should ideally fill the cross-sectional area of the stumps. Usually, two or three segments of graft are cut and used to fill the area (Figure 34.15). When possible, different fascicular patterns are matched individually to lead the regenerating axons to the proper motor fascicles of the distal nerve. An understanding of the anatomic topography of the nerves at different levels can be helpful to align fascicles. Several 8-0 to 10-0 nylon epineurial sutures are commonly placed between each nerve graft and the proximal and distal nerves under microscope or loupe magnification. Tissue adhesive can be used to approximate multiple strands of nerve graft and simplify the coaptation with proximal and distal nerves (Figure 34.16). We generally

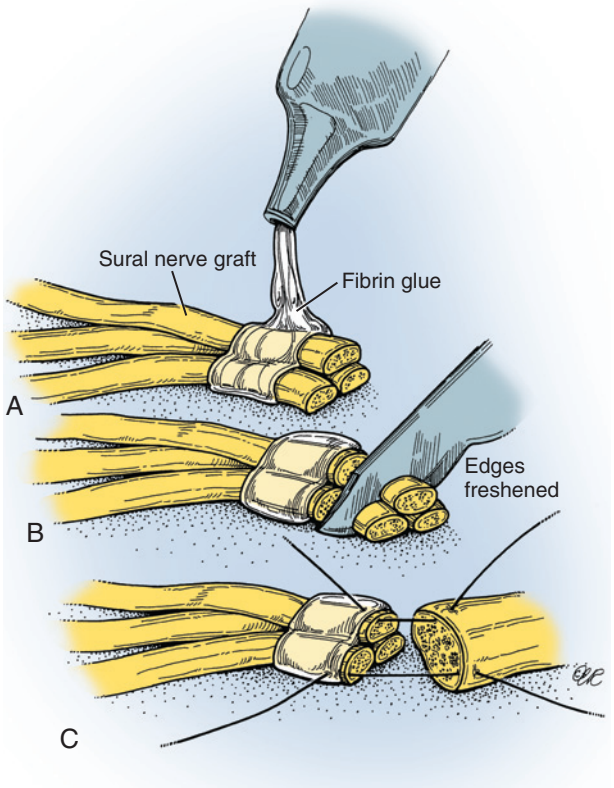

FIGURE 34.16 Nerve repair with tissue adhesive. The graft strands are first glued together **(A),** the graft ends are freshened with a sharp blade **(B)** and then coapted with conventional epineurial sutures **(C).** (Copyright © Elizabeth Martin.)

reinforce the nerve coaptation sites with the use of a bivalved nerve conduit and tissue adhesive.

Nerve Conduits

Nerve conduits are increasingly being used in nerve surgery for small-caliber (more commonly sensory) nerves, for short nerve gaps, or as an adjunct to nerve repair or transfer; however, in proximal brachial plexus injuries, this technique is not recommended at this time as a substitute for nerve grafts.

Processed Nerve Allografts

The use of nerve allografts that have been decellularized by a variety of methods has gained popularity in short-gap digital sensory nerve defect reconstruction as well as larger mixed nerve defect reconstruction. Use of these allografts in proximal brachial plexus reconstruction or for long nerve or motor graft reconstruction is not recommended at this time unless nerve autograft is unavailable.[86]

Nerve Transfer

The terms *nerve transfer*, *neurotization*, and *nerve crossing* have been used interchangeably in the literature[138] and describe the transfer of a normal or nearly normal fascicle or nerve branch to an important sensory or motor nerve that has sustained irreparable proximal damage. The term *nerve transfer* is used most frequently in the current literature; *nerve transfer* and *neurotization* will be used in this text without distinction. It should be noted that *muscular neurotization* is different in that the term describes direct implantation of nerve ends into a denervated muscle for reinnervation.

The indications for nerve transfer are irreparable preganglionic injury, selected postganglionic injury, and reinnervation of FFMTs. Important attributes of nerve transfers are as follows: They are closer to the end organ (which means that there is increased likelihood of more rapid recovery or more reliable recovery, or both). There is delivery of a large number of "pure" axons. Repair takes place outside the injured and scarred zone. Nerve grafting, with its two repair sites, is avoided. Rehabilitation is more easily accomplished, especially with synergistic transfers.

Common intraplexal and extraplexal nerve transfers are described in the following sections.

Spinal Accessory Nerve Transfer

SURGICAL ANATOMY

The spinal accessory nerve (cranial nerve XI) innervates the sternocleidomastoid and trapezius muscles. It originates in the posterior cranial fossa from spinal and cranial nerve roots, passes through the jugular foramen, and divides into an internal branch (containing fibers originating from the "cranial part"), which joins the vagus (X) nerve, and an external branch (consisting of fibers from the "spinal part"), which innervates the sternocleidomastoid and trapezius muscles. After supplying the sternocleidomastoid muscle, the nerve descends obliquely in the posterior triangle of the neck between the superficial and deep layers of the deep cervical fascia (Figure 34.17). In this area the nerve is embedded in loose connective tissue and is in contact with the cervical lymph node chain. This is the most common location for iatrogenic injuries to the spinal accessory nerve during lymph node biopsies. The spinal accessory nerve provides two or three branches to the upper part of the trapezius muscle before passing under its anterior edge. Intramuscularly, the nerve follows an oblique caudal course toward the middle and lower parts of the trapezius and gives off branches to the muscle throughout its course. There is great variability in connections between the spinal accessory nerve and the roots of the cervical plexus.[54]

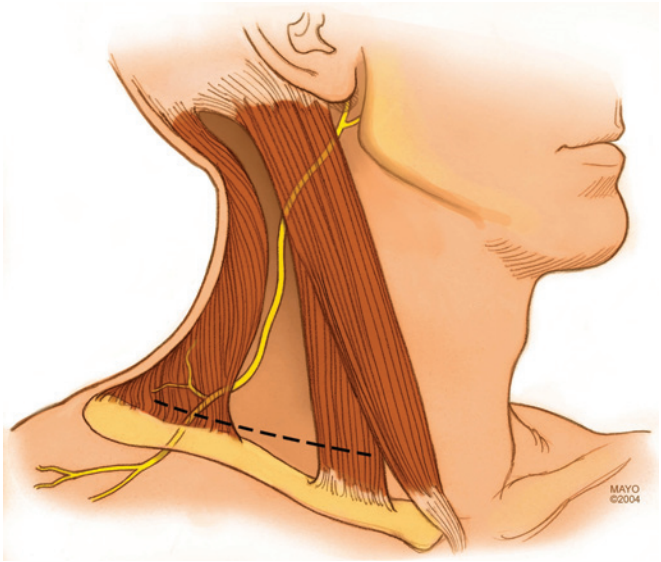

FIGURE 34.17 The course of the spinal accessory nerve. The nerve can readily be identified in the lateral portion of a supraclavicular incision on the anterior surface of the trapezius muscle several centimeters above the clavicle. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Spinal Accessory Nerve Dissection. As with exploration of the supraclavicular plexus, turning the neck to the contralateral side and elevating the shoulder and neck off the surgical table facilitate access to the spinal accessory nerve. Muscle relaxation is avoided to allow the use of electrical stimulation to confirm identification of the spinal accessory nerve.

The spinal accessory nerve is usually taken from the posterior border of the sternocleidomastoid muscle and traced as far as possible along the undersurface of the trapezius to its decussation, where it is transected. The nerve can be transferred to the supraclavicular area for neurotization.[185] Although this is the most popular approach to the spinal accessory nerve, there are some disadvantages. First, it creates a large longitudinal scar on the neck. Second, this extensive approach can inadvertently denervate proximal branches to the upper part of the trapezius, which should be preserved.

Our preferred technique uses the lateral portion of the transverse supraclavicular cervical incision described above; this approach makes a less conspicuous scar over the clavicle. The spinal accessory nerve can be identified several centimeters above the clavicle on the anterior surface of the trapezius. This nerve should not be confused with more superficial cervical plexus elements that may run in similar directions. These branches from the cervical plexus can be distinguished from the spinal accessory nerve by their size, which is comparatively small, and by the response of the nerves to electrical stimulation. The spinal accessory nerve should produce vigorous contraction of the trapezius.

The spinal accessory nerve should be dissected as far distally as possible. A proximal branch to the upper portion of the trapezius should be preserved. The nerve can then be divided and transferred. Some authors transect the spinal accessory nerve more proximally, just distal to the sternocleidomastoid muscle; we do not recommend this approach, because an intervening nerve graft will be required to reach the distal target, which may reduce the success of the procedure.

Contraindications. Patients with spinal accessory nerve dysfunction preoperatively are not candidates for this procedure. Because trapezius function is difficult to assess on physical examination in patients with paralyzed shoulder muscles, preoperative EMG can help identify an abnormality. Intraoperative stimulation is the definitive assessment of spinal accessory nerve function.

Complications. There are generally no serious complications from this procedure as long as the proximal branch of the spinal accessory nerve to the upper fibers of the trapezius muscle is preserved. If the proximal branch to the trapezius is injured, shoulder depression and dysfunction may occur.

Transfer to the Suprascapular Nerve. The suprascapular nerve, which innervates the supraspinatus and infraspinatus muscles, originates from the upper trunk 2 to 3 cm above the clavicle. In some patients, its origin can be higher, whereas in those with ruptures or avulsion injuries of the upper trunk, the nerve can retract to the retroclavicular or infraclavicular area. The suprascapular nerve courses laterally and posteriorly, deep to the omohyoid muscle, and enters the supraspinatus fossa through the suprascapular notch, deep to the superior transverse scapular ligament. The nerve then traverses the supraspinatus fossa deep to the supraspinatus muscle and winds around the lateral border of the spine of the scapula (the spinoglenoid notch) to enter the infraspinatus fossa. Its course renders it particularly vulnerable to traction lesions at the suprascapular notch, at the spinoglenoid notch, and within the supraspinatus and infraspinatus fossae. The suprascapular nerve is dissected bluntly with finger dissection to the suprascapular notch to confirm its integrity. This is done even when the location of a lesion proximal to the upper trunk is obvious to ensure that a secondary (distal) lesion is not present. To perform the nerve transfer, the suprascapular nerve is transected at its origin from the upper trunk (Figure 34.18). If there is no scarring, it may be possible to dissect it further proximally and separate it from the upper trunk to increase the available length. The suprascapular nerve is coapted to the spinal accessory nerve without an intervening nerve graft.

Others have proposed a posterior approach when the spinal accessory nerve is used to reinnervate the suprascapular nerve, particularly when a segmental injury to the suprascapular nerve at the suprascapular notch is suspected.[12,52,93] The advantage of this approach is a more distal repair to a healthy portion of the suprascapular nerve. The disadvantage is perhaps a reduced number of myelinated axons in the more distal terminal spinal accessory nerve and the need for prone or lateral decubitus positioning to enable a posterior approach to the scapula. Both the spinal accessory and the suprascapular nerves can be exposed via a transverse incision at the superior border of the scapula. The suprascapular nerve is located midway between the superior angle of the scapula medially and the acromion laterally. After identifying the nerve at the suprascapular notch, the superior transverse ligament is divided, and the nerve is dissected as far proximally as possible. The spinal accessory nerve is located at a point 40% of the distance between the dorsal midline (spinous processes) and the acromion. It can be identified deep to the trapezius muscle, which is separated parallel to the course of its fibers. The spinal accessory nerve is divided as far distally as possible to achieve a coaptation without tension.

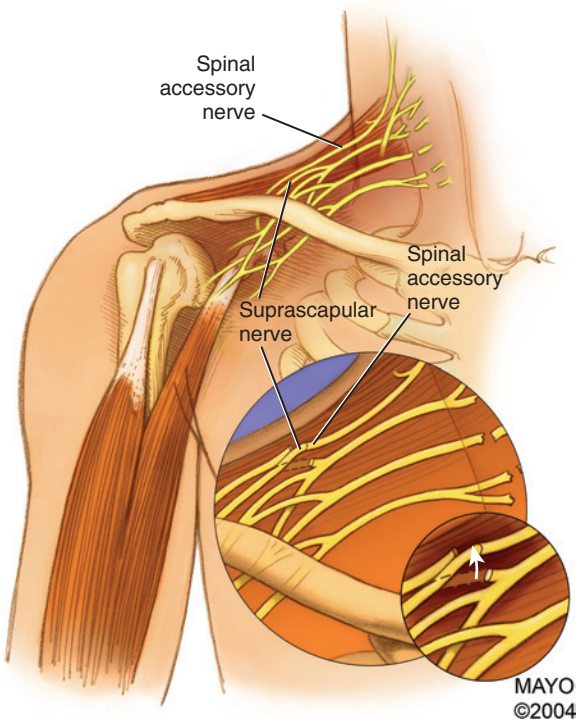

FIGURE 34.18 Transfer of the spinal accessory nerve to the suprascapular nerve. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

CRITICAL POINTS *Transfer of the Spinal Accessory Nerve to the Suprascapular Nerve*

Indications
- Most commonly used for C5-C6, C5-C7, and complete plexus injuries
- Ideal for injuries that have occurred less than 6 to 9 months previously

Pearls
- Spare the most proximal branch of the spinal accessory nerve.
- Sufficient distal dissection will permit direct transfer of the spinal accessory nerve to the suprascapular nerve without an intervening nerve graft.

Technical Points
- Use a transverse skin incision over the distal clavicle.
- Transfer only the middle and distal branches of the spinal accessory nerve.

Pitfall
- Outcomes are less favorable in patients with C5-C7 or complete injuries.

Postoperative Care
- Shoulder immobilization is maintained for 3 weeks.
- EMG-documented reinnervation begins by 6 months postoperatively.

Expected Outcomes. The expected outcome of transfer of the spinal accessory nerve to the suprascapular nerve for restoration of shoulder abduction is influenced by multiple factors, including the type of injury (C5-C6 vs. pan-plexus injury)[20,199] and the number of transfers performed (concomitant axillary reinnervation or not).[34] The range of outcomes reported in the literature is wide. A metaanalysis of the world literature reported that 92% of patients recovered some antigravity shoulder abduction with nerve transfer to the suprascapular nerve.[139] Multiple other groups[20,34,46,128,206] have reported a range of results, with mean degrees of abduction of between 45 and 122 degrees. Patients with an isolated C5-C6 palsy seem to have better outcomes than patients with a C5-C7 palsy, who seem to have better outcomes than those with a complete brachial plexus injury.[20,206] The function of the serratus anterior muscle may play a role in these outcomes. Patients with partial innervation of the serratus anterior (from an intact C7 nerve) may achieve significantly better range of shoulder abduction and flexion because of better scapular stability. The variability in results may also be due to the difficulty and complexity of assessing the outcome of shoulder motion (either by range of motion or muscle grading). The outcome of transferring the spinal accessory nerve to the suprascapular nerve for restoration of external rotation is less frequently reported, but it varies from 0 to 118 degrees of external rotation,[20,206] depending on the injury pattern and the studies (Figure 34.19).

Transfer to the Musculocutaneous Nerve. Transfer of the spinal accessory nerve to the musculocutaneous nerve is occasionally used to restore elbow flexion[185] (Figure 34.20). However, we more frequently choose to transfer ulnar nerve fascicles (in C5-C6 injuries) or intercostal nerves (in pan-plexus injuries) to the motor branch of the biceps. Use of the spinal accessory nerve requires an interposition nerve graft, which may degrade results.[139]

Operative Procedure. The musculocutaneous nerve may be exposed through an extended deltopectoral or a proximal arm skin incision. The musculocutaneous nerve originates from the lateral cord of the brachial plexus just distal to the coracoid process. After it pierces the coracobrachialis muscle, the nerve runs on the deep surface of the biceps. The musculocutaneous nerve then gives rise to the motor branch or branches to the biceps, which enter the muscle approximately 12 cm distal to the acromion. Two types of distribution of motor branches to the two heads of the biceps are found: a common trunk (pattern 1), which will divide into two branches (to the short and long heads of the biceps), and two separate nerve branches (pattern 2), the branch to the short head generally originating more proximally on the musculocutaneous nerve. Intercommunicating nerve fibers can be found between the motor branches. After traveling a distance within the short and long heads of the biceps (median distance of 1 and 2 cm, respectively, in pattern 1 or 3 cm for each branch in pattern 2), the main branches divide into terminal branches distributed throughout the muscle bellies. The musculocutaneous nerve then gives rise to the motor branch or branches of the brachialis muscle (≈17 cm distal to the acromion) and continues as the lateral antebrachial cutaneous nerve. Once the musculocutaneous nerve and its branches are identified and dissected, the nerve is cut just after it branches to the coracobrachialis muscle. A sural nerve graft (typically 9 to 10 cm long) is used to connect the spinal accessory nerve to the musculocutaneous nerve. The nerve graft is usually placed beneath the clavicle, coapted first to the spinal accessory nerve and then to the musculocutaneous nerve. The neurotization is performed with 9-0 or 10-0 nylon without tension under magnification with the operating microscope.

FIGURE 34.19 This patient with a C5-C7 lesion regained excellent external rotation after transfer of a spinal accessory nerve to the suprascapular nerve. Note the supraclavicular transverse incision. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

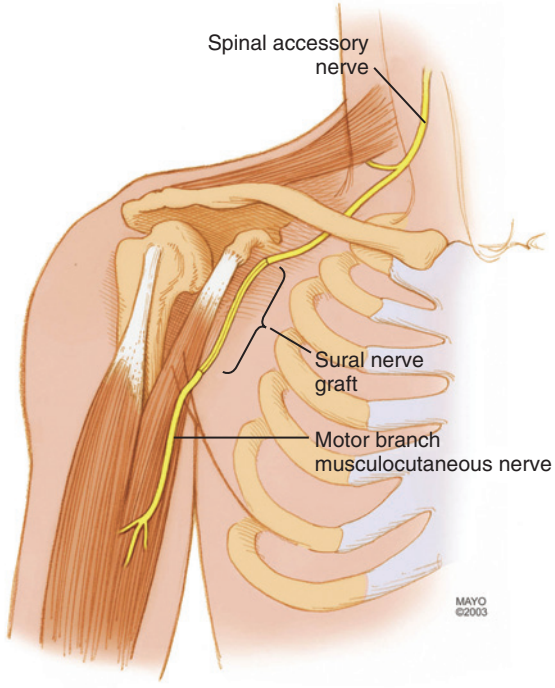

FIGURE 34.20 The spinal accessory nerve can be used to neurotize the musculocutaneous nerve (as shown) or the biceps and brachialis branches with an interpositional graft. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Expected Outcomes. A metaanalysis of the outcome of transfer of the spinal accessory nerve to the musculocutaneous nerve for restoration of elbow flexion showed that 77% of patients achieved biceps strength of M3 and 29% achieved strength of M4.[139] The results of spinal accessory nerve transfer (with an interpositional graft) versus intercostal nerve transfer (without an interpositional graft) for restoration of M3-strength elbow flexion were comparable (77% vs. 72%), but significantly lower for restoration of M4-strength elbow flexion (29% vs. 41%; $P < .001$).[139]

Ulnar Nerve Fascicular Transfer to the Biceps Motor Branch

In patients with preserved C8-T1 function, transfer of a functioning ulnar nerve motor fascicle for reinnervation of the biceps muscle has gained popularity because of its technical ease and reliability.[161] This technique has largely replaced the use of intercostal nerve transfers for reinnervation of elbow flexion in cases of C5-C6 palsy. It is often done in patients with C5-C6 injury in conjunction with other nerve transfers, such as transfer of the spinal accessory nerve to the suprascapular nerve and the triceps motor branch to the axillary nerve for reconstruction of shoulder function. Some authors have recommended not performing this technique in patients with C5-C7 injury (because the ulnar nerve is formed by C7-T1) because there may be insufficient motor fibers to reinnervate the biceps and maintain strength in the ulnar-innervated muscles. However, we and others have used it in patients with C5-C7 injury and have achieved satisfactory recovery without any sequelae of ulnar nerve weakness.

SURGICAL ANATOMY

The larger of the two terminal branches of the medial cord of the brachial plexus continues as the ulnar nerve, whereas the smaller terminal branch is the medial cord contribution to the median nerve. In the axilla and upper part of the arm, the ulnar nerve runs inferior and medial to the axillary artery. It passes anterior to the triceps muscle and enters the ulnar groove between the medial epicondyle of the humerus and the olecranon. In the upper half of the arm, the ulnar nerve has rich interfascicular connections and 6 to 10 fascicles, each of which contains both motor and sensory nerve fibers. According to Sunderland's intraneural topography,[196] the posteromedial fascicles contain the motor fibers to the forearm muscles and the anterolateral fascicles tend to contain the motor fibers to the intrinsic muscles of the hand.

Dissection and Transfer. Both the musculocutaneous and ulnar nerves are exposed through a longitudinal medial skin incision in the proximal upper part of the arm. The musculocutaneous nerve and its three branches (motor branch to the biceps, motor branch to the brachialis, and lateral antebrachial cutaneous nerve) are identified. After the type of motor branch to the biceps (common or separated branches pattern) is confirmed, the branch is divided sufficiently proximal to be long enough to reach the ulnar nerve (Figures 34.21 and 34.22). The

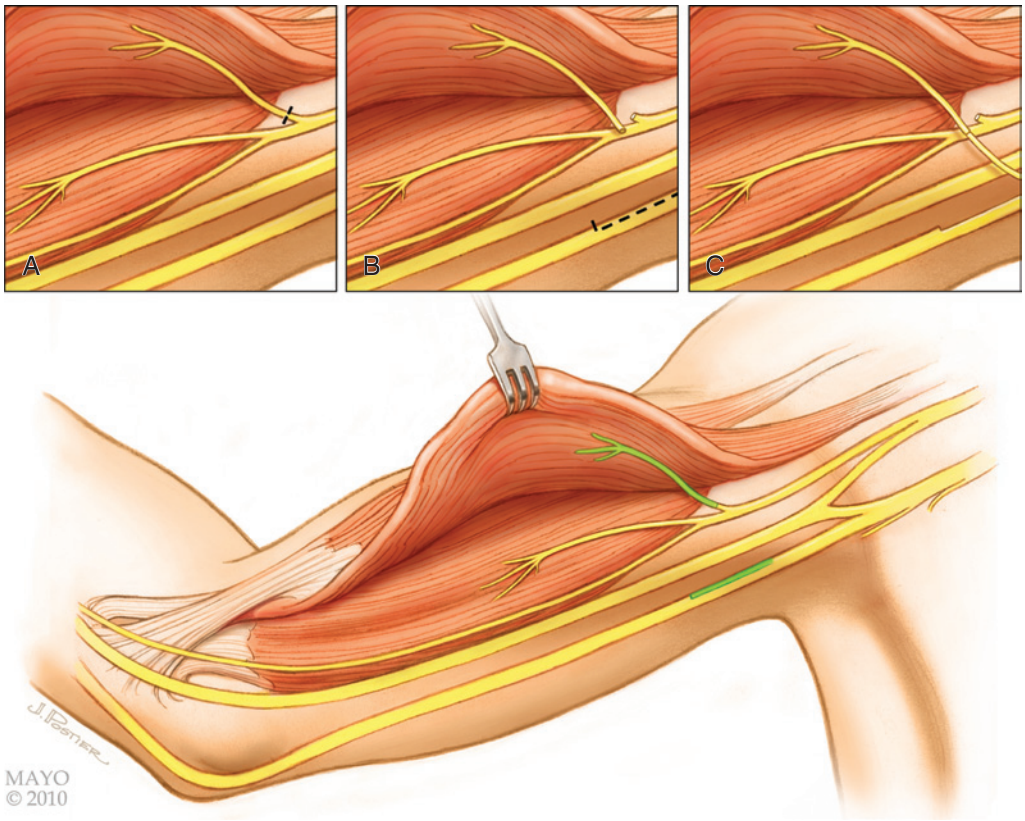

FIGURE 34.21 Ulnar fascicular transfer to the biceps motor branch (Oberlin method). **A,** The biceps motor branch is identified and carefully dissected from the musculocutaneous nerve. **B,** The ulnar nerve undergoes internal neurolysis, and a nerve stimulator is used to choose an appropriately sized fascicle for stimulation of wrist flexion without stimulation of intrinsic hand function. **C,** The ulnar nerve fascicle is divided and transferred under an operative microscope to the biceps motor branch. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

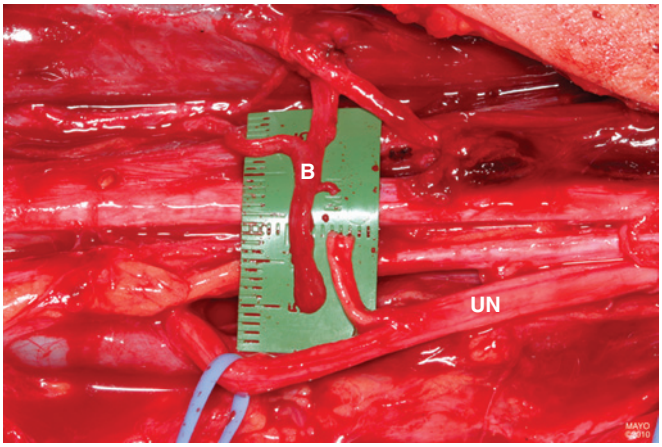

FIGURE 34.22 Operative example of the Oberlin transfer before neurorrhaphy. *B,* Biceps motor common branch; *UN,* ulnar nerve. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

ulnar nerve is identified and intraepineurial dissection is performed under loupe or microscope magnification. The ulnar fascicles are tested with a nerve stimulator, and the fascicles that innervate the flexor carpi ulnaris muscle, generally located posteromedially, are identified. Others that do not use nerve stimulation have not reported complications[115]; the ulnar nerve fascicles at this level are mixed and redundant, and all fascicles contain a mix of motor and sensory nerve fibers. Depending on the size of the motor branch to the biceps, one or two fascicles are selected. These chosen fascicles are transected under magnification and with enough length to approximate to the biceps motor branch without tension. They are coapted to the motor branch with 9-0 or 10-0 nylon epineural suture and reinforced with fibrin glue.

Contraindications. Patients with ulnar nerve distribution weakness and sensory deficit preoperatively are not candidates for this technique.

Complications. Some patients will experience transient numbness in the ulnar nerve distribution postoperatively. These sensory changes will improve over a period of days to months and are rarely permanent. Occasionally, patients will have transient muscle weakness of the ulnar-innervated hand intrinsic muscles. Few permanent deficits have been reported. Most patients gain powerful grip and pinch strength during the postoperative rehabilitation program; it may be better than their preoperative strength. Whether this is due to progressive muscle strengthening exercises or a tincture of time in a patient who is spontaneously recovering is unknown.

Expected Outcomes. Most authors emphasize the quick reinnervation of the biceps muscle after this procedure as an important advantage. Many patients have good recovery of biceps contraction beginning several months after the procedure. More than 90% of patients achieved biceps strength of British Medical Research Council (BMRC) grade 3 or 4 (Figure 34.23)[115]; outcomes are better in patients with C5-C6 patterns of injury than in those with C5-C7 injury.[162]

Median Nerve Fascicular Transfer to the Brachialis Motor Branch

Recently, double-nerve transfer to restore elbow flexion has been described.[125,127] This procedure combines reinnervation of the biceps muscle as described earlier with reinnervation of the brachialis muscle, a second powerful elbow flexor (Figure 34.24). Double neurotization has improved outcomes in some series.[125,127] In patients with C5-C7 injury patterns, single-nerve transfer of a median nerve fascicle may be selected over an ulnar nerve fascicle depending on the distribution of the hand and forearm weakness. As is the case with the ulnar nerve fascicular transfer, some authors have recommended not performing this technique in patients with C5-C7 injury. However, we and others have used it in patients with C5-C7 injury and achieved satisfactory recovery without adverse sequelae. The question of whether a single-nerve transfer versus a double-nerve transfer for elbow flexion is necessary has been the subject of recent publications. Our group compared the torque strength of a single-fascicle versus a double-fascicle nerve transfer to the biceps and brachialis motor branches, respectively.[35] Overall, single-nerve transfers did not outperform double-nerve transfers and the two types of transfers had similar torque strength. In a prospective comparative study, elbow flexion strength did not differ between groups treated with a single-fascicle or double-fascicle transfer.[135] For this reason, the surgeon needs to carefully decide if the second fascicle transfer from the median nerve to the brachialis is necessary in their patients.

FIGURE 34.23 Excellent recovery of biceps bulk and strength after an ulnar nerve fascicular transfer. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Dissection and Transfer. The same medial arm exposure described for the ulnar nerve fascicular transfer is used to expose the median nerve and the brachialis motor branch. As described previously, the musculocutaneous nerve is identified in the proximal part of the arm. The biceps motor branch is seen, and several centimeters more distally, the brachialis motor branch is identified along with the lateral antebrachial cutaneous nerve. Identification of the brachialis motor branch can be confirmed by seeing it enter the muscle. It is distinguished from

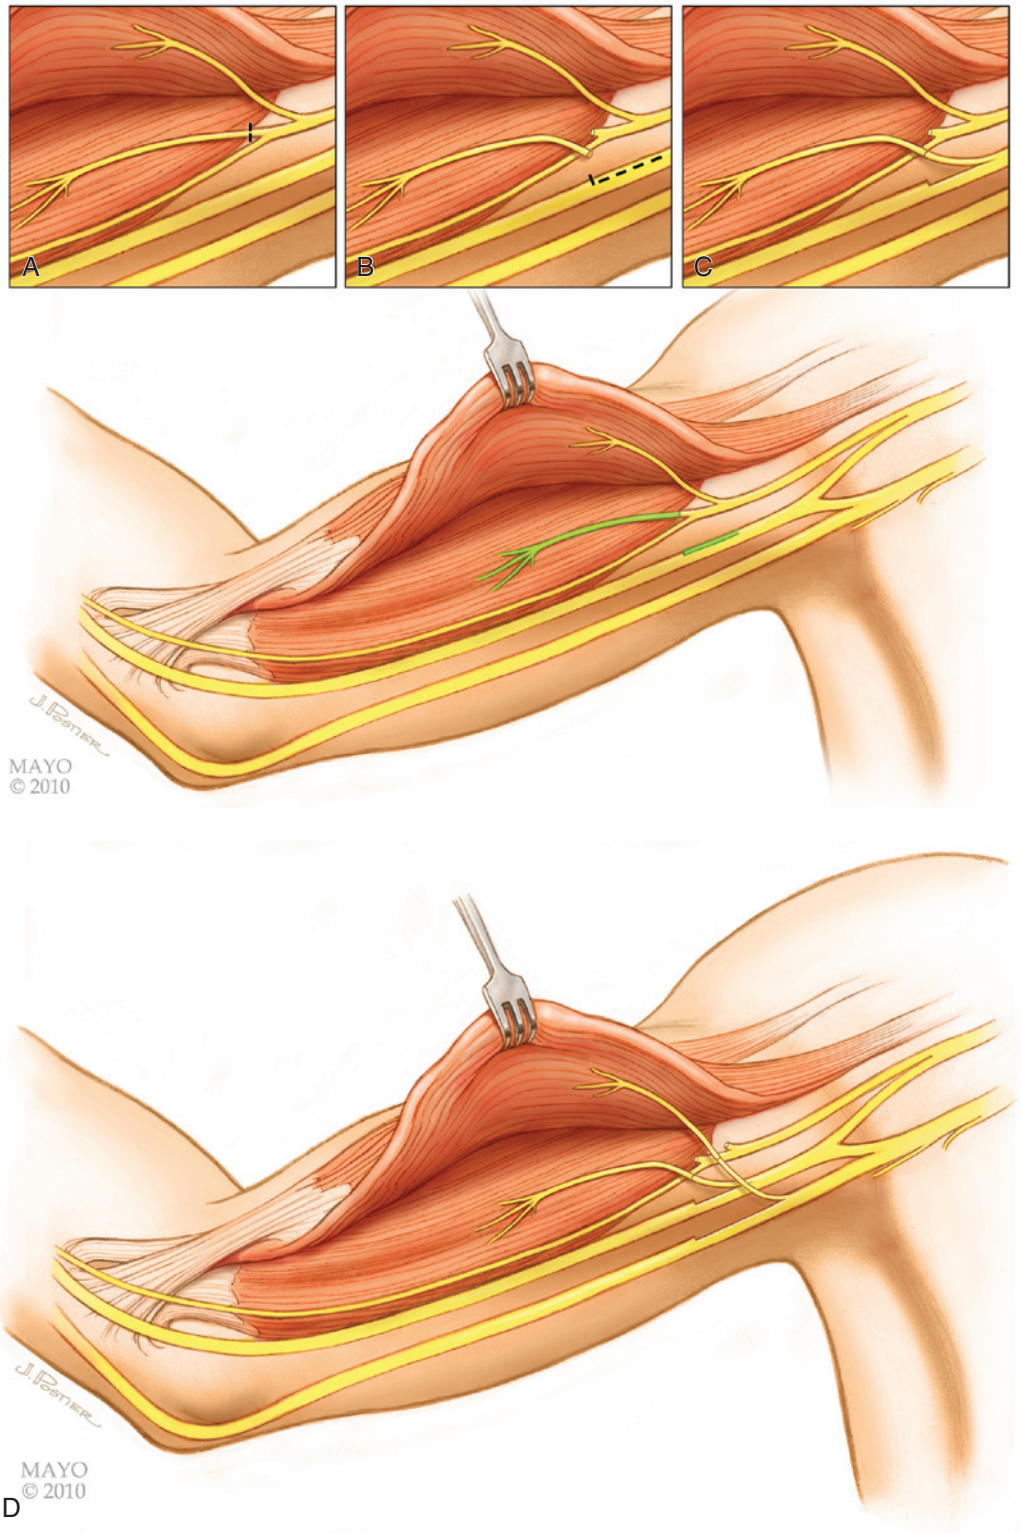

FIGURE 34.24 Median fascicular transfer to the brachialis motor branch. **A,** The brachialis motor branch is identified and carefully dissected from the musculocutaneous nerve. **B,** The median nerve is identified and undergoes internal neurolysis. A nerve stimulator is used to identify an appropriately sized fascicle that stimulates the wrist flexors. **C,** The median nerve fascicle is then transferred to the brachialis motor branch under the operative microscope. **D,** This technique is often done in conjunction with ulnar nerve fascicular transfer to the biceps branch. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

the lateral antebrachial cutaneous nerve, which is larger and runs more superficially; gentle traction on the lateral antebrachial cutaneous nerve will tent the skin in the proximal part of the forearm. The brachialis branch can be dissected proximally up to the common stem, where the biceps branch originates. The median nerve is identified near the brachial artery and vein; it is the largest of the nerves at this level. The nerve is dissected intraepineurially under magnification, and several fascicles are isolated. We prefer to map the nerve with a portable stimulator to identify a fascicle producing wrist flexion (via the flexor carpi radialis). Other groups have used fascicles innervating the flexor digitorum superficialis. The chosen fascicle is dissected over a segment long enough that when it is divided distally, it can be transferred and reach the brachialis motor branch. The nerves are coapted with epineurial 9-0 or 10-0 nylon suture without tension and reinforced with fibrin glue.

Contraindications. Patients with weakness in the median nerve distribution preoperatively are not candidates for this technique.

Complications. As for ulnar nerve fascicular transfers, some patients will experience transient numbness in the median nerve distribution postoperatively that will improve over a period of days to months and is rarely permanent. Occasionally, patients will have transient muscle weakness of the intrinsic hand muscles innervated by the median nerve. Few permanent deficits have been reported.

CRITICAL POINTS *Ulnar and/or Median Nerve Fascicular Transfer*

Indications
- Most commonly used for reconstruction of elbow flexion in patients with C5-C6 injury
- Used occasionally for patients with C5-C7 injury and preserved median and ulnar nerve function
- Ideally done less than 6 to 9 months after injury

Pearls
- Technical ease of the surgery
- Reliable, earlier recovery
- Limited skin incision and less invasive surgery
- Possibly a viable salvage surgery for patients initially seen 9 to 15 months after injury

Technical Points
- Division and transfer to a motor branch of the biceps brachii muscle or brachialis muscle, or both
- Meticulous intraneural dissection of the ulnar and median nerves
- Selection of the fascicles for transfer with the aid of a portable stimulator

Pitfall
- Improper selection of fascicles, leading to transient or permanent ulnar or median nerve deficit

Postoperative Care
- A shoulder immobilizer is maintained for 3 weeks.
- Reinnervation begins 3 to 6 months after surgery.

Intercostal Nerve Transfer

Intercostal nerves have been widely used over several decades for reinnervation of the musculocutaneous nerve,[47,114,142,154] and their application has been extended to reinnervation of the triceps, deltoid, and serratus anterior muscles; an FFMT; and for hand sensation. Historically, transfer to more distal motor targets has been attempted, but the long-term outcomes of these transfers were unreliable and too frequently they were functionless. Currently, intercostal to musculocutaneous nerve transfers are most frequently performed for reconstruction of elbow flexion in patients with pan-plexus injuries, and less commonly for patients with upper brachial plexus injury (C5-C6 or C5-C7). They are likewise used for innervation of the triceps and median sensory reinnervation in the second stage of a double FFMT for prehensile reconstruction (discussed later).

Patients who are being considered for this procedure should be selected with caution if they have a history of rib fracture, thoracotomy, or chest tube placement because there is an incidence of an unusable corresponding intercostal nerve. Although it is possible to use both the sensory and motor components of each intercostal nerve to provide sensory and motor reinnervation,[47,102] motor reinnervation alone is usually the goal of this procedure. In our experience, the third to sixth intercostal nerves have the most length for reaching the musculocutaneous nerve. By extending the dissection anteriorly to the costochondral junction, sufficient intercostal nerve length is gained, which permits direct coaptation to the target motor branch and thus eliminates the need for interpositional nerve grafts. There are anthropomorphic differences between races, and it has been the experience of some authors that direct transfer may be more difficult in caucasian individuals. The second or seventh intercostal nerve can also be used as needed, but adequate length and good positioning for transfer are less reliable for the musculocutaneous nerve. The second intercostal is readily transferred to the long thoracic nerve in patients with C5-C7 injuries and a denervated serratus. Finally, transfer of the first intercostal nerve to the suprascapular nerve was suggested in an anatomic study and case report.[71]

SURGICAL ANATOMY

Intercostal nerves run within the intercostal space along the pleural side of the internal intercostal muscles (Figure 34.25). Posteriorly, these nerves pass between the two layers of intercostal muscles that insert on the posterior thirds of the ribs. Just posterior to the axilla, they enter deep to the intercostal muscles and run anteriorly between the transverse thoracic muscles and the endothoracic aponeurosis. The lateral cutaneous branch pierces the intercostal muscle toward the skin and divides into a dorsal and a ventral branch. The anterior cutaneous branch pierces the pectoralis major close to the sternum and ramifies into the skin.

Intercostal Nerve Dissection. The third to sixth intercostal nerves are explored through an inframammary incision extending from the midaxillary line to the costochondral junction (Figure 34.26). This incision typically connects with the proximal arm incision used for exposure of the musculocutaneous nerve. Other groups are using different incisions, such as a vertical one in the anterior axillary line or a shorter transverse one on the chest, with tunneling of the intercostal nerves; we have found that with the classic inframammary incision we can achieve dissection of multiple intercostal nerves of adequate length. The subcutaneous tissue and underlying pectoralis major and minor muscles are elevated from their distal

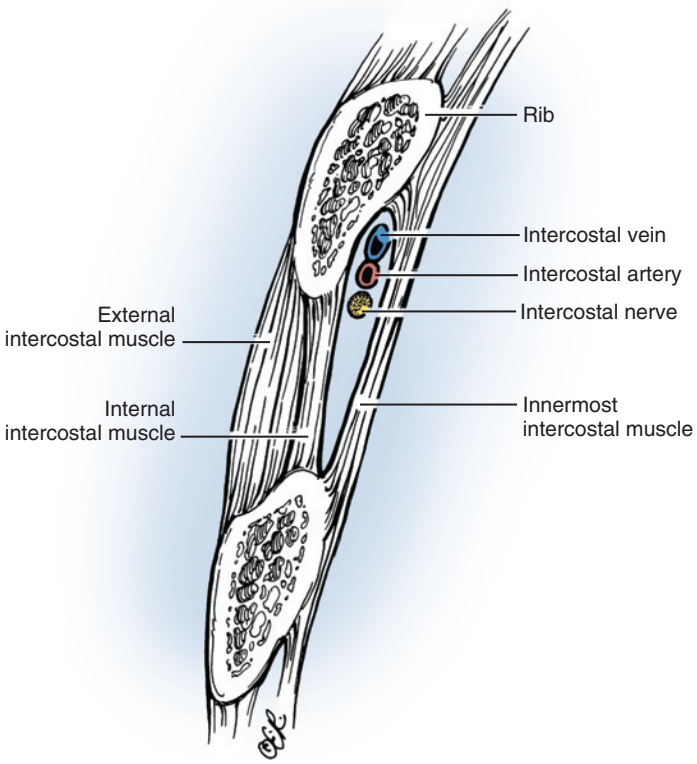

FIGURE 34.25 Anatomy of the intercostal nerve. (Copyright © Elizabeth Martin.)

insertions so that the muscles themselves are not injured. In the axillary region, the intercostobrachial nerve, a large branch of the second intercostal nerve, is identified and protected. Care should be taken to not injure this nerve, because it may be used as a donor nerve for sensory restoration of the hand. The anterior surfaces of the selected ribs, as well as their intercostal musculature, are exposed. When the serratus anterior muscle is functional, it should be preserved with its nerve supply; the long thoracic nerve is found on the chest wall coursing down posterior to the midaxillary line along with the thoracodorsal vessels. The anterior surface of each rib is incised and the periosteum is circumferentially elevated while great care is taken not to injure the underlying pleura. We prefer to mobilize the rib with a periosteal elevator, place an umbilical tape around it, and with the help of an assistant elevating the rib, identify and dissect the intercostal nerve. We do not perform osteotomy of the rib or partial rib resection as is occasionally done by others. The intercostal nerve is identified by carefully incising the periosteal sleeve of the rib in the midclavicular line. This incision is performed at the caudal border of the rib where the motor intercostal nerve is located. The motor intercostal nerve can also be identified by tracing the lateral sensory branch proximally, if it was previously identified, or by finding the flash of bleeding from the intercostal artery and vein, which are in close proximity to the nerve. Electrical stimulation can be used to confirm the motor branch. When identified, the nerve is

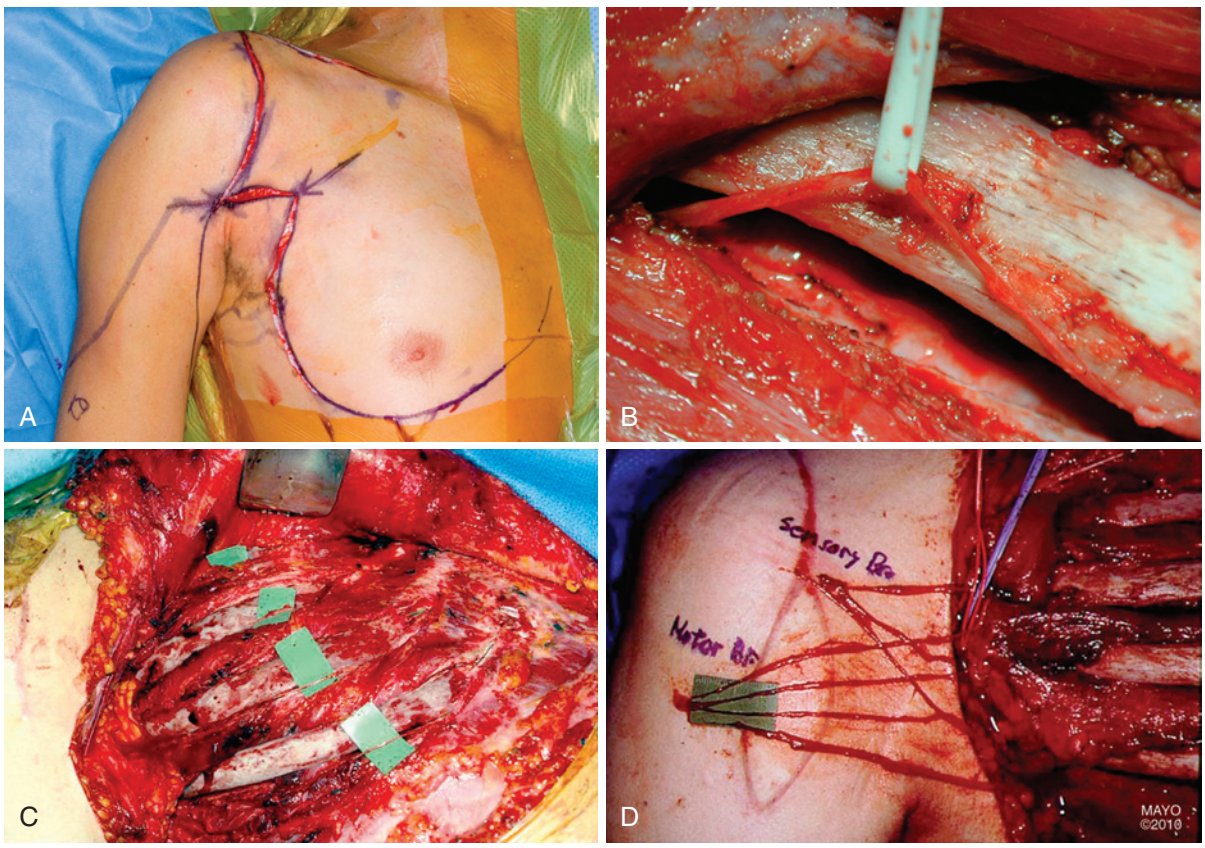

FIGURE 34.26 Intercostal nerve harvesting. **A,** Inframammary incision. **B,** Close-up of intercostal nerve exposure. **C,** Full-field view after harvesting several intercostal nerves from the costochondral junction to the mid-axillary line. **D,** Sensory and motor intercostal nerves destined for targeted sensory and motor nerve transfer, respectively. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

mobilized in a vessel loop and dissected. The motor branch is traced anteriorly toward the costochondral junction by gentle spreading of the intercostal muscles to gain the required length to reach the target nerves. The nerve is dissected to the midaxillary or posterior axillary line posteriorly. The lateral cutaneous sensory branch of the nerve (larger than the motor nerve) is found at a point between the anterior and midaxillary lines; it may be separated from the motor component as far posteriorly as necessary. Care is taken to open the rib periosteum posteriorly and inferiorly so that it will not compress the nerve once it is reflected for transfer. The technique is repeated for harvesting the other intercostal nerves required for reconstruction. After appropriate dissection, each intercostal nerve is transected distally and passed through the serratus anterior muscle into the axillary region. Pleural tear and air leak should be noted and treated either by pleural repair, tight skin closure, or placement of a chest tube, depending on the extent of the tear or leak.

Transfer to the Musculocutaneous Nerve. When intercostal nerves are used for restoration of elbow flexion, three or four intercostal nerves are generally coapted to the musculocutaneous nerve; an alternative is to transfer two to three intercostal nerves directly to the biceps motor branch (Figure 34.27). To accomplish the nerve transfer, dissection of the musculocutaneous nerve is performed as described in a previous section. Special care is taken when dissecting the motor branch to the biceps, occasionally with the brachialis motor branch, proximally toward its branching from the lateral cord to separate the motor (biceps and brachialis motor branch) and sensory (lateral antebrachial cutaneous nerve) portions of the musculocutaneous nerve as far proximally as possible. This technique will maximize the number of motor fibers and minimize the number of sensory fibers that will be targeted by the transfer. Moreover, it will provide a biceps (with or without the brachialis) motor branch with enough length to reach the transferred intercostal nerves without any tension and without the use of intervening nerve grafts. This retrograde dissection of the musculocutaneous nerve should be done carefully, and one should err on cutting on the lateral antebrachial cutaneous portion of the musculocutaneous nerve so that the biceps motor branch portion of the nerve is not injured or thinned. If the length of the biceps motor branch is insufficient for direct transfer, we prefer to perform the intercostal nerve transfer into the musculocutaneous nerve itself. We always try to perform a direct intercostal nerve transfer (i.e., without the use of interpositional grafts) because of the improved outcomes with this technique, even if this translates into the use of an intercostal nerve that has been transected distally. Others, knowing that the intercostal nerves have more motor axons in their proximal parts, prefer to use the more proximal portion of the intercostal nerves (e.g., just distal to the lateral sensory branches). Transferring intercostal nerves requires balancing use of the proximal intercostal nerve (more motor axons) and performing direct transfers without the use of intervening nerve grafts (better outcomes). The nerve repair is done with the arm abducted and externally rotated to ensure that these motions will not lead to undue tension on the coaptation site.

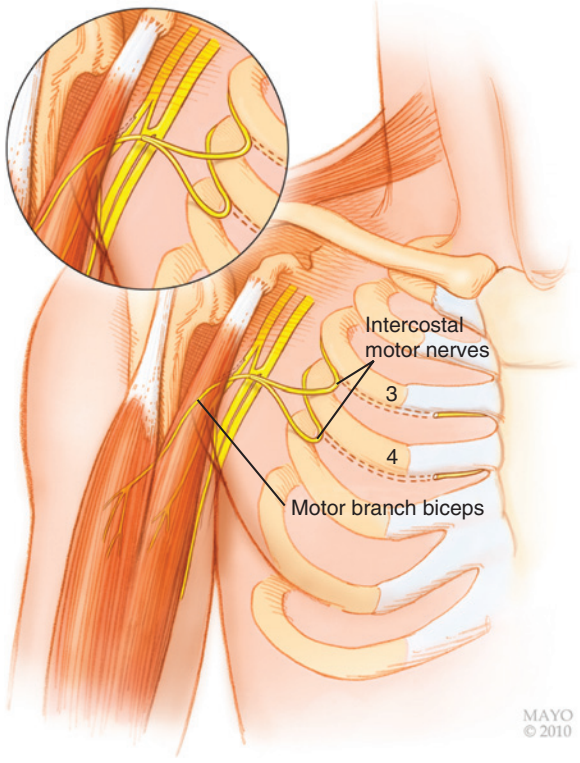

FIGURE 34.27 Intercostal neurotization (T3-T4) of the biceps branch of the musculocutaneous nerve. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Postoperative Care Specific to Intercostal Nerve to Musculocutaneous Nerve Transfer. An early sign of reinnervation is the presence of chest pain when the biceps is pinched (positive squeeze test); this sign may be apparent 4 to 5 months postoperatively. Proximal biceps contraction without elbow joint movement, especially during deep inspiration, is usually recognized by 6 to 8 months postoperatively. With further reinnervation, distal biceps contraction without elbow joint movement is seen and a Tinel sign may appear in the distal part of the arm, lateral to the biceps tendon. Percussion of this area causes tingling in the chest; it develops around 12 months postoperatively. Elbow flexion against gravity generally appears 12 to 18 months after surgery, and voluntary flexion against resistance is recovered gradually.[47]

A relationship between elbow movement and respiration is observed for 4 to 8 months after motor recovery, and volitional small action potentials synchronized with respiratory movement are noted. After 12 months, patients learn to flex the joint voluntarily without relating it to their respiratory rhythm. Twenty-four months after surgery, the respiratory rhythm will still affect the interval of spiked discharges on EMG, but after 32 months, biceps activity is completely distinct from the respiratory cycle. Involuntary muscle contractions continue to occur when the patient coughs or sneezes.[154] Some authors recommend aerobic conditioning programs with deep inspiration exercises (treadmill, stationary bike, abdominal "crunches") to expedite recovery in the postoperative period, although no definitive studies are available.

Contraindications. Patients with a history of chest trauma, rib fractures, or phrenic nerve dysfunction can still be candidates for intercostal nerve transfer. However, both the surgeon and the patient should be aware that rib fractures are associated with

CRITICAL POINTS *Intercostal Nerve Transfer to the Musculocutaneous Nerve*

Indications
- Most commonly performed in patients with complete brachial plexus injuries; also C5-C6, C5-C7
- Ideally done less than 6 to 9 months after injury

Pearls
- This procedure is reliable in achieving elbow flexion in the hands of an experienced surgeon.
- Distal dissection of the intercostal nerve to the costochondral junction and proximal dissection of the biceps motor branch will allow direct nerve transfer without an intervening nerve graft.

Technical Points
- Expose the third to sixth intercostal nerves through an inframammary incision.
- Each intercostal nerve dissection and transfer is done without osteotomy of the ribs.
- Proximal dissection of the motor nerve to the biceps (to separate it from the musculocutaneous nerve) is performed.
- Direct neurorrhaphy of the intercostal nerves without tension provides a better outcome.
- The repair is done with the arm maximally externally rotated and abducted 90 degrees.

Pitfalls
- Pleural tear
- Technically demanding
- Separation of the nerve repair when neurorrhaphy is performed under tension

Postoperative Care
- Shoulder immobilization is maintained for 3 weeks.
- Gradual increases in shoulder range of motion are made to avoid tension on the repairs.
- Reinnervation starts approximately 6 to 9 months postoperatively.

a 10% chance of the associated intercostal nerve not being functional. Moreover, preoperative pulmonary function tests may be useful to assess respiratory reserve, especially in patients with concomitant phrenic nerve dysfunction; very rarely do low pulmonary function test results prevent use of the intercostals.

Complications. Intercostal nerve harvesting can generally be performed safely. Pleural effusion and acute respiratory distress syndrome are rare. Pulmonary function normalizes by 3 months.[42] Lack of tension at the coaptation site and proper positioning of the shoulder are imperative to prevent rupture of the nerve repair and subsequent failure of the transfer.

Expected Outcomes. Intercostal to musculocutaneous nerve transfers without interposition grafts for restoration of elbow flexion achieve strength of at least M3 in 72% of patients. If interpositional nerve grafts are used, only 47% of patients will achieve strength of M3 or better. A metaanalysis did not show significant differences in outcome with the transfer of two or three to four intercostal nerves without an intervening graft, but the analysis lacked sufficient power.[139] The time interval between the trauma and the reconstructive surgery and the age of the patient may influence the outcome.[47,154]

Transfer of the Triceps Motor Branch to the Axillary Nerve

This nerve transfer has been widely accepted (Figures 34.28 and 34.29) and used for patients with strong triceps function (usually isolated C5-C6 injuries) in an effort to provide dual muscular reinnervation for the shoulder.

Dissection and Transfer. A longitudinal incision is made on the posterior aspect of the arm from the acromion to the midarm region. The deltoid is retracted superiorly. The axillary nerve is identified in the quadrilateral space. It is useful to identify and trace the axillary sensory branch back toward the quadrilateral space to help identify the main nerve. The anterior division of the axillary nerve is selectively targeted. It is dissected toward the quadrilateral space and transected as far proximally as possible. Depending on the size match, the axillary nerve proper is occasionally reinnervated by one or more triceps motor branches; more commonly, we perform reinnervation of only the anterior division of the axillary nerve. A theoretical rationale for targeting the entire nerve is to simultaneously reinnervate the teres minor muscle, which may improve strength of external rotation.[18]

Next, the interval between the long and lateral heads of the triceps is deepened to expose the radial nerve and its branches to the three heads of the triceps. We typically select the triceps long head motor branch, as originally described by Leechavengvongs and colleagues,[116] and confirm its identity and functionality with stimulation. The chosen triceps motor branch is mobilized proximally and distally, including all subbranches to the muscle. One should determine how long the triceps branch needs to be to reach the anterior division of the axillary nerve before distal transection of this branch. If needed, release of the teres major fascia is performed to increase proximal mobilization of the motor branch. Direct repair can then be accomplished without tension. Some have recommended the use of different triceps branches; there is no agreement on the importance of each triceps head, and triceps weakness is rare regardless of the branch used, provided that the triceps muscle was of normal strength preoperatively.

Contraindications. Patients with triceps weakness preoperatively (BMRC grade < 4) are not candidates for this technique. Differential EMG studies of all three heads can be helpful for decision making, particularly in patients with a partial C7 injury.

Complications. Immediately postoperatively, patients may have some transient triceps weakness. This weakness typically seems to be related more to lack of effort, pain, or fear than to a new neurologic deficit. We have not observed new triceps weakness on physical examination at the first postoperative visit.

Expected Outcomes. Deltoid contraction is often noticeable by 6 months (Figure 34.30). Leechavengvongs and coauthors reported a 124-degree arc of motion in patients with concomitant transfer of the spinal accessory nerve to the suprascapular nerve.[116] The operative results in patients with C5 and C6 avulsions were better than those in patients with C5, C6, and C7 avulsions. The outcome of our isolated axillary nerve injuries treated with this transfer resulted in a BMRC grade that averaged 3.5 ± 1.1. Deltoid muscle strength correlated with the age of the patient, delay from injury to surgery, and body mass index of the patient. In the multiple linear regression model, the delay from injury to surgery, age of the patient, and body

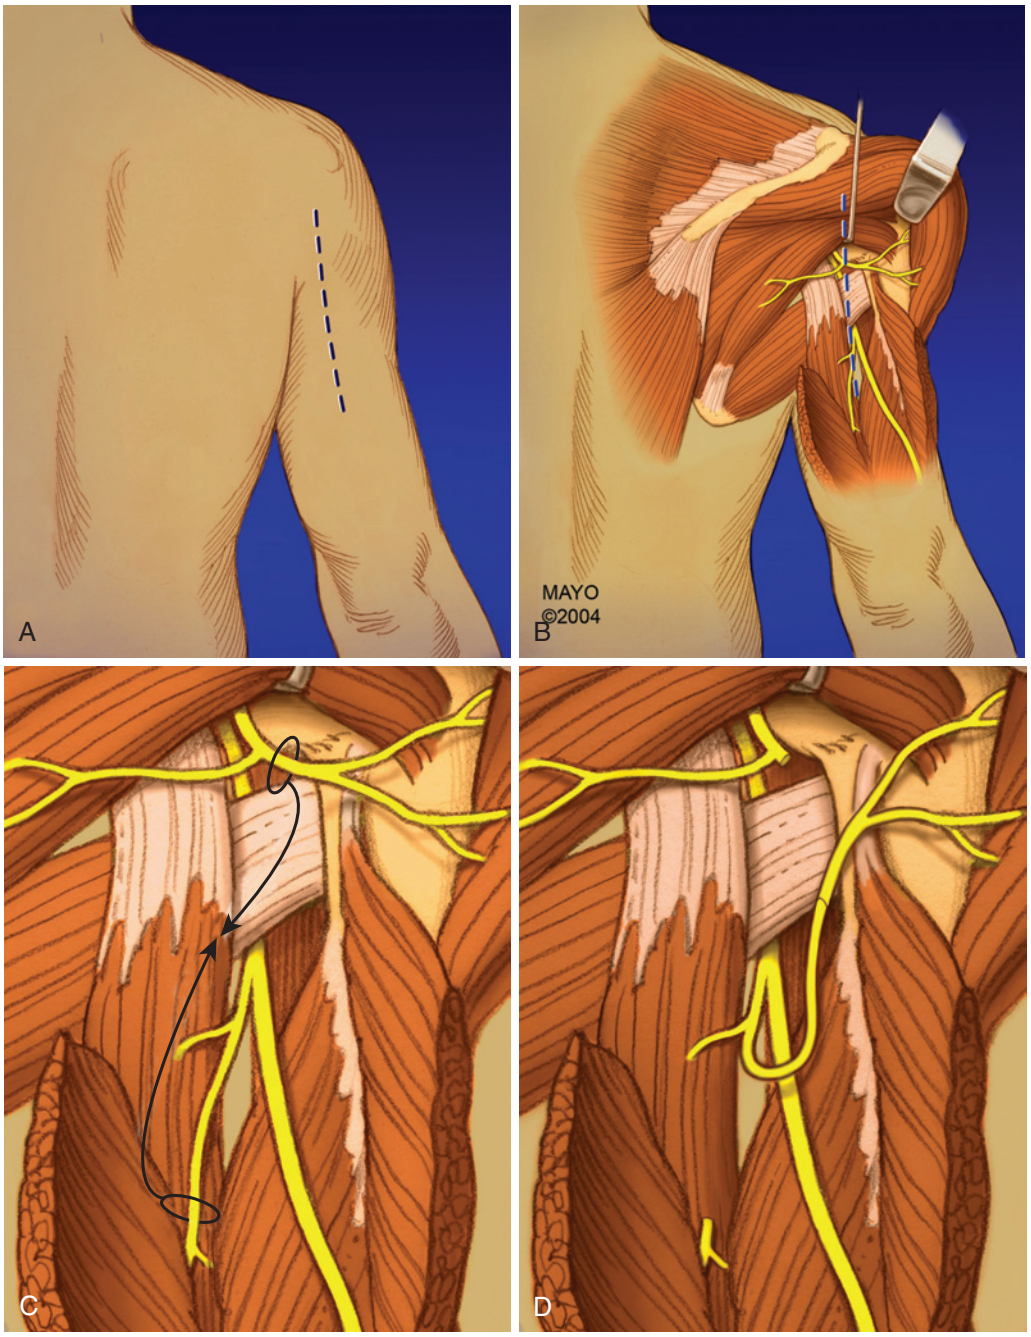

FIGURE 34.28 Transfer of the right triceps branch to the axillary nerve (Leechavengvongs procedure). **A,** Skin incision. **B,** Identification of the axillary nerve in the quadrilateral space and the radial nerve and triceps branches in the triangular interval. **C,** The long head triceps motor branch is selected and transferred to the anterior division of the axillary nerve. **D,** Direct nerve repair without tension. mass index of the patient were the important factors, in that order, that affected the outcome of this procedure.[120]

Contralateral C7 Nerve Transfer

Contralateral C7 nerve transfer remains a controversial option with three potential issues: (1) whether it can be done safely, (2) whether it works well enough to justify the risk, and (3) whether independent function can be relearned in adults. Some surgeons have difficulty accepting that this normal nerve can generally be transected and transferred without any neurologic sequelae. Based on a large clinical experience in Asia over a period of several decades, the safety and efficacy of this procedure have become accepted by many. It has been used as a donor nerve for shoulder, elbow, and hand targets (Figure 34.31) and in some cases as a donor for an FFMT with variable reported outcomes. The ability of adult patients to learn independent function is also unknown. When transfer of the contralateral C7 nerve is being considered, the risks associated with the procedure must be carefully weighed against its potential benefit.

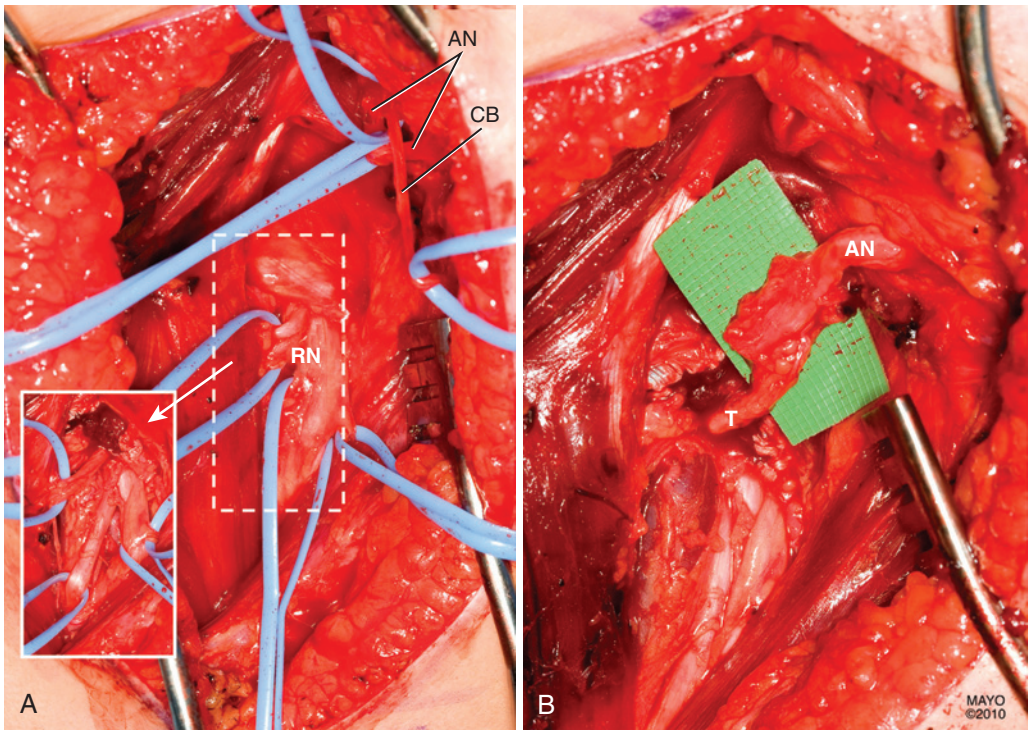

FIGURE 34.29 Transfer of the right triceps branch to the axillary nerve (Leechavengvongs procedure). **A,** The axillary nerve (AN), radial nerve (RN), and triceps branches have been identified (*inset*). Note the cutaneous branch (CB) of the axillary nerve. **B,** The long head triceps motor branch (T) has been transected distally and is about to be coapted to the anterior division of the axillary nerve (AN). (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

CRITICAL POINTS *Transfer of the Triceps Motor Branch to the Axillary Nerve*

Indications
- Most commonly for patients with C5-C6 injuries
- Patients with a C5-C7 pattern if triceps strength is good
- Ideally done for injuries incurred less than 6 to 9 months earlier

Pearls
- Avoid the temptation of selecting too small a triceps nerve branch (inadequate size match).
- The sensory cutaneous branch of the axillary nerve can be followed to help identify the axillary nerve.
- Sufficient mobilization allows direct coaptation of the triceps branch and anterior division of the axillary nerve without a nerve graft.

Technical Points
- Use a posterior arm skin incision below the deltoid to the midarm region.
- Transfer a large enough triceps motor branch (one or two) to achieve an adequate size match.
- Perform direct (without graft) coaptation to the anterior division of the axillary nerve.

Pitfall
- Less favorable outcomes in patients with C5-C8 injury or triceps weakness of less than BMRC grade 4 preoperatively

Postoperative Care
- Shoulder immobilization is maintained for 3 weeks.
- EMG-documented reinnervation occurs by 6 months postoperatively.

FIGURE 34.30 This 12-year-old boy underwent a right triceps motor branch transfer for an isolated axillary nerve lesion after initially being seen 12 months earlier. At 10 months postoperatively he had already demonstrated good bulk in the deltoid and a full arc of abduction. Note the healed incision. FIGURE 34.32 Vascular anatomy of the ulnar nerve. (Copyright © Elizabeth Martin.)

SURGICAL ANATOMY

Although anatomic variability exists, the supraclavicular plexus usually receives contributions from five spinal nerves: C5, C6, C7, C8, and T1. It is important to realize that each spinal nerve generally sends axons to more than one major nerve and, in turn, each major nerve contains axons from more than one spinal nerve. Accordingly, muscles in the upper limb are often innervated by multiple nerves. Although the C7 spinal nerve contributes to the posterior cord as well as to the median, musculocutaneous, and even ulnar nerves, C7-innervated muscles are cross-innervated by other spinal nerves, primarily C6 and C8. Because isolated C7 division does not result in significant loss of any individual muscle function, both the ipsilateral and contralateral C7 nerve roots are a potential transferable source of axons.[90] The posterior portion of C7 contains more motor fibers than the anterior portion does. Both the entire nerve and half of the C7 nerve (the latter procedure done to minimize risk) have been harvested with similar, albeit transient, deficits.

Contralateral C7 Nerve Dissection and Transfer. When contralateral C7 nerve transfer is planned, the contralateral neck and shoulder should be prepared and draped. The contralateral "normal" plexus is exposed as described earlier. Many groups routinely expose all five nerves of the brachial plexus to determine its anatomic configuration and the contribution of each spinal nerve. The contralateral C7 nerve is identified. It may be divided into two portions at the level of the middle trunk or dissected distally to its anterior and posterior divisions. The motor function produced by the nerve is evaluated with a nerve stimulator. If the entire contralateral C7 nerve is being used as a transfer, elbow and wrist extension with C7 nerve stimulation is evaluated before its division. Recognizing the potential devastating effects of permanent weakness in the one remaining normal upper limb, we believe that if stimulation of C7 produces any contraction of hand muscles, its use is contraindicated. The nerve is transected distally at the level of the middle trunk or at the anterior and posterior divisions. When half of the contralateral C7 is transferred, the half producing maximal pectoralis major contraction is selected and transected distally. A subcutaneous tunnel is prepared in the upper chest region that leads to the skin incision in the ipsilateral brachial plexus. A prespinal[210] or intraspinal (from a separate posterior exposure) route can shorten the distance for subsequent regeneration in comparison with the subcutaneous route.

If the contralateral C7 nerve is used to neurotize the median nerve in a patient with a pan-plexus injury, the ipsilateral ulnar nerve can be used as pedicled graft based on the superior ulnar collateral (SUC) vessels to eliminate the need for vascular anastomosis (Figure 34.32). The SUC artery arises from the medial surface of the brachial artery at the midhumeral level, 14 to 22 cm proximal to the medial epicondyle of the humerus. It pierces the medial intermuscular septum, courses distally posterior to it, and joins the ulnar nerve on its posterior surface. The artery accompanies the ulnar nerve for 4 to 15 cm and gives rise to an average of three arteriae nervorum, which pass directly into the nerve. The SUC artery descends between the medial epicondyle and the olecranon. It ends deep to the flexor carpi ulnaris muscle by anastomosing with the posterior ulnar recurrent artery and the inferior ulnar collateral artery. Venae comitantes accompany the SUC artery and terminate in the venae comitantes of the brachial artery.

If the ulnar nerve is to be used as a pedicled vascularized nerve graft, its distal end is cut at the wrist and mobilized in its full length to the level of the SUC by dividing the dorsal cutaneous branch as well as the motor branches to the extrinsic finger and wrist flexors (Figure 34.33). The distal stump is passed under the skin of the upper part of the chest to the exposed contralateral (entire or hemi) C7 nerve. Bleeding should be seen from the end of the vascularized nerve. The C7 nerve is matched and coapted to the distal end of the ulnar nerve. The proximal end of the ulnar nerve is divided proximal to the SUC at a level that allows direct connection to the target nerve, such as the median nerve in the proximal part of the arm. When a vascularized ulnar nerve is not used in cases of C5 to C8 root avulsion or in cases of distal ulnar nerve injury, a vascularized superficial radial nerve or sural nerve graft can be used. For shoulder targets, some groups have recommended using the ulnar nerve as a free vascularized nerve graft. In this case, the proximal end of the ulnar nerve is connected to the contralateral C7 nerve first, and the SUC artery and vein are anastomosed to locally available vessels such as the ipsilateral thoracodorsal trunk or

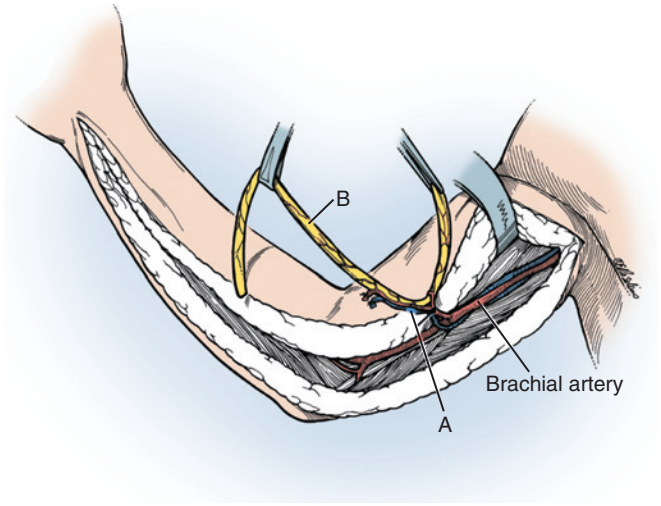

FIGURE 34.33 A vascularized ulnar nerve graft with a pedicle containing the superior ulnar collateral artery and vein. *A* points to the segmental vascular pedicle, and *B* points to the longitudinal vascularity. (Copyright © Elizabeth Martin.)

the contralateral transverse cervical artery and vein. The distal end of the ulnar nerve is passed into the subcutaneous tunnel in the upper chest region and connected to the target nerve in the supraclavicular or infraclavicular region, such as the suprascapular nerve or the posterior cord. Other groups have used two conventional sural nerve grafts to connect the hemicontralateral C7 nerve to the shoulder targets.

Postoperative Care Specific to Contralateral C7 Nerve Transfer. For the first 3 weeks postoperatively, the ipsilateral upper limb is immobilized. Over time, regeneration into the repaired nerve can be traced by an advancing Tinel sign. Because of the long distance to target muscles, reinnervation may take several years. After reinnervation, reeducation of the targeted muscle or muscles with EMG biofeedback techniques is started. Usually, muscles reinnervated by the contralateral C7 nerve can be activated by adducting, internally rotating, and extending the contralateral shoulder and by extending the contralateral elbow. A rehabilitation protocol for muscle strengthening is then initiated so that patients can try to learn to activate the muscle without assistance of the contralateral limb.

Complications. Immediately after surgery, temporary motor deficits can occur in shoulder extension and adduction, elbow extension, forearm pronation, wrist extension, and hand movement. Latissimus dorsi weakness can often be detected. Full functional recovery is usually documented within 6 months, and no long-term functional deficits have been reported in the literature.[90,186] Sensory abnormalities in the C7 distribution are expected in all patients undergoing contralateral C7 transfer[123,197] and may resolve after a few months or persist.

When an anatomic variation is present, such as a prefixed plexus with a significant C4 contribution or a postfixed plexus with a substantial T2 contribution (and a diminished C5 component), considerable deficits can occur after C7 transfer. Millesi suggested that preliminary ligation of the C7 nerve with subsequent patient evaluation, before division (at a subsequent stage), prevents this complication.[140] Others recommend exploration of all five nerves and examination for the existence of a prefixed or postfixed plexus by identification of normal anatomic relationships and intraoperative use of electrical nerve stimulation.

The other potential complication is the development of severe neuropathic pain from division of the contralateral, normal C7 nerve. This problem has been particularly noted by surgeons in Europe and appears to be much less common in Asian patients.

If contralateral C7 nerve transfer is being considered, informed consent should be obtained; the complications and expected benefits of this procedure should be exhaustively discussed with the patient and family before a decision is made. Despite reports of minimal complications in the literature, the possibility of complications in the contralateral donor arm exists. Contralateral C7 transfer should not be undertaken without a thorough understanding of the potential risks and complications associated with this procedure.

Expected Outcomes. Despite many authors recommending contralateral C7 nerve transfer to the median nerve, our outcomes have been disappointing, and patients achieve only minimal recovery of forearm motor strength, far from functional recovery.[90,186] Other authors have recommended using the contralateral C7 to neurotize the suprascapular nerve or posterior cord or musculocutaneous nerve because of a better functional outcome.

❖ AUTHORS' PREFERRED TECHNIQUE

Because of other options for achieving hand prehension and our poor results with this technique, we have abandoned the use of hemicontralateral C7 transfer, which was performed in more than 50 adults at our institution.[174] We still occasionally perform a contralateral C7 nerve transfer in children with pan-plexal injuries acquired at birth or caused by trauma.

Other Nerve Transfers

Other intraplexal and extraplexal sources of nerve transfer have been introduced or are being investigated in an attempt to expand the available donors for primary nerve reconstruction in patients with brachial plexus injury. These transfers are less commonly used than the ones described earlier and will be discussed only briefly. In patients with partial brachial plexus injuries, intraplexal sources include the ipsilateral C7, medial pectoral, and thoracodorsal nerves; in patients with pan-plexus injuries, extraplexal sources include the phrenic, hypoglossal, platysma motor branch, and cervical plexus nerves, which are also available in patients with partial injuries. The use of a more "aggressive" approach to nerve transfer allows the reconstruction of additional targets, the reconstruction of more distal targets, and the possibility of improving outcomes. However, these transfers are still controversial because of different opinions on their risk-benefit ratio and functional outcome.

Intraplexal Nerve Transfers

Ipsilateral C7 Nerve Transfer. In patients with C5-C6 brachial plexus injury, transfer of a portion (anterior division) or the whole ipsilateral C7 nerve has been suggested and used by some groups.[89] Use of the ipsilateral C7 nerve is an extension of the contralateral C7 transfer as described previously.

Medial Pectoral Nerve Transfer. Transferring the medial pectoral nerve to reinnervate brachial plexus elements is not a novel technique but remains controversial. Several authors have advocated use of the medial pectoral nerve for upper-pattern

avulsion injuries to reinnervate the musculocutaneous or axillary nerve, or an isolated long thoracic nerve, with good success. Other authors do not recommend its use and instead prefer to use available alternative nerve transfers and to preserve the innervation of the pectoralis muscles for shoulder adduction. Because there are typically several large branches of the medial pectoral nerve, it is possible to use one branch while maintaining innervation of the pectoralis sternal head. The muscle is synergistic to shoulder abduction, and transfers to the axillary nerve have been reported with success.

Thoracodorsal Nerve Transfer. The thoracodorsal nerve, which innervates the latissimus dorsi, has been proposed and used by some as a donor nerve for transfer. It originates from the posterior cord and receives nerve fibers from the seventh, eighth, and sometimes sixth cervical nerves. It has been used to neurotize the long thoracic nerve,[206] as well as the musculocutaneous and axillary nerves.[173] The better functional outcomes obtained after nerve reconstruction in patients with preserved serratus anterior function suggest that reinnervation of the serratus anterior may be beneficial. Generally, sufficient length can be obtained (8 to 19 cm) for tension-free direct coaptation with all target nerves.

Extraplexal Nerve Transfers

Phrenic Nerve Transfer. The phrenic nerve, located directly within the surgical field of the supraclavicular plexus, is an attractive source for nerve transfer. Because of its C3 and C4 contributions, it is often functional even in cases of complete brachial plexus avulsion. The phrenic nerve has been used to neurotize the suprascapular, musculocutaneous, and axillary nerves; excellent results have been achieved by several Asian and European groups.[91,126,198] The techniques used include (1) supraclavicular harvesting with direct coaptation (e.g., suprascapular nerve neurotization), (2) supraclavicular harvesting with the use of intervening nerve grafts (e.g., musculocutaneous or axillary nerve neurotization), and (3) harvesting via a video-assisted thoracic surgery approach[212] in which a longer phrenic nerve is obtained, one that can be directly transferred to the musculocutaneous nerve without an intervening nerve graft or extended with an interpositional graft to the median nerve.[213]

Despite good results obtained by certain groups,[91,126,198] many surgeons have been reluctant to sacrifice the phrenic nerve because of the potential consequences of hemidiaphragm paralysis. The literature reports a 10% initial decrease in vital capacity and pulmonary function test results with few subjective symptoms, which return to baseline within 6 to 24 months. Long-term data are only beginning to emerge. Most studies have included young, thin, Asian patients, and extrapolation of the pulmonary risks to older, heavier patients, for example, is difficult. Our group has used the phrenic nerve as a transfer in 10 patients but stopped after the occurrence of serious but transient postoperative respiratory difficulties in one patient and lack of normalization of pulmonary function test values after 2 years in several others.

Hypoglossal Nerve Transfer. The hypoglossal nerve, commonly used to neurotize the facial nerve, has been suggested as a possible donor nerve for neurotization of brachial plexus elements. Both hemihypoglossal transfers and complete hypoglossal nerve transfers (with the use of an intervening nerve graft) have been attempted in small series with disappointing results.[78,130] A few patients (complete hypoglossal nerve transfer) had morbidity related to the donor site, but despite tongue movement–related EMG activity in target muscles, only a few patients with a complete hypoglossal transfer achieved muscle strength of grade 3 or better. Regardless of the degree of reinnervation, no patient regained voluntary control of the reinnervated muscle. A single patient who underwent hemihypoglossal transfer to the musculocutaneous nerve has been reported to have independent BMRC grade 4 elbow flexion at long-term (8 years) follow-up.[17] Because of the largely poor results reported in the literature, hypoglossal nerve transfer is typically not an option for reconstruction of brachial plexus injuries.

Platysma Motor Branch Transfer. A recent anatomic study and case report proposed the platysma motor branch (from the facial nerve) as a nerve donor.[17] In this single case, the motor branch of the platysma was used to neurotize the pectoralis major muscle with an intervening nerve graft. There was no deficit noted in platysma (lip depressor) function, probably because of supplementary innervation from the cervical plexus, and the patient regained shoulder adduction strength of M4. Further studies are needed, but use of the platysma motor branch seems promising because it is an expendable nerve, it can be sectioned without deficit, and relearning of motor control can be achieved.

Transfer of Cervical Plexus Nerves. Cervical plexus anterior nerves have been proposed for neurotization of elements of the brachial plexus.[32] However, many surgeons consider the cervical plexus nerves to be predominantly sensory nerves and therefore not useful for motor neurotization.

Postoperative Care for Nerve Grafts and Nerve Transfers

In the immediate postoperative period after nerve repairs, our preference is to maintain the limb in a shoulder immobilizer for 3 weeks to allow strengthening of the nerve repair. However, others do not immobilize the limb. In all patients, physiotherapy is restarted after this period (3 weeks), with attention initially directed toward maintaining passive movement of all joints in the affected upper extremity. Follow-up is performed at regular intervals for a minimum of 2 to 3 years (preferably 5 years). When early clinical or electrophysiologic signs of motor reinnervation appear, active muscle exercises are started. Physiotherapy focused on reeducation and strengthening, including biofeedback, is very important. With therapy, patients can improve their control of the reinnervated muscles, and in those with antagonistic cocontractions, it can decrease the problem.

Timing of reinnervation of the target muscles depends on the length from the nerve donor source and the muscle end plates. Visible and palpable muscle contractions are not seen for an additional 2 months, and the strength of the muscle gradually increases afterward.

In patients with traumatic brachial plexus injury, long-term follow-up is necessary regardless of whether primary nerve surgery has been performed. Over time, patients can be evaluated for secondary reconstructive options once reinnervation has plateaued. Frequently, function can be further improved or refined with a range of surgical interventions, from minor to complex. The possible options are discussed in the later section on Secondary Reconstruction.

FUNCTIONING FREE MUSCLE TRANSFER

An FFMT is the microvascular transfer of a muscle, as well as its nerve, for the purpose of restoring limb function. Use of an FFMT for brachial plexus reconstruction was first reported by Ikuta and colleagues, who used it to restore elbow flexion in a child seen in delayed fashion.[103] Subsequently, FFMT has become an attractive option for many brachial plexus injuries, certainly in late presentations with absent function due to delay in referral or failed prior nerve surgery. Another valuable role has been to restore grasp in acute cases with avulsion of four or more nerve roots.[1,14,64,68,181] The use of a long muscle with a proximally located neurovascular pedicle, such as the gracilis, makes such reconstructions possible. A viable gracilis transfer, when fixed to the clavicle proximally and tunneled to the forearm, can animate the wrist or hand. Because the motor point of the muscle is located at the shoulder, a nerve transfer to this area will reinnervate the muscle within 6 months or less. Because of the long distances, conventional or vascularized nerve grafts for reinnervation of the forearm and hand musculature have been demonstrated to be ineffective.

In this section, use of FFMT for reconstruction after acute brachial plexus injuries (primary reconstruction, primarily for grasp) is discussed. Its use in chronic situations, primarily for elbow flexion, is provided as part of secondary reconstruction options later in this chapter. The basic science, anatomy, and principles of free muscle transfer are briefly included but are described in detail in articles by Manktelow and by Doi and colleagues.[60,132,133] We refer the reader to these detailed articles for this important theoretical information.

Prerequisites for Functioning Free Muscle Transfer

Shoulder and Elbow

Free muscle transfers performed in the first 3 to 6 months after brachial plexus injury are indicated primarily to restore prehension. Independent hand function requires fingers to independently close for grasp and open for release, with independent thumb positioning for key, precision, and chuck pinch. The complex coordinated activity of the many wrist, thumb, and finger extrinsic and intrinsic muscles required for this activity cannot generally be restored in adult patients with a global or complete plexus injury. The goal of achieving even simple composite grasp by nerve grafting or transfer has proven unreliable. Free microsurgical transfer of one or more expendable autogenous lower extremity muscles eliminates the problem of any preexisting period of muscle denervation. Proper selection of a transferred muscle, having both sufficient length and a proximal motor point, results in both a shortened reinnervation time and ability to move the wrist and/or finger motors. Motor control is generally provided by an extraplexal nerve transfer, because most acute cases for which FFMT is a consideration will have four or five nerve root avulsions.

Shoulder stability, as well as simultaneous reconstruction of elbow flexion and antagonist elbow extension function, is essential when restoring hand and wrist function with an FFMT.[60] The concept of "one muscle, one function," important in planning tendon transfers, also applies to free muscle transfer. A gracilis muscle fixed to the clavicle and acromion and used to provide finger flexion must first cross the glenohumeral, elbow, and wrist joints. If not addressed by other means, FFMT contraction will first act to reduce shoulder subluxation resulting from paralysis of the rotator cuff and deltoid, diminishing the muscle's potential excursion and force available for distal joints. Restoration of shoulder stability, whether by nerve graft, tendon transfers, or arthrodesis of the glenohumeral articulation, is imperative.

At the elbow, the need to provide an active stabilizing antagonist muscle is even more important. The same gracilis muscle crossing anterior to the axis of rotation will use most of its available force and excursion elbow flexion moment *unless* triceps (extensor) function is provided. The wrist must also be positioned by arthrodesis or a separate free muscle transfer if useful finger flexion is to be achieved. These concepts have been clearly detailed by Doi and coworkers.[64,66,68]

Other important prerequisites for FFMT include adequate skin coverage, a stable and well-vascularized bed for tendon gliding, an available motor nerve, vasculature permitting successful microvascular anastomoses, and supple finger joints. Patients must be willing and able to undergo a complex and lengthy microsurgical procedure and comply with a supervised postoperative rehabilitation protocol that minimizes problems associated with scar formation and strengthens and reeducates the neurotized muscle flap for the needed function. Preoperative planning must assess these requirements and should include vascular imaging (arteriogram, CT or MRI angiogram) and assessment of skin and tissue quality, as well as passive joint range of motion (shoulder, elbow, wrist, and hand). There must be an expendable motor nerve in the vicinity of the muscle neurovascular pedicle. In most brachial plexus injury cases, this will mean an extraplexal source, most commonly cranial nerve XI (spinal accessory nerve) or two to three intercostal motor nerves. Other nerves may be used as available, including regenerated contralateral C7 nerve transfer or elements of the brachial plexus in partial injuries.[184] Function of the spinal accessory nerve is assessed by strength testing of the trapezius and by EMG. Intercostal motor function is generally not practically measured preoperatively. We have found intercostal nerve injury to be relatively infrequent even in the presence of rib fracture.[113] Availability of adequate numbers of extraplexal nerve donors cannot be absolutely assured preoperatively, however. Intraoperative assessment by nerve stimulation may require a change in surgical plans and goals.

Vascular injuries are common in adult brachial plexus injury, occurring in 10% or more of patients.[194] The incidence is higher when the first rib is fractured. Avulsion of the subclavian or axillary vessels is generally considered a contraindication for free muscle transfer because patency of the thoracoacromial or thoracodorsal vessels is usually needed for FFMT to be successful. At times, collateral flow may permit filling of these vessels. If imaging of the subclavian and axillary branches shows that their blood flow is sufficient, even when a more proximal arterial occlusion is present, FFMT may be successful and provide appropriate function.[97]

Some patients with avulsion injury develop a stiff and edematous intrinsic-minus posture with a flattened palm and fixed finger metacarpophalangeal joint extension. Success in these situations will require restoration of supple joints or later positioning of metacarpophalangeal joints in a flexed posture by tenodesis, capsulodesis, or arthrodesis. In addition, total active motion of fingers can be improved by stabilizing the

wrist with an arthrodesis. This has been found to be useful in the double free muscle procedure described in the following,[2] as well as in single free muscle transfers for finger and thumb grasp/pinch.

Selection of a Donor Muscle

When planning free muscle transfer, a suitable potential donor muscle must have a vascular pedicle permitting transfer, sufficient length and excursion for its new role, and adequate force, and must also be expendable. The latissimus dorsi, gracilis, adductor longus, and rectus femoris muscles have all been used as donor muscles for FFMT and meet the general criteria just listed.[3] When reconstruction is planned for elbow flexion alone, another option is to reinnervate the ipsilateral latissimus dorsi and transfer it as a functioning pedicled flap. This is ideally performed within 6 to 9 months after injury. In addition, it is used occasionally as a free functioning transfer from the contralateral side. The rectus femoris muscle is also a powerful muscle and can be used to restore elbow flexion. Transient reduction in knee extension strength occurs after its harvest, so some physiotherapy is required. It provides a good fit for strength but not excursion when compared with the biceps.

The gracilis is the most frequently used free functioning muscle. It is a strap muscle rather than a pennate muscle, with excellent fiber length, but it has considerably less cross-sectional area than the biceps that it is intended to replace. Thus, data suggest that it is poorly matched for strength but well matched for needed excursion. Experience has demonstrated that both the gracilis and the latissimus can provide useful function.[60] The gracilis generates sufficient force to flex the elbow against gravity in most cases, however, and has other desirable qualities. Most importantly, the proximal position of its neurovascular pedicle permits rapid reinnervation from either the spinal accessory or intercostal motor nerves, whereas its length and shape facilitate its passage into the forearm to animate the wrist and hand. Sananpanich, Tu, and Pookhang and colleagues have described the use of a combined gracilis/adductor longus transfer, using a common vascular pedicle and two independent obturator nerve branches to permit a one-stage double-muscle transfer useful for combined finger flexion and wrist extension, for example.[175] The same flap has been used by others to provide shoulder abduction and elbow flexion.[200,201]

Operative Procedures

Gracilis Harvest

The gracilis is a superficial muscle that lies on the medial aspect of the thigh. A branch of the obturator nerve enters the muscle obliquely just cephalad to the major vascular pedicle, at a point 6 to 12 cm from its origin. The dominant arterial supply is provided by a branch from the profunda femoris artery 8 to 12 cm from the muscular origin and is approximately 4 to 6 cm long. The vascular pedicle is dissected between the adductor magnus (posteriorly) and adductor longus (anteriorly).

Harvest of the gracilis[84] for FFMT starts with identification of the distal tendon at the tibial insertion (Figure 34.34). A longitudinal incision is made over the pes anserinus, and the sartorius fascia is elevated. The pes anserinus is identified. The superior tendon is that of the gracilis muscle, whereas the inferior tendon is that of the semitendinosus muscle. The gracilis tendon is isolated; its distal attachment is maintained. A distal medial thigh incision is made to identify the myotendinous junction of the gracilis. All attachments to the gracilis tendon are freed at this level. By distal and outward retraction, the muscle is placed on tension and can easily be palpated; the outline of the underlying muscle is drawn on the skin along its length.

The gracilis is routinely transferred with a proximal skin paddle for postoperative flap monitoring.[133] A handheld Doppler device is used to identify myocutaneous perforators in the proximal third of the muscle flap. An elliptical incision is designed to incorporate these perforators in the skin paddle. The anterior incision is made, and dissection is directed toward the adductor longus muscle. The fascia over the adductor longus muscle is incised and mobilized with the skin paddle to preserve any septocutaneous perforators. The adductor longus thus exposed is retracted gently anteriorly to expose the interval between the adductor longus and adductor magnus. The gracilis covers this interval superficially. Its major vascular pedicle can be visualized traversing this interval perpendicularly, entering the gracilis together with its obturator motor nerve. The motor branch from the superficial division of the obturator nerve follows an oblique course toward the gracilis, lying in the same adductor interval cephalad to the vessels and oriented approximately 45 degrees to them. It is identified with a nerve stimulator at this point and mobilized toward the obturator foramen. Additional motor and cutaneous branches encountered may be preserved by blunt proximal mobilization from the nerve, providing a longer gracilis motor nerve stump, often 10 cm or more in length. It is important to maximize the nerve length if a nerve graft is to be avoided. This is particularly true when the spinal accessory nerve is used and the gracilis motor nerve must be passed into the supraclavicular fossa.

The major vascular pedicle is adherent to the adductor longus due to multiple vascular perforators to this muscle. These must be identified and ligated, thus progressively mobilizing the arteriovenous pedicle from medial toward its profunda femoris artery and vein origin. Dissection can be continued to the profunda vessels to obtain the maximal pedicle length. The posterior incision of the skin paddle is made, and dissection is directed posteriorly to the fascia covering the adductor magnus muscle. The adductor magnus fascia is incised and mobilized to form a fascial sling together with the adductor longus fascia that envelops the gracilis muscle and helps to ensure skin paddle viability.

Before harvest and division of the muscle's proximal and distal attachments, resting tension can be marked with sutures placed at 5-cm intervals to facilitate appropriate tensioning of the muscle. The distal tendon is divided, passed into the proximal thigh wound, and pulled through. The secondary pedicle is identified and ligated at this time. The fascial sling around the gracilis is preserved by complete release of the fascia from the adductor magnus and adductor longus muscles. The distal tendon is temporarily replaced in its native bed, and the proximal tendon is released from the pubic ramus. The vascular pedicle is not divided until the recipient site is fully prepared, preferably by a second surgical team. This includes dissection of the recipient vessels, donor nerves, as well as fixation in the proximal clavicle and acromion. A subcutaneous tunnel or pocket is prepared in the arm and the distal tendon of insertion exposed, depending upon the purpose of the procedure. Only

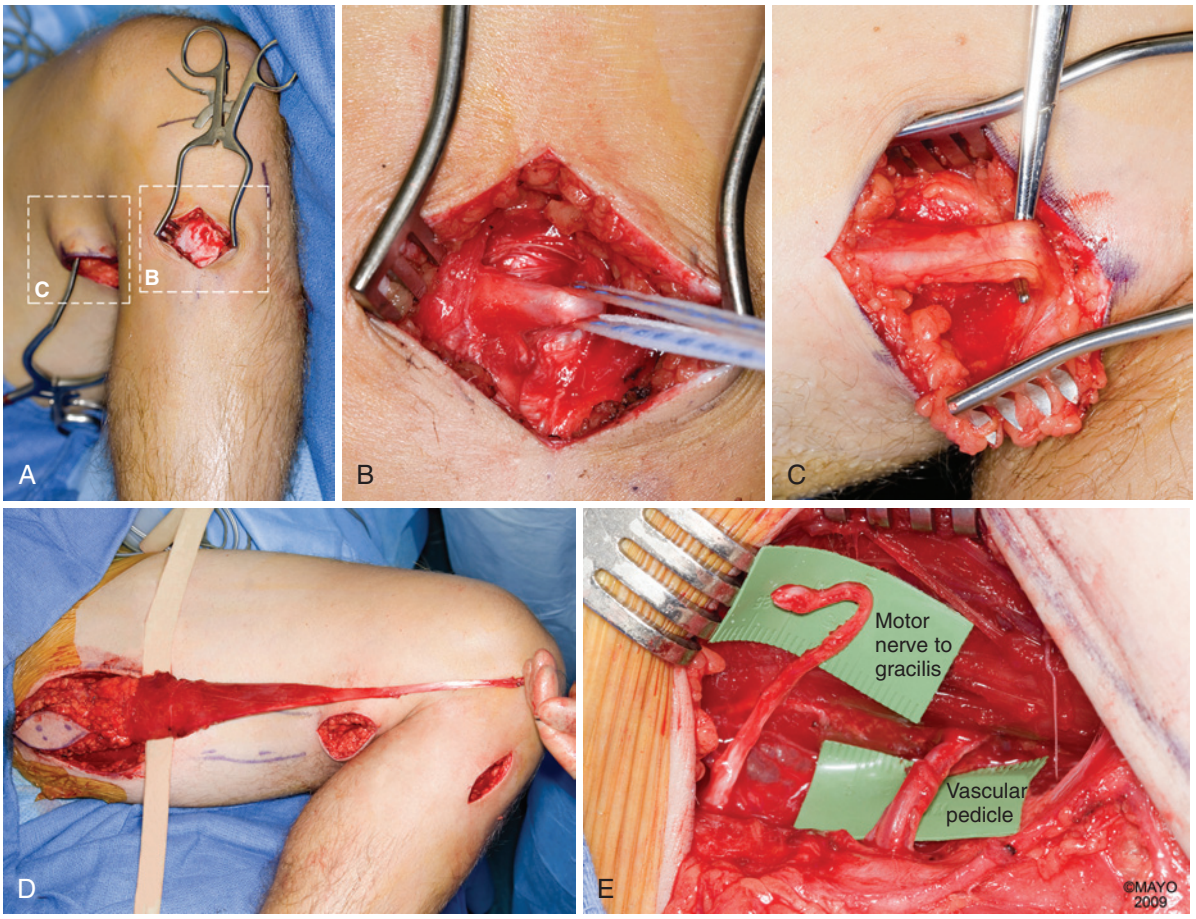

FIGURE 34.34 Gracilis harvest for free functioning muscle transfer. **A,** Harvest begins with distal exposure of the gracilis tendon via a longitudinal incision made over the pes anserinus. After the gracilis tendon is identified, a distal medial thigh incision is made to identify the gracilis myotendinous junction. The *dashed boxes* are insets that are further clarified in **B** and **C. B,** The gracilis tendon (*in umbilical tape*) is identified underneath the sartorius fascia; the cephalad tendon is the gracilis, whereas the caudad one is the semitendinosus. **C,** The gracilis myotendinous junction is identified in the distal medial thigh incision. All attachments between the myotendinous junction and the distal insertion are then released. **D,** The proximal gracilis muscle is dissected while maintaining a fascial sling around it to preserve the septocutaneous perforators. A skin paddle with myocutaneous perforators is taken with the muscle to act as a monitoring flap. **E,** The vascular pedicle and motor nerve are identified in the interval between the adductor longus and gracilis muscles. The motor branch to the gracilis is dissected as far proximally as possible. The vascular pedicle is dissected laterally to the profunda femoris vessels, which requires identification and ligation of the vascular perforators to the adductor longus muscle. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

then is the vascular pedicle ligated proximally and divided. Any remaining soft tissue attachments are released, and the muscle is transferred to the arm.

Once transferred, the proximal tendon is expeditiously secured to the acromion and clavicle. We use suture anchors preplaced in the lateral aspect of the clavicle and acromion to quickly attach the gracilis. The muscle is placed in a premade subcutaneous tunnel and provisionally secured to adjacent tissue in its final position, but without distal tenorrhaphy and adjustment of final tension until the vascular connections and nerve transfer are completed. The vascular anastomoses are typically performed to a branch of the thoracoacromial artery end-to-end and the cephalic vein end-to-end. Perfusion is reestablished with less than 1 hour of ischemia time. Meticulous neurorrhaphy to two to three intercostal motor nerves or to the spinal accessory nerve is performed with epineural sutures and fibrin glue as close to the muscle as possible to minimize reinnervation time. When intercostal neurorrhaphy is performed, the shoulder is abducted 90 degrees and maximally externally rotated to minimize the effect of later shoulder motion on nerve tension.

Appropriate muscle tension is important for a good result and can most easily be achieved by restoration of the original muscle resting length via superficial sutures placed at measured intervals along the length of the muscle before dissection as originally described by Manktelow and colleagues.[131,133] Observation of an appropriate tenodesis effect of the transfer is another indication of appropriate resting muscle length.

Free Muscle Transfer for Reconstruction of Grasp After Complete Avulsion of the Brachial Plexus

Rationale. One of the major advances in brachial plexus surgery has been the application of FFMT in the acute setting. As described by Doi and associates, the goal is to obtain voluntary elbow flexion and extension, hand sensation, and grasp and release function in patients with avulsion of four or five nerve

roots.[62,64,68] After complete brachial plexus avulsion, several surgical approaches have been developed to restore prehension.[58,59,141,144] The goal of obtaining grasp in these adult patients has been elusive, the most promising other method being transfer of the contralateral C7 nerve with a bridging vascularized ulnar nerve graft.

A potential method to obtain hand function is the restoration of active wrist extension, with a later Moberg key pinch procedure (thumb interphalangeal joint arthrodesis and flexor pollicis longus tenodesis, resulting in a tenodesis-powered prehensile pinch powered by wrist extension). Unlike the patients with spinal cord injury for whom the key grip procedure was designed, a patient with a brachial plexus injury maintains both a normal contralateral upper limb and normal lower extremity function. Further, most activities of daily living can be accomplished with one hand. Patients with complete brachial plexus palsy need restoration of a few important bimanual activities, such as lifting with a bimanual hook grasp or holding a bottle while opening its cap rather than key pinch.[67,68] A powerful grip independent of the contralateral limb and the independent use of both hands are desirable in brachial plexus injury. Active rather than passive (tenodesis) finger flexion is imperative for a powerful grip.

Release of grasp is another useful function in prehension. Release reconstructed by secondary tenodesis of the finger extensor tendons, as in a Moberg-type reconstruction, will need gravity-aided wrist flexion[143-145,215] and can be achieved only with the elbow flexed. This synergistic action cannot be accomplished when the elbow is extended. To achieve voluntary finger extension independent of elbow position, a second free muscle transfer is required. The complexity of this undertaking for the patient, the surgeons, and the therapist, as well as the need for all aspects of the procedure to function properly, makes this procedure among the most challenging and, when successful, most rewarding of the reconstructive options for a patient with a complete avulsive injury.

Prerequisites for Grasp Surgery. Stability of the shoulder and elbow joints is necessary for proper transmission of the power of the transferred muscle to achieve effective hand function. Double free muscle transfer acts to supplement shoulder stabilization but may not be adequate. Shoulder stabilization can be achieved by scapulohumeral arthrodesis when shoulder instability persists after double FFMT, but also by a variety of existing and newly described tendon transfer options.[73] Restoration of both extension and flexion of the elbow is extremely important for optimal use of the hand in day-to-day activities. Although elbow flexion is readily accomplished with nerve or tendon transfer, triceps reanimation has proven difficult.[141] The use of a functioning muscle crossing the elbow to reconstruct finger flexion or extension cannot function without some means of reconstructing elbow extension.[69] A patient may, for example, demonstrate powerful wrist extension or finger flexion when asked, but only when using the opposite hand to stabilize and prevent involuntary elbow flexion. Bimanual use does not occur unless elbow extension is restored. Available intercostal nerves are used to neurotize the triceps brachii muscle for elbow extension. This enables the patient to stabilize the elbow independently, without need of the contralateral hand, and use the powerful finger flexion afforded by the muscle transfer effectively.

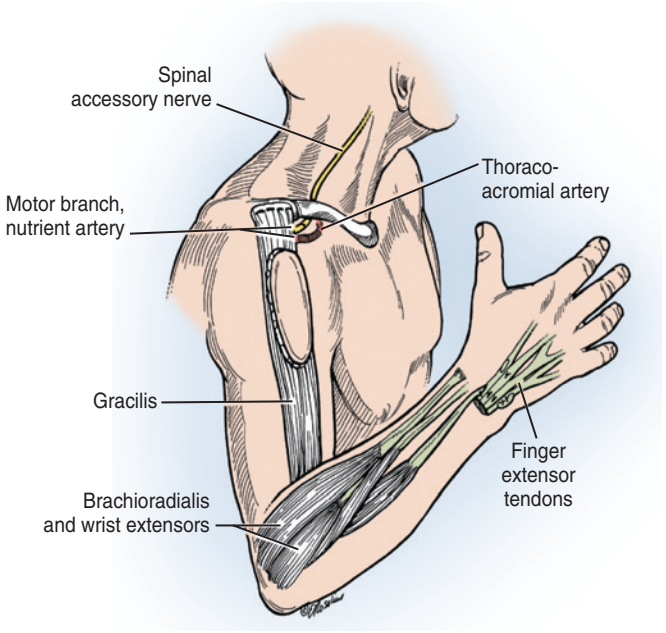

FIGURE 34.35 The first-stage operative procedure for reconstruction of prehension after complete brachial plexus avulsion is a free muscle transfer to restore elbow flexion and finger extension simultaneously. The gracilis is transferred and innervated by the spinal accessory nerve. (Copyright © Elizabeth Martin.)

Operative Technique

Double Free Muscle Transfer. Our modified double free gracilis muscle transfer technique consists of five reconstructive steps performed in two operative procedures. During the first operation, the steps are (1) exploration of the brachial plexus and reconstruction of the proximal ruptured motor nerves, if possible; and (2) transplantation of the contralateral gracilis, neurotized by the spinal accessory nerve, for elbow flexion and finger or wrist extension (Figure 34.35). In the second operation, three remaining steps are performed: (3) a second free functioning gracilis transfer, neurotized by the fifth and sixth intercostal nerves, for finger flexion (Figure 34.36); (4) use of the third and fourth intercostal nerves to neurotize the motor branch of the triceps brachii muscle for elbow extension (Figures 34.37 and 34.38); and (5) coaptation of the intercostal sensory rami to the medial cord of the brachial plexus to restore sensibility of the hand (see Figure 34.38). In addition, a sixth set of procedures for secondary reconstruction are often required, including tendon transfers for glenohumeral stabilization and abduction/external rotation, as well as arthrodesis of the thumb carpometacarpal and/or interphalangeal joints and the wrist joint. Tenolysis of one or both of the transferred muscles may also be necessary.

Timing of the various reconstructive procedures is important and guided by several criteria. Steps 1 and 2 are performed at the first stage of the operation, and steps 3 to 5 are performed at the second stage, usually 2 or 3 months after the first operation. The secondary reconstruction is done approximately 1.5 years after the first stage of the operation, depending on the extent of recovery.

Brachial plexus exploration is described in detail earlier. In the first stage, simultaneous elbow flexion and finger extension are reconstructed with an FFMT by using the spinal accessory

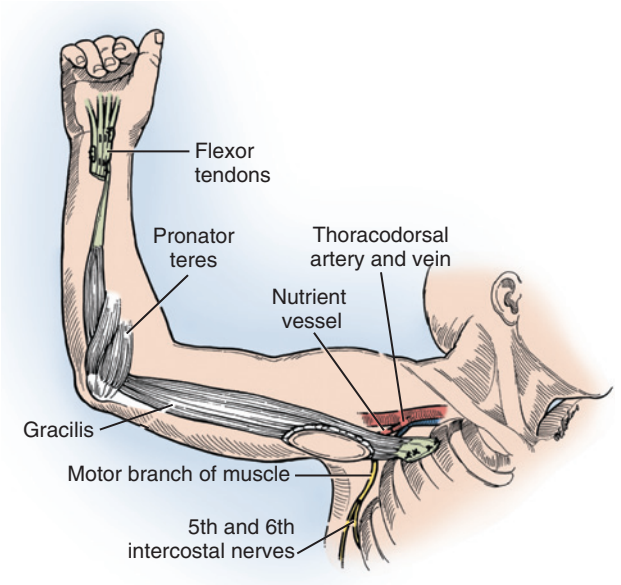

FIGURE 34.36 The second-stage procedure for reconstruction of prehension after complete brachial plexus avulsion is a free muscle transfer to restore finger flexion. The gracilis is transferred and is innervated by the fifth and sixth intercostal (T5 and T6) nerves. (Copyright © Elizabeth Martin.)

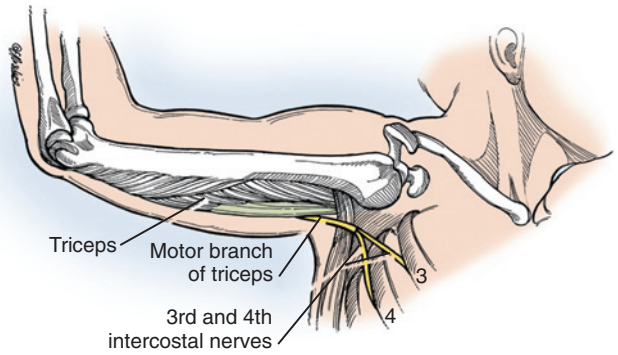

FIGURE 34.37 Intercostal (T3 and T4) nerve transfer to the motor branch of the triceps brachii is also performed in the second-stage procedure for reconstruction of prehension after complete brachial plexus avulsion. The goal of this neurotization is to stabilize the elbow against the antagonist flexors. (Copyright © Elizabeth Martin.)

as the motor nerve. We have preferentially connected the muscle for wrist extension rather than the extensor digitorum, as described by Doi, for three reasons: (1) The free muscle at times is not able to extend the wrist as well as the fingers, thereby resulting in wrist drop and poor hand function; (2) the development of independent wrist extension augments grasp strength by the tenodesis effect; and (3) the release function of fingers is still possible with passive wrist flexion. The donor gracilis muscle from the contralateral thigh is selected because the orientation and location of its neurovascular bundle match the site of the donor vessels. The length of the gracilis muscle should be sufficient to span the distance between the acromion and midforearm without tension. This is verified by measuring the length of the gracilis muscle from its pubic origin to its tibial insertion. The donor muscle is harvested from its proximal origin to the distal attachment.

Correct muscle tension is critical for good postoperative function. Before detaching the muscle, the resting length of the muscle is reproduced and silk sutures can be placed on the surface of the muscle at 5-cm intervals, as described by Manktelow and colleagues.[132,133]

The distal portion of the spinal accessory nerve is dissected, divided, and transferred. The motor nerve of the transferred muscle is passed behind the clavicle and coapted to the distal branch of the spinal accessory nerve in the supraclavicular area. The nutrient vessels of the free gracilis muscle are anastomosed to the thoracoacromial artery and vein or to the cephalic vein. The transferred muscle is placed superficially over the anterior part of the deltoid and is attached to the acromion with nonabsorbable sutures or a soft tissue anchoring system. A simple and straight route for the free muscle is created from its new origin to its final insertion to maximize the force of contraction. It is placed on the anterolateral aspect of the arm and dorsal surface of the forearm. To prevent bowstringing, the free muscle is passed deep to the brachioradialis and radial wrist extensor muscles just distal to the elbow.

This position of the muscle is optimal for elbow flexion and finger extension; however, grip strength may weaken when the elbow is flexed. Correct muscle tension is reproduced in the upper limb before final suturing of the muscle to the finger or wrist extensors. The original muscle length is restored by stretching the muscle until the distance between the markers is once again 5 cm. Tension is adjusted with the shoulder in 60 degrees of abduction and 15 degrees of anterior flexion, the

elbow in 150 degrees of flexion, the wrist in neutral, and the fingers in full extension. After adjusting the tension, the position of coaptation is marked over the tendon of the extensor digitorum and the donor muscle tendon. The elbow is flexed to 90 degrees, and with the wrist in neutral and the fingers fully flexed, the tenorrhaphies between the donor muscle tendon and extensor digitorum tendon are completed at the previously marked sites. The appropriateness of tension in the transfer is evaluated by using the tenodesis principle.

Reconstruction of finger flexion is done by using a second free muscle transfer. It is performed 2 to 3 months after the first operation, once improvement is noted in postoperative contracture of the elbow and finger joints. The third to sixth intercostal nerves are dissected as far as the midclavicular line and transferred to the axillary region. The fifth and sixth intercostal nerves are used as the donor motor nerve for the second gracilis muscle transplant. The gracilis is harvested from the ipsilateral thigh after ensuring that it will reach the midforearm from the second rib. The proximal end is sutured to the second and third ribs. To activate finger flexion, it is placed on the medial aspect of the upper part of the arm and forearm so that it does not act as a secondary elbow flexor.

The distal gracilis tendon is passed deep to the flexor pronator origin, just distal to the elbow, to lie adjacent to the flexor digitorum profundus muscles and tendons. The flexor digitorum profunda tendons are first interconnected to provide a cascade of increasing flexion from the index finger to the small finger, and they are then joined with the gracilis tendon with a Pulvertaft weave; an additional flexor carpi radialis tendon graft is often required to prolong the gracilis. Muscle tension is determined with the principles described earlier. When the tension is adjusted, the shoulder, elbow, and wrist are in the same position as described earlier. The fingers are kept in full flexion. The nutrient vessels of the gracilis are anastomosed to the thoracodorsal artery and vein. The fifth and sixth intercostal nerves are transferred directly without tension and without an intervening nerve graft to the motor nerve of the second muscle transplant. The third and fourth intercostal nerves are similarly transferred to the motor branch of the triceps brachii muscle to activate the elbow extensors.

To restore hand sensibility, the sensory rami of the intercostal nerves are sutured to the medial cord contribution to the median or ulnar nerve or to the lateral cord contribution to the median nerve of the brachial plexus at the second operation. The sensory-dominant fascicles of the medial cord can be easily distinguished from the motor-dominant fascicles by measuring SNAPs, if available. Sensory nerve fibers do not undergo wallerian degeneration, because most dorsal ganglion cells survive after preganglionic injury to the nerve roots.

Postoperative Protocol. Postoperative monitoring of the muscle is important, because prompt detection of vascular impairment may allow salvage of the gracilis flap. A variety of methods are in clinical use, including implantable Doppler systems, duplex sonography, near infrared spectroscopy laser Doppler flowmetry, and, recently, assessment of muscle contractility.[57] We have generally relied upon skin perfusion for monitoring, together with Doppler examination of the cutaneous perforators. Aftercare is critical for outcomes. Conventionally, the elbow is immobilized for 6 weeks in a position of 100 degrees of elbow flexion and neutral supination of the forearm in a shoulder immobilizer. After this period, passive range of motion is begun, avoiding shoulder abduction greater than 60 degrees if intercostal nerves have been transferred. Once reinnervation has begun, active range-of-motion exercises (with gravity eliminated and aided by electromyographic biofeedback) are begun. Maximum recovery requires 18 to 24 months.

Recently, this conventional postoperative regimen has been compared with an early passive mobilization protocol that began immediate elbow and digit passive mobilization.[61] Doi uses compression of the tendinous portion of the transferred gracilis at the elbow to move the fingers beginning 1 week after surgery, with the elbow in extension to apply tension to the transferred muscle. Early motion has prevented the need for tenolysis in the early motion group, as compared with a 26% incidence of tenolysis with conventional methods.

Low-intensity electrical stimulation of the paralyzed target muscles (the two transferred gracilis muscles, the triceps brachii, and the supraspinatus and infraspinatus if the suprascapular nerve has been repaired) can be started during the third postoperative week and may be continued until EMG-confirmed reinnervation is noted in the muscles. An early motion protocol as described by Doi may provide superior results rather than 6 weeks of elbow and finger immobilization.

After EMG documentation of reinnervation of the transferred muscle (usually 3 to 8 months postoperatively), EMG biofeedback techniques are started to train the transferred muscles to move the elbow and fingers. Muscular reeducation is indicated when patients display minimal active contraction of an identified muscle or muscle group. The initial goal of reeducation is for patients to reactivate voluntary control of the muscle. As the muscle strengthens, active motion begins, first with gravity eliminated and lastly against gravity. Rehabilitation should continue for at least 2 years after surgery so that use of the reconstructed hand for daily activities can be mastered.

Subsequent Surgery. Following recovery of extrinsic finger flexion, paralysis of intrinsic muscles innervated by the median and ulnar nerves will result in a worsening claw deformity and impaired pattern of grasp and pinch. Absence of lumbrical function causes the reanimated flexor digitorum profundus tendons to initiate flexion at the interphalangeal joints, preventing an efficient wrapping of the hand around the desired object. This results in a resting claw finger stance that may in time become a fixed deformity with metacarpophalangeal joint hyperextension and proximal interphalangeal joint flexion. Postoperative physiotherapy, including a lumbrical bar or hand-based anticlaw splint, may be helpful, as well as one of the variety of anticlaw passive tenodesis procedures described in the literature. In addition, the thumb is unable to pinch effectively due to unopposed thumb interphalangeal flexion and lack of active motors to position the metacarpophalangeal and carpometacarpal joints. There is a need to "simplify" the multiple joint chain of the thumb, most frequently by arthrodesis of the carpometacarpal or interphalangeal joints, or both.[85] Most patients will also benefit from a wrist arthrodesis to enhance the effect of an FFMT for finger function. Claw deformity can be improved by a passive Zancolli lasso or other static anticlawing procedures (see Chapters 31 and 33 for details of these procedures).

Basic sensory functions such as protective sensation and position sense should be restored when motor function is being

reconstructed in a severely paralyzed limb. Supraclavicular (cervical plexus) or intercostal nerve transfers provide limited sensibility of the hand after double FFMT.

CRITICAL POINTS *Double Free Muscle Transfer for Reconstruction of Prehensile Function*

Indications
- Total paralysis of the brachial plexus
- Acute cases less than 6 months after injury
- No injury to the subclavian artery, spinal accessory nerve, and intercostal nerves
- Age younger than 40 years

Preoperative Evaluation
- Normal function of the trapezius muscle
- Supple joints

Pearls
- The basic function of the upper extremity, prehension, can be restored by this procedure.

Technical Points
- Dissection of the donor nerve and recipient vessels: obtaining maximum length of intercostal motor nerves
- Harvest of the donor muscle
- Suture of the proximal attachment of the muscle
- Suture of the motor nerve of the muscle: for intercostal nerves, with the shoulder abducted 90 degrees and maximally externally rotated
- Vascular anastomosis of the nutrient vessels of the muscle
- Suture of the distal tendon of the muscle to the target muscle in proper tension
- Performance of the procedures accompanying nerve transfer for shoulder reconstruction in the first stage and performance of nerve transfers for elbow extension and sensory reconstruction in the second stage

Pitfall
- Proximal joint stability is imperative to achieve useful recovery.

Postoperative Care
- The shoulder is immobilized in 30 degrees of abduction and flexion and 60 degrees of internal rotation with the elbow in 100 degrees of flexion, the wrist in neutral position, and the fingers in forced flexion or extension, depending on the reconstruction; the reconstruction is protected by a shoulder immobilizer for 3 weeks. Thereafter, shoulder abduction is restricted to 60 degrees to prevent inadvertent tension on the intercostal nerve transfer.
- EMG-documented reinnervation begins 3 to 8 months postoperatively.

Complications. Vascular compromise after FFMT is fortunately infrequent, and reinnervation of the muscle is generally successful. Adhesions of the transferred muscle to the surrounding tissue are a problem that may be minimized by an early range-of-motion protocol. The most important factor affecting the outcome for grasp is the extent of recovery of the triceps, as previously explained. If reinnervation of the triceps brachii fails, secondary reconstruction, such as reinnervated infraspinatus or deltoid transfer to the triceps brachii, is recommended to restore elbow stability.

If the glenohumeral joint remains unstable even after recovery of these muscles, glenohumeral tendon transfers or arthrodesis should be performed. Care must be taken to prevent fractures of the proximal humerus after arthrodesis. After recovery of active finger motion, arthrodesis of the thumb carpometacarpal joint and/or interphalangeal joint may be helpful. In addition, tenodesis flexion of the metacarpophalangeal and interphalangeal joints of the thumb and proximal and distal interphalangeal joints of the fingers may augment stable pinch function. A passive Zancolli lasso procedure may be used to minimize the expected claw deformity manifesting as flexor digitorum profundus function improves.

Expected Outcome. Thirty of 36 patients undergoing reconstruction by the double free muscle procedure and monitored for more than 24 months after the second free muscle transfer (mean follow-up, 40 months) were assessed for the long-term outcome of prehension, including motion and stability of the shoulder and elbow (Figure 34.39), voluntary and independent motion of the fingers, sensibility, and performance of activities of daily living.[64,66] The functional outcome of prehension according to the authors' classification was excellent in 6 patients (which implies restoration of more than 90 degrees of elbow flexion, dynamic stability of the elbow while moving the fingers, and more than 60 degrees of total active motion of the fingers), good in 11 patients (same as excellent, except for total active motion of 30 to 60 degrees), fair in 3 patients (total active motion of less than 30 degrees), and poor in 10 patients. Satisfactory results (excellent and good) were achieved in 17 of 30 patients (57%).

Half the patients recovered sensibility of the palm and adequate positional sense. However, protective sensation in the ulnar side of the hand and fingers was not recovered in half of the patients. Minor injury and burns can easily occur in these parts of the hand.

Single-Stage Functioning Free Muscle Transfer for Prehension

Despite reported success with double FFMT for prehension, it remains a daunting undertaking for both the surgeon and patient. Two to three major surgeries followed by significant dedicated rehabilitation may be both financially and emotionally difficult for patients. It has been our current practice to use a single FFMT in one operation that can provide elbow flexion and extension, grasp, and sensation. Only finger extension is not reconstructed. The indications for this method are the same as for a double free muscle transfer: avulsion of four or five nerve roots. It is important that surgery be performed no later than 6 to 8 months following injury so that critical triceps function can be restored.

A supraclavicular exploration is performed, and if a viable proximal stump is available (i.e., postganglionic injury), sural nerve grafts are used to target the suprascapular and axillary nerves. Two intercostal motor nerves (T5 and T6) are transferred to the biceps motor branch of the musculocutaneous nerve, and another pair (T3 and T4) to a free functioning gracilis. The gracilis is attached to the acromion and distal clavicle, and the distal tendon is woven into the flexor digitorum profundus and flexor pollicis longus to produce finger flexion and thumb pinch (Figures 34.40 and 34.41). An antecubital pulley must be used to avoid bowstringing. The intact lacertus fibrosus, reinforced if needed by weaving the flexor carpi ulnaris across the antecubital fossa to the lateral epicondyle and back, is generally used for this purpose. To balance the elbow flexion motion, the spinal accessory nerve is transferred to the triceps branches of the radial nerve with an interpositional nerve graft (often the superficial radial nerve). A secondary wrist and thumb carpometacarpal and interphalangeal joint arthrodesis is performed when motor function returns, usually accompanied by a passive Zancolli lasso procedure to prevent an intrinsic-minus claw deformity.

The outcomes of the single-stage FFMT for hand and elbow function have been encouraging. Although the results of the double-stage FFMT described by Doi and associates[64] are anecdotally better than those of the single-stage FFMT, the rudimentary grasp has been beneficial for our patients. The fiscal and psychological burden of undergoing two extensive surgical procedures within 6 weeks has been challenging in our patient population. A single-stage major surgery with secondary minor surgeries (for wrist fusion and thumb interphalangeal and carpometacarpal fusions) has been better accepted by our patients. We have been using the procedure for approximately 7 years and are in the process of analyzing our results.

Nerve Reimplantation

Experimental studies of the implantation of avulsed ventral roots into the spinal cord in rats, cats, and then primates over a period of several decades suggested that spinal motor neuron axons may regenerate.[36] These studies led to small clinical trials.[37] This procedure, pioneered by Carlstedt and colleagues, remains controversial and is still under investigation.

SECONDARY RECONSTRUCTION

Shoulder Reconstruction in Adult Patients With Brachial Plexus Injury

Persistent shoulder instability and lack of mobility are common and debilitating problems in adult patients with brachial plexus injury. The lack of shoulder mobility significantly hinders use of the upper extremity even if the elbow, wrist, and fingers are functioning normally. Recovery of deltoid and rotator cuff function is often incomplete, regardless of whether brachial plexus reconstruction has been performed; such incomplete recovery results in poor abduction and limited or no external rotation.[20,206] Traditionally, recovery of active elbow flexion and reduction of shoulder subluxation, which lead to improvement in glenohumeral stability and pain, are interpreted as clinical successes. However, with the limited or absent shoulder external rotation, most of these patients maintain an internal rotation position of the shoulder, and this in turns results in a "hand-on-belly position." In these instances, patients cannot position the hand in front of the body in the coronal plane, thereby resulting in significant limitation of the functional use of the limb.

Options for improving shoulder function and stability include fusion and tendon transfers. Shoulder fusion is a reliable procedure for stabilizing the glenohumeral joint; however, it is irreversible and relies entirely on scapulothoracic motion for shoulder motion. The procedure is consequently contraindicated in patients with limited scapulothoracic motion or paralysis of the periscapular muscles.[51,160] Saha[172] and Goldner[87] both recommended tendon transfer for a paralytic shoulder and used shoulder fusion only as a last resort. We agree with these authors, and it is our preference to attempt shoulder reconstruction with either nerve transfers or tendon transfers and leave shoulder fusion as a salvage procedure when no other options exist.

Because of the complexity of shoulder joint motion, it is important to have a basic understanding of the biomechanics of the shoulder before attempting shoulder reconstruction with tendon transfers. In this section, the basic biomechanics of the shoulder and the anatomy and function of the muscles around the shoulder will be reviewed. Both classic and novel tendon transfers for paralytic shoulder reconstruction will be discussed.

BASIC BIOMECHANICS AND RELEVANT ANATOMY OF THE SHOULDER

Fourteen muscles work around three joints (glenohumeral, acromioclavicular, and sternoclavicular joints) and one scapulothoracic articulation to create three-dimensional shoulder motion. Eight muscles specifically move the glenohumeral joint, including the latissimus dorsi, pectoralis major, deltoid, supraspinatus, infraspinatus, subscapularis, teres minor, and teres major. The first two muscles originate from the chest wall, spine, and clavicle, and the latter six originate on the scapula and insert on the humerus. Additionally, six muscles support the scapula on the chest wall and include the serratus anterior, trapezius, rhomboid minor, rhomboid major, levator scapulae, and pectoralis minor. These muscles originate from the chest wall and spine and insert onto the scapula.

Goldner divided the muscles around the shoulder into four functional groups: group 1, *the prime movers*, includes the clavicular head of the pectoralis major and deltoid; group 2, *the stabilizers*, includes the subscapularis, supraspinatus, and infraspinatus; group 3, *the depressors*, includes the teres major, biceps, latissimus dorsi, pectoralis major, and triceps; and group 4, *the accessory stabilizers of the scapula*, includes the trapezius, serratus anterior, pectoralis minor, levator scapulae, and rhomboids.[85] The concepts described by Saha and Goldner imply that smooth and normal shoulder function requires stable and normal scapulothoracic motion in addition to a normal deltoid and rotator cuff.[75]

The muscle's ability to contract and move an articulation is related to its tendon excursion. It has been shown that the excursion of the rotator cuff muscles is considerably less than that of the deltoid muscle with simple scapular plane abduction, thus implying that the rotator cuff muscles are the primary stabilizers of the glenohumeral joint during shoulder motion.[99] The stabilizing effect of the rotator cuff muscles (via a force couple created by the subscapularis anteriorly and the infraspinatus posteriorly) resists a relative upward shearing moment at the glenohumeral joint created by the contracting deltoid muscle during early abduction. To illustrate this concept, it should be understood that effective function of the deltoid (prime mover of the shoulder) is significantly compromised if the stabilizing function of the rotator cuff is lost or deficient.

Among the four rotator cuff muscles, the subscapularis and infraspinatus are the most important ones in stabilizing and contributing to the overall abduction moment arm to the shoulder. It has been estimated that the functional contribution of the supraspinatus to the overall abduction moment arm is only 14%; the subscapularis, 52%; and the infraspinatus and teres minor combined, 32%.[15,106] Similarly, the subscapularis provides 42% of the internal rotation moment, and the infraspinatus and teres minor combined provide 45% of the external rotation moment.[106] The importance of the infraspinatus in abduction and external rotation has been demonstrated by Gerber and coworkers, who showed that a nerve block to paralyze the infraspinatus led to loss of only approximately 45% of abduction strength and 70% of external rotation strength of the shoulder independent of the abduction angle.[82]

The accessory stabilizers of the scapula are an important group of muscles that stabilize and mobilize the scapula on the chest wall and are essential to complement shoulder motion in abduction and flexion.[87] The serratus anterior muscle is an important complement to deltoid function.[53] Better shoulder functional outcomes have been reported in patients with brachial plexus injury who had partial or full recovery or preservation of the serratus anterior than in those without serratus function.[206] Therefore, when tendon transfers about the shoulder are planned, the first priority is given to reconstruction of the prime movers and stabilizers, followed by the scapular stabilizers/movers. In most adult brachial plexus cases, reconstruction of active scapular stabilization by tendon transfer is rarely possible because of the scarcity of available adequately functioning muscles.

Principles of Tendon Transfer

There are well-known important principles that should be followed to improve the chance for successful tendon transfer, and

they are discussed in Chapter 31.[28] Understanding the relative tension and potential excursion of the shoulder muscles is essential for preoperative planning.[99] All parameters should be taken into consideration, although a perfect match of donor-to-recipient tendon tension, excursion, and vector is not possible.

Tendon Transfer for Reconstruction of Shoulder Function

It has classically been taught that reconstruction of shoulder flexion-abduction is the primary priority in reconstruction of a paralytic shoulder. However, in discussing priorities of reconstruction with our patients, we have found that the majority of patients complain most about the lack of external rotation, even more so than the lack of forward flexion or abduction. External rotation of the shoulder is a critically important function in daily activities and is performed by the infraspinatus and teres minor muscles. External rotation allows the humerus to be rotated away from the body so that when elbow flexion occurs, the hand and forearm can clear the abdomen or chest wall. An inability to externally rotate the shoulder to clear the abdomen or place the hand in front of the body can be frustrating, especially when elbow flexion is good or close to normal.

One of the most important factors in determining outcome after shoulder reconstruction in patients with brachial plexus injury is the level and degree of brachial plexus injury. In previous reports on shoulder reconstruction by tendon transfer after brachial plexus injury, detailed evaluation of the available muscles around the shoulder and the feasibility of transfer of these muscles to restore the biomechanics of the shoulder are not adequately addressed. For example, shoulder instability is expected after brachial plexus injury because of paralysis of the rotator cuff muscles (dynamic stabilizers of the shoulder). The techniques described to stabilize the shoulder address the sequelae rather than the biomechanical cause of the instability, and subsequently, glenohumeral fusion for shoulder subluxation has been described to solve this problem.

Prerequisites necessary for tendon transfer about the shoulder include a shoulder that has an adequate soft tissue envelope and is passively mobile. Pain and limb edema must be controlled before surgery. Finally, a cooperative patient who understands the objectives of the surgery and participates in the arduous rehabilitation process is necessary for success.[119] Other relevant questions related to the tendon transfer procedure that should be addressed before surgery include the following:

1. Restoration of which function or functions will yield the greatest functional result?
2. What muscles are available?
3. Are the available muscles expendable, and do they have sufficient strength (M4 or greater), adequate excursion, and a proper vector to permit function?

Decisions are based on a large number of anatomic, biomechanical, and clinical outcome studies. In the adult shoulder there is little information to guide the surgeon. Relatively few functional muscles are available, and their expendability is unclear. Accurate isolation and determination of strength are difficult because of the complex forces about the shoulder girdle. In plexus injuries, the trapezius, levator scapulae, and rhomboids have been reported to be preserved or recovered in 96% of patients.[159] The trapezius innervation is extraplexal, and the dorsal scapular nerve supplying the rhomboids and levator scapulae receives contributions from more proximal cervical nerves.[159] Additional muscle groups may be available in patients with incomplete plexus palsy as well, which greatly expands the opportunity for reconstruction. Finally, division of multipennate muscles into their functional subcomponents, as described by Herzberg and colleagues,[99] can provide additional tendon transfer options.

Upper Trapezius Transfer

Historically, the trapezius is the most common tendon transfer performed for adult patients with brachial plexus injury, including those who undergo spinal accessory nerve transfer as part of their brachial plexus reconstruction.* In most of these patients, the upper part of the trapezius is preserved and hypertrophies over time, thereby gaining sufficient strength for transfer.[53] Trapezius transfer was described by Hoffa in 1891, followed by Lewis in 1910 and Lange in 1911. Tendon prolongation with fascia lata led to poor results attributed to stretching and scarring.[171] Bateman reported transfer of the muscle along with its acromial insertion into the proximal end of the humerus in 1955,[16] later modified by Saha,[172] whose name is now associated with the operation.[171] However, Saha originally defined three basic shoulder functions that need to be reconstructed with available nonparalyzed local muscles. He rarely recommended this transfer in isolation, and he was an advocate of multiple tendon transfers in an attempt to restore normal shoulder function. However, it should be mentioned that most of his patients were younger and had shoulder weakness or paralysis as a result of poliomyelitis rather than traumatic brachial plexus injury. There is a significant difference in the pattern of weakness and muscles available for transfer between these two groups of paralytic conditions. The transfers that were performed for polio were selected on the basis of the type of paralysis and residual power of the available local muscles.[177] Most commonly, it was recommended that transfer of the upper trapezius be used to restore function of the deltoid and clavicular head of the pectoralis major, which Saha called the "prime movers." He transferred the levator scapulae or sternocleidomastoid muscle to replace the supraspinatus, which he described as a vertical "steerer." The anterior horizontal steerer (subscapularis) can be substituted for by the pectoralis minor, the upper two slips of the serratus anterior, or a residual part of the pectoralis major. The posterior horizontal steerers (infraspinatus, teres minor) can be replaced by a part of the latissimus dorsi or teres major.

Despite Saha's recommendation for multiple tendon transfers to restore shoulder function in the paralytic polio shoulder, most of what has been published in the literature as the Saha procedure refers to the single, upper trapezius tendon transfer. Kotwal and coauthors reported an average of 60% of good results with upper trapezius transfer using the Saha technique.[112] Nineteen percent of their patients had a poor outcome, with persistent subluxation of the glenohumeral joint. Aziz and associates reported a reduction in shoulder joint subluxation after upper trapezius transfer in all their patients, with an average of 40 degrees of abduction and flexion gained.[11] Karev reported on a single case of severe atrophy of the deltoid, supraspinatus,

*See references 11, 16, 105, 112, 148, and 170 to 172.

and infraspinatus with an intact subscapularis after excision of a neurilemmoma of the brachial plexus.[105] The patient underwent upper trapezius transfer 6 months after his original surgery and had almost full return of shoulder function. In this single case, it is likely that the remarkable gains were the result of spontaneous improvement of the native deltoid and rotator cuff. Monreal and colleagues reported a reduction in glenohumeral subluxation and an average gain of 40 degrees of abduction and flexion after upper trapezius transfer in 10 patients with brachial plexus injury.[149]

Ruhmann and coworkers repeatedly published the outcome of upper trapezius transfer in adult patients with brachial plexus injury.[170,171] Originally, the Saha technique was used, although in more recent publications the method has been modified.[170,171] In Saha's technique, the trapezius is detached from the spine of the scapula and transferred with the acromion to the proximal humerus just distal to the greater tuberosity. Fixation is provided by two 6.5-mm cancellous screws with the shoulder positioned in 80 to 90 degrees of abduction. In the modified technique, the partially detached deltoid is sutured in a medial direction on top of the trapezius muscle. This technique may transmit additional power by contraction of any remaining deltoid fibers. The authors demonstrated increased function in all patients and decreased multidirectional instability in 95% of patients. The mean increase in abduction and flexion was around 30 degrees.[171] The best results were achieved in patients with a functioning biceps, coracobrachialis, triceps, or pectoralis major muscle, or any combination of these muscles. The improved outcome in this group of patients is most likely related to the additional number of functioning muscles, as well as the less severely injured patient cohort. In these patients the average abduction was 42 degrees and the average flexion was 56 degrees. By contrast, those with a completely flail shoulder (presumably complete brachial plexus injuries) gained just 28 degrees of abduction and 19 degrees of flexion. None of these studies addressed the lack of shoulder external rotation and focused solely on shoulder stability and shoulder abduction-flexion.

Latissimus Dorsi Transfer

Latissimus dorsi tendon transfer, with or without teres major transfer, is commonly used in patients with residual brachial plexus birth palsy to restore abduction and external rotation.[119] This transfer has not been used traditionally in adult patients. Most pediatric plexus injuries involve C5 and C6; in such injuries, some latissimus function is preserved. In addition, partial recovery of deltoid and subscapularis function is usually present and is critical for transfer of the latissimus dorsi to be effective. Accordingly, some authors consider paralysis of the deltoid and subscapularis muscles to be contraindications to transfer of the latissimus dorsi.[81] In patients without deltoid and subscapularis function, latissimus transfer to the greater tuberosity may magnify the inferior subluxation and adduction-extension of the shoulder. When latissimus dorsi transfer is performed to reconstruct irreparable rotator cuff tears in the presence of a normal subscapularis and deltoid, however, it functions appropriately as a humeral head depressor and external rotator.

An alternative use of the latissimus dorsi muscle is as a bipolar transfer in which the muscle is rotated about its vascular pedicle to improve its position and vector.[55,79,104] For example, reconstruction of anterior deltoid function requires release of the latissimus origin and insertion, rotation of the muscle 180 degrees, passage through the deltopectoral interval, and attachment to the acromion and humerus. Itoh and coauthors reported good results in 10 patients.[104] All of them had a good shoulder contour, six had active flexion of more than 90 degrees, and all but one had M4 power. De Smet[55] and Ferrier and associates[79] used the same technique with similarly good results. It should be emphasized that most of these patients had isolated paralysis of the deltoid and a partially innervated or completely normal rotator cuff.

Pectoralis Muscle Transfer. Hou and Tai reported on seven patients who underwent transfer of the upper portion of the pectoralis either alone (four patients) or combined with upper trapezius transfer (three patients) for deltoid paralysis.[100] They defined the functional anatomy of the pectoralis major muscle as having three parts: clavicular (originating from the clavicle), sternocostal (originating from the first to sixth sternocostal regions), and abdominal (originating from the junction of the lower sternocostal and rectus abdominis fascia). These muscular parts converge laterally and insert along the lateral lip of the bicipital groove. The tendinous portions of the clavicular and upper sternocostal heads make up the anterior tendon. These portions of the muscle are supplied by the thoracoacromial artery and innervated by the lateral pectoral nerve, whereas the lower or abdominal head is supplied by either the thoracoacromial artery or the internal thoracic branch of the axillary artery and innervated by the medial pectoral nerve. During transfer of the pectoralis major muscle, the upper portions (clavicular and upper sternocostal parts) are harvested on their pedicle, and the muscle is then turned over 180 degrees with the deep surface being superficial. The muscular portion is attached to the lateral aspect of the clavicle and the acromion, whereas the tendinous portion is anchored to the deltoid tuberosity of the humerus. In isolation, this technique restored an average of 40 degrees of abduction. When an upper trapezius transfer was added, however, the average abduction improved to 70 to 90 degrees with forward flexion of 60 to 150 degrees. Lin and coauthors reported similarly good results in patients with brachial plexus injury.[121] Shoulder mobility and stability were improved in all their patients. Functioning and preservation of the pectoral nerves are prerequisites in considering and undertaking this transfer.

Lower Trapezius Transfer

Our original description of lower trapezius transfer to restore shoulder external rotation was in a patient who sustained a brachial plexus injury that resulted in complete paralysis of the deltoid, infraspinatus, and teres minor.[74] The trapezius was prolonged by insertion of an Achilles tendon allograft at the infraspinatus tendon footprint. The patient gained 70 degrees of external rotation and was very satisfied with the outcome of surgery. The authors subsequently reported the outcome of lower trapezius transfer isolated or combined with multiple tendon transfer in 52 patients with brachial plexus injury.[73] All patients had a stable shoulder at the latest follow-up, with significant improvement of shoulder external rotation but only marginal improvements of shoulder abduction and flexion.

If a single tendon transfer is planned to restore external rotation, our original technique involves using an incision placed medial to the scapula, through which the lower trapezius is

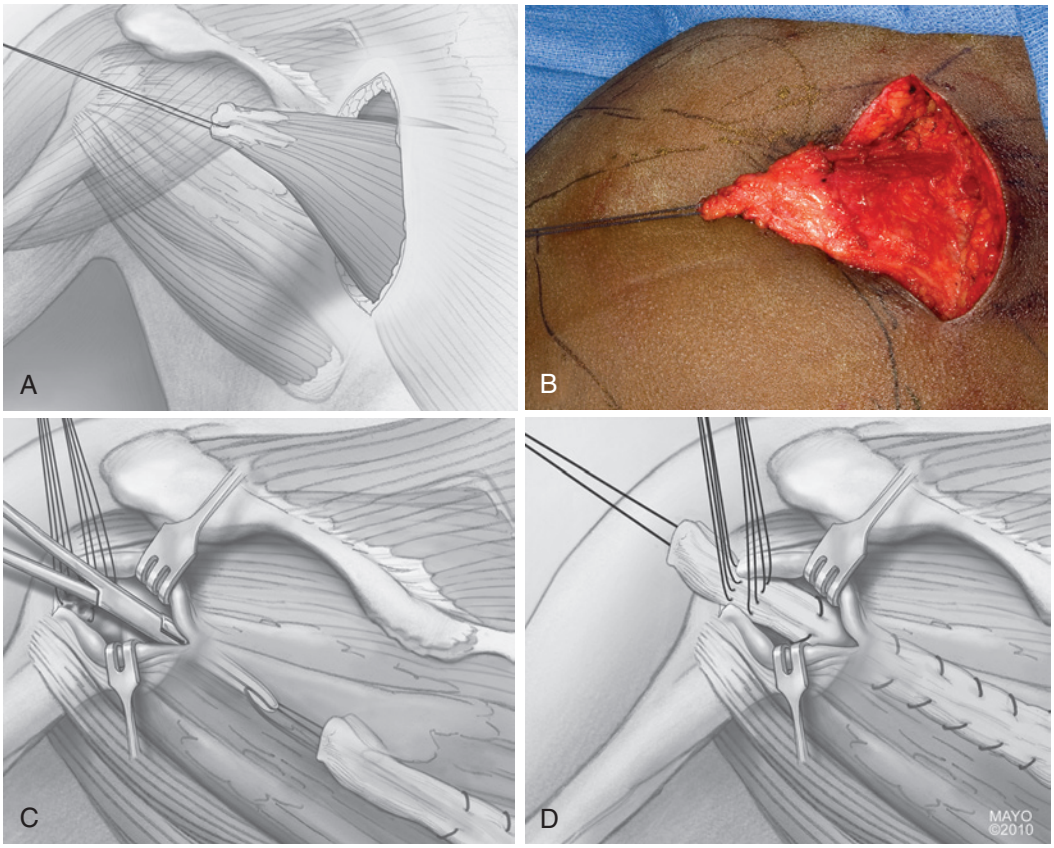

FIGURE 34.42 **A,** Lower trapezius tendon transfer starts with an incision medial to the scapula to harvest the lower portion of the trapezius. **B,** Intraoperative photograph demonstrating the lower trapezius tendon harvested through this approach. **C,** After an Achilles allograft is used to prolong the trapezius tendon, it is passed beneath the deltoid and infraspinatus to get to the level of the infraspinatus insertions. **D,** The Achilles tendon allograft is appropriately tensioned and secured to the infraspinatus footprint. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

harvested (Figure 34.42, *A* and *B*). The muscle is lengthened (with an Achilles or posterior tibialis tendon allograft or a hamstring autograft), passed underneath the deltoid and infraspinatus, and anchored to the infraspinatus insertion site (see Figure 34.42, *C* and *D*). However, after the original 52 patients on whom we reported, we performed more than 50 additional tendon transfers using the lower trapezius for shoulder external rotation, as an isolated transfer or combined with other tendon transfers; in the latter cases, the trapezius was transferred directly to the infraspinatus. Because almost all patients with brachial plexus injury have an intact infraspinatus tendon insertion, we were able to obtain on average 5 to 7 cm in length of the infraspinatus tendon with additional dissection (Figure 34.43); this allowed direct transfer of the lower trapezius tendon to the infraspinatus tendon without the need for tendon allograft augmentation (Figures 34.44, *A* to *C*).

Contralateral Lower Trapezius Origin Transfer

In the absence of available muscles in the ipsilateral side of the injury to transfer to the infraspinatus to restore shoulder external rotation, contralateral trapezius transfer is a unique and, possibly, the only option available to achieve this purpose.

We have demonstrated in a prior cadaveric and human volunteer study that the contralateral lower trapezius, when prolonged with lumbosacral fascia, is feasible for transfer to the affected infraspinatus to restore shoulder external rotation.[76] The contralateral lower trapezius muscle origin is detached from the thoracic spine and transferred to the denervated infraspinatus tendon (Figure 34.45, *A* to *C*). We have performed this transfer in 12 patients, with a very rewarding outcome of restoring shoulder external rotation (Figure 34.46, *A* and *B*).

Recently, Satbhai and colleagues demonstrated encouraging results in three patients who underwent contralateral trapezius transfer to restore shoulder external rotation after they regained elbow flexion from free muscle transfer.[176] The patients experienced an average improvement of more than 95 degrees of external rotation arc and an average improvement in Disabilities of the Arm, Shoulder, and Hand (DASH) scores of 14 points. No patients experienced any donor site deficits in range of motion.

❖ AUTHORS' PREFERRED PROCEDURE

Consideration of shoulder reconstruction should take place when the initial decision is being made on how to reconstruct the upper extremity. It is our routine practice to include a discussion of shoulder reconstructive options, as well as priorities of treatment, with each patient. Even after reinnervation and recovery from nerve grafting or transfers, secondary surgery may be needed to improve the stability and function of the shoulder.

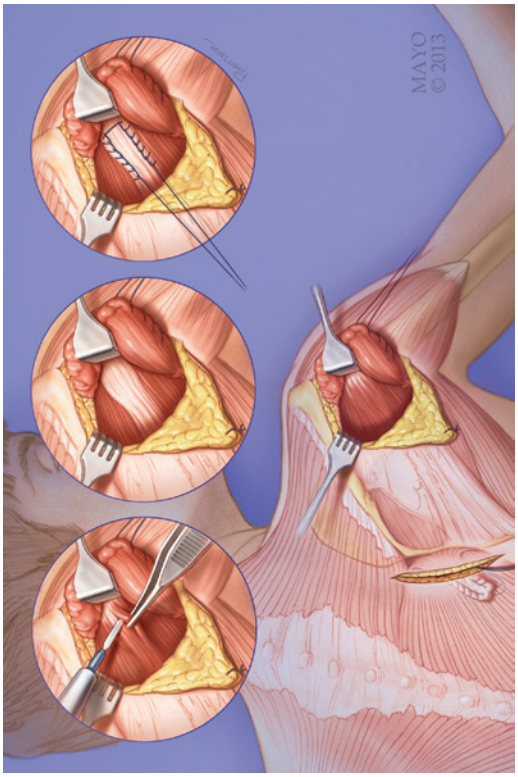

FIGURE 34.43 Exposure of the infraspinatus with dissection and exposure of the tendinous portion of the infraspinatus tendon by teasing the muscle fibers off the tendon. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

It has been our preference to restore both the rotator cuff force couple (subscapularis and infraspinatus) and deltoid function. To have effective shoulder abduction by the deltoid muscle, both the subscapularis and infraspinatus need to be functioning appropriately because they are more important contributors to abduction than the supraspinatus and provide additional rotational control. In complete brachial plexus injuries, the trapezius and levator scapulae are usually functioning, and the serratus anterior may be available, depending on the type of injury. We have observed that the three parts of the trapezius (upper, middle, and lower) are activated independently, so they could potentially be used independently as separate transfers. For this reason the upper and middle trapezius can be used for transfer to stabilize and possibly improve shoulder abduction (Figure 34.47, *A* and *B*). Additionally, the levator scapulae (reported by Narakas[159]) can be used, and finally, depending on the type of injury, the upper serratus anterior muscle (reported by Saha[172]) may also be available. Our current reconstruction options for a completely paralytic shoulder include transfer of the upper serratus or pectoralis minor (if functioning) to the subscapularis insertion for internal rotation, the levator scapulae to the supraspinatus for abduction, the lower trapezius to the infraspinatus for external rotation, and the upper and middle trapezius to the deltoid for abduction. If the latissimus is functioning with enough strength, it is also added as a bipolar transfer for shoulder contouring and to improve shoulder flexion. These potential transfers are our preferred method, but their combined use has not been substantiated yet in the literature. Thirty-nine out of the 52 patients on whom we previously reported underwent multiple tendon transfers, and though almost all of them had significant improvement of shoulder external rotation, the improvement in shoulder flexion and abduction was not statistically significant.

We did modify our original technique of upper/middle trapezius transfer; in this modification, we no longer perform acromial osteotomy as part of the transfer because we believe this decreases the lever arm of the transferred trapezius. We have been transferring the upper and middle trapezius prolonged with Achilles tendon allograft on top of the acromion and inserting the transfer on the proximal humerus at the site of the deltoid insertion (Figure 34.48, *A* and *B*). We have observed better improvement in shoulder abduction with this technique.

When options are more limited, we prefer to reconstruct external rotation alone because we believe that the ability to position the hand anterior to the coronal plane restores greater overall function than does abduction alone. For this reason, in patients who have no muscles available for transfer on the side of injury, contralateral lower trapezius origin transfer is performed to the infraspinatus tendon to restore shoulder external rotation.

Shoulder Arthrodesis

Shoulder arthrodesis is a well-established operative procedure that involves fusion of the humeral head to the glenoid. Indications include total paralysis after brachial plexus injuries and upper-type paralysis.[13,146,169,209] We prefer procedures other than shoulder arthrodesis because the decreased arc of shoulder motion after arthrodesis limits use of the reconstructed hand after prehensile reconstruction. In contrast, other brachial plexus centers routinely perform arthrodesis of the glenohumeral joints to use the available nerve sources for elbow flexion-extension and prehension.

Patients have reported difficulty with turning during sleep, and fracture of the humerus is not a rare complication of shoulder arthrodesis. Contraindications to shoulder arthrodesis include extensive paralysis of the trapezius and shoulder stabilizers (levator scapulae, serratus anterior, or rhomboid muscles); if these scapular stabilizing muscles are paralyzed, scapulothoracic subluxation or pain will result. Richards and coworkers[165,166] reported that if these muscles are nonfunctional, the extremity will be severely impaired despite successful glenohumeral fusion.[5] In these cases, scapulothoracic fusion will be required to alleviate pain. Providing stability of the glenohumeral joint by fusion can be helpful if the patient is to be able to move the elbow and fingers, even if glenohumeral arthrodesis results in some instability of the scapulothoracic joint.

The shoulder is a difficult joint to fuse because the humerus has a long lever arm, the area of contact at the glenohumeral joint is small, and additionally paralyzed muscles cannot contribute as a compressive force to aid in union. The optimum position for arthrodesis of the shoulder is debatable. Patients with total paralysis of the brachial plexus and normal function of the trapezius and serratus anterior muscles should undergo arthrodesis in 30 to 40 degrees of abduction and flexion and 30 degrees of internal rotation. In contrast, in total paralysis of the brachial plexus with absence of serratus anterior or trapezius

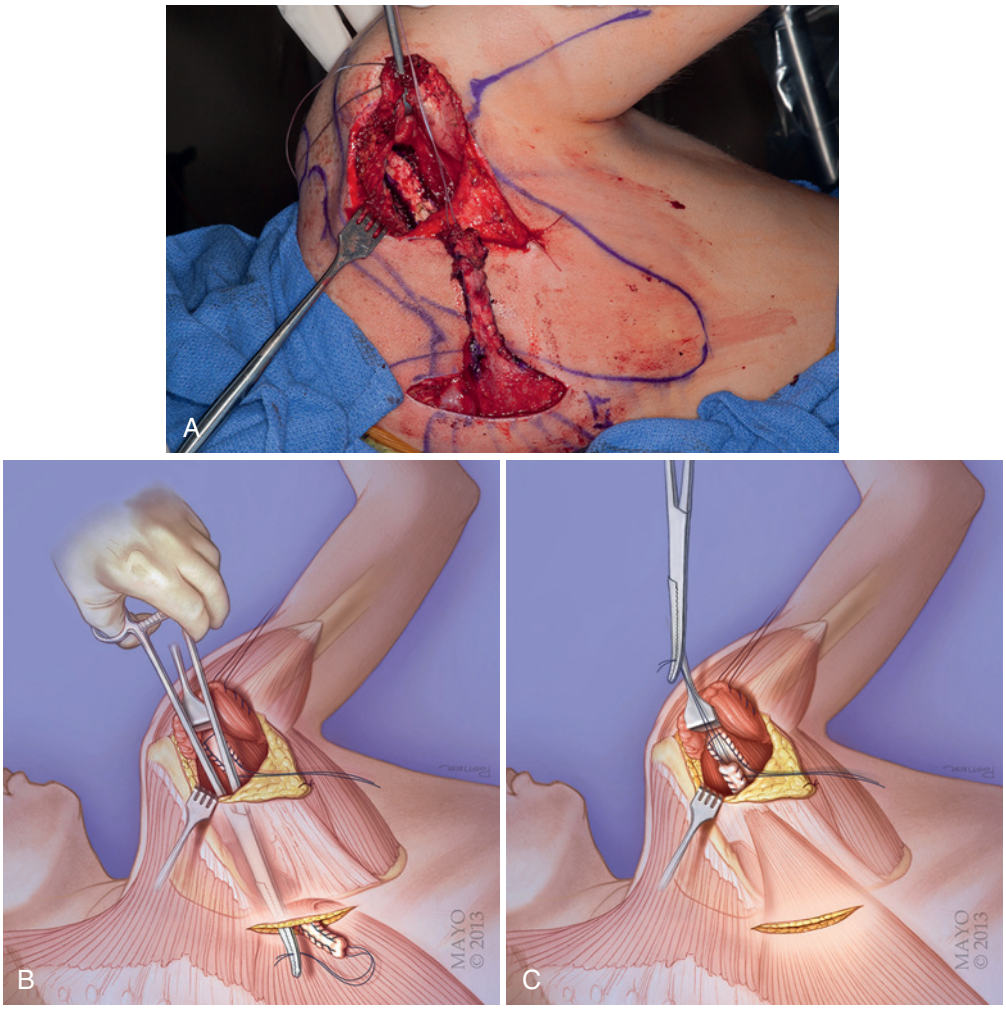

FIGURE 34.44 **A,** Intraoperative picture showing the lower trapezius muscle and tendon harvested and retrieved through a medial incision, and the infraspinatus tendon dissected and exposed and tacked with a nonabsorbable suture through the lateral incision. **B** and **C,** After creating a large tunnel, the lower trapezius could be retrieved from the medial incision to the lateral incision, and direct repair of the tendinous portions of the lower trapezius and infraspinatus is possible while the shoulder is placed in maximal external rotation. function, shoulder arthrodesis should be avoided and possibly performed only when inferior shoulder subluxation is associated with extensive symptoms. In this situation, the position of arthrodesis should be 20 degrees of abduction, 10 degrees of flexion, and 30 degrees of internal rotation.

Many operative techniques for shoulder arthrodesis have been described.[43,56,153] Rigid internal fixation with a long 4.5-mm reconstruction plate and compression screws across the glenohumeral joint has been reported with good results. However, it carries the risk of increased devascularization and occasional problems from prominent screws and loosening of the hardware in osteoporotic bone. External fixation has its own complications, including neurovascular injury, pin tract infection, pin loosening, and fractures through pin sites, but it is particularly useful for infected joints.

❖ AUTHORS' PREFERRED METHOD: Glenohumeral Arthrodesis

We prefer to use long cancellous screws and a reconstruction plate for transarticular fixation of both the glenohumeral and acromiohumeral joints, supplementing the fixation with autogenous bone graft. The operation is performed in the beach-chair position. Through a posterior incision that follows the spine of the scapula and extends down the lateral humeral head and shaft, the posterior half of the deltoid is detached from the scapular spine and acromion and retracted distally. All soft tissue under the acromion is removed, and the rotator cuff muscles are also detached from the greater and lesser tuberosities to expose the joint capsule, glenohumeral joint, and acromiohumeral joint. Articular cartilage from each joint is removed to facilitate contact of the subchondral bone of the humeral head and glenoid cavity. Bone graft from the iliac crest is then inserted into the subacromial space. The glenohumeral and acromiohumeral joints are transfixed with long cannulated screws of 7.3 mm in diameter in the position of 30 degrees of abduction-flexion and internal rotation. Because most patients with brachial plexus injury have osteopenic bones, adequate compression of the acromion on the superior surface of the humerus is important. This allows additional contact surface, which may maximize the fusion rate. A 4.5-mm pelvic reconstruction plate is contoured to the scapular spine and humerus and secured in place, which adds substantially to the stiffness of the fusion construct. Cancellous bone chips are used to pack the vacant space of both joints (Figure 34.49).

Postoperative Protocol. A splint is used to immobilize the glenohumeral joint until radiographic union, which may take up to 4 months. Movement of the elbow and distal joints is encouraged. Gentle passive and active range of motion of the scapulothoracic joint is initiated, and radiographs are taken monthly until bone union occurs.

Expected Outcome. The purpose of shoulder arthrodesis after brachial plexus injuries is to stabilize the glenohumeral joint and permit the patient to move the upper part of the arm through the scapulothoracic joint with the use of innervated scapular muscles. The postoperative range of shoulder movement depends on the residual strength of the periscapular muscles, such as the trapezius, levator scapulae, serratus anterior, latissimus dorsi, and rhomboid muscles.

Previous reports have shown a satisfactory outcome of range of scapulothoracic motion, with an average of 60 degrees of abduction and flexion,[48,51,166,168] because most of the patients had normal function of the serratus anterior muscle. In a recent study by Atlan and associates of 54 patients who underwent shoulder fusion for a paralytic shoulder in the setting of brachial plexus injury, the authors reported improved abduction of at least 45 degrees in 65% of patients and improved active shoulder rotation of at least 45 degrees in 65% of patients.[9] They recommended the use of abundant subacromial bone graft to decrease the risk of pseudarthrosis.

Late Reconstruction of Elbow Function

Paralysis of elbow flexion resulting from brachial plexus injury should be addressed when feasible by nerve repair, graft, or

CRITICAL POINTS *Glenohumeral Arthrodesis*

Indications
- Failed or neglected cases with glenohumeral instability or arthritis
- Total or upper-type paralysis with or without paralysis of the serratus anterior
- Normally functioning trapezius

Preoperative Evaluation
- Good strength of the trapezius and rhomboid
- No contracture of the scapulothoracic joint

Pearls
- Provides stability to the shoulder
- Improvement in range of shoulder motion, depending on the strength of the scapulothoracic muscles

Technical Points
- Posterior saber-cut skin incision
- Removal of all soft tissues, including the rotator cuff in the subacromial joint
- Removal of cartilage of the subacromial and glenohumeral joints
- Iliac bone graft between the acromion and humeral head
- Transarticular fixation of the subacromial and glenohumeral joints with large cannulated screws of 7.3 mm in diameter in the position of 30 degrees of abduction-flexion and internal rotation of the shoulder
- Bone chips in vacant areas around the joints

Pitfalls
- Postoperative fracture of the humerus
- Risk of nonunion
- Impairment of turning during sleep

Postoperative Care
- Splint or shoulder immobilizer for 3 months
- Gentle range-of-motion exercises of the scapulothoracic joint
- Radiographs monthly until healing

transfer in the first 6 to 9 months after injury. Thereafter, nerve reconstruction becomes increasingly less reliable and generally fails when delayed 12 or more months because of irreversible ultrastructural changes in muscle. In some cases, even early intervention may be impossible because of extensive damage to the anterior compartment of the arm, including muscle scarring or loss of or injury to the motor nerve at its motor innervation point. In these cases other options are needed to restore elbow flexion. Such options broadly include tendon transfers and FFMT. Examples of tendon transfer include proximal advancement of the flexor-pronator origin (Steindler's flexorplasty)[189-191] and transfer of the pectoralis major,* pectoralis minor,[188] sternocleidomastoid,[33,117] triceps,[39] and latissimus dorsi muscles.[101,147,216] Microsurgical transplantation of autogenous muscle (FFMT) to replace the function of the damaged anterior arm compartment will also be discussed.

Tendon transfer can generally be used only with incomplete brachial plexus injury because most transfers other than the sternocleidomastoid are innervated by brachial plexus nerves. The final outcome is influenced by a number of factors, including the cross-sectional area, fiber length, and vector of the transferred muscle, as well as fascial connections, the number of joints crossed, and the function of antagonist muscles. In brachial plexus injury, it is common to encounter donor muscles that have partial denervation resulting from the original plexus injury. The adequacy of such a muscle is not necessarily easy to predict preoperatively, although a BMRC grade of 4 (submaximal muscle strength against resistance) is generally regarded as the minimum required. Preoperative evaluation of muscle power can be difficult, however, as when more than one muscle contributes to a given motion (e.g., latissimus dorsi for shoulder adduction) or the muscle has dual innervation (pectoralis major). Unfortunately, BMRC grading is notoriously imprecise in assessing the ability of a muscle to do work, especially following its transfer to a new location.

The alternative of FFMT is appealing, although technically more challenging and requiring a lengthy recovery time. Prerequisites include an adequate and stable soft tissue bed; blood vessels in good condition for microsurgical anastomoses; and an available expendable donor muscle with a favorable vascular supply, a single motor nerve, and strength and excursion comparable to one or more elbow flexors. Additionally, motor nerves must be available for transfer to the motor nerve of the transplanted muscle. In brachial plexus cases, the original nerve pathways are injured, most commonly at the C5-C6 nerve or upper trunk level. Because rapid reinnervation of the muscle is required to prevent muscle atrophy and loss of motor end plates, nerve transfers from previously uninjured nerves are preferred. Two or more intercostal motor nerves, the spinal accessory nerve, or the fascicles of the ulnar nerve[94] that innervate the flexor carpi ulnaris are the most common choices. Alternatively, free muscle transfer may be delayed until motor nerve reinnervation from a proximal repair or transfer has occurred.

When selecting the best procedure for a given patient from the available choices, one must consider multiple factors, including the specifics of the nerve injury; elapsed time from

*See references 8, 29, 40, 49, 101, 149, and 216.

injury; status of the soft tissue envelope, blood vessels, and muscle; expertise of the surgical team; and desires and expectations of the patient. A careful history, physical examination, and evaluation by electrophysiologic testing and appropriate imaging studies are required. Patient education and informed participation in the decision making are imperative.

❖ AUTHORS' PREFERRED METHODS

Modified Steindler Procedure. Arthur Steindler described a method to restore flexor function to the elbow in a classic 1918 article.[118,189,192] The flexor-pronator muscles arising from the medial epicondyle are transposed to a more proximal and anterior position on the humerus to increase their moment arm for elbow flexion. As with all potential candidates for tendon transfer, preoperative evaluation of the strength of the donor muscles is critical to the success of the muscle transfer. After transfer, these muscles (the pronator teres, flexor carpi radialis, palmaris longus, flexor carpi ulnaris, and flexor digitorum superficialis) continue to provide their original function in addition to elbow flexion; consequently, they must have normal or nearly normal power (BMRC grades 4 to 5). Results are generally better in patients who require only augmentation of weak elbow flexion or who can flex the elbow before surgery and achieve wrist flexion and forearm pronation with gravity eliminated (the Steindler effect). In the absence of a demonstrable Steindler effect, the postoperative result is likely to be less optimal. Unlike isolated C5-C6 injury, patients with C5-C7 palsy may have wrist and finger extensor weakness in addition to absent elbow flexion. In these patients concomitant wrist arthrodesis should be considered.[148] We prefer the modified technique described by Mayer and Green.[137]

Operative Procedure. The midpoint of the incision lies just posterior to the medial epicondyle of the humerus. It is directed proximally and anteriorly for 8 to 10 cm over the distal upper part of the arm and distally over the anterior aspect of the forearm for 8 to 10 cm along the course of the pronator teres muscle (Figure 34.50, *A*). The resulting anterior skin flap is retracted gently anteriorly and laterally, and the posterior margin is undermined to identify the ulnar nerve at the medial epicondyle. The articular branch is sacrificed, but the branches to the flexor carpi ulnaris are preserved and protected while the nerve is mobilized for 5 cm distal to the elbow. The median nerve is similarly identified deep to the proximal border of the pronator teres. Its muscular branches to the pronator originate 2.5 to 5 cm proximal to the elbow on its medial side and must be preserved. The common flexor pronator origin is next detached, along with a 1.5-cm fragment of medial epicondylar bone with an osteotome (see Figure 34.50, *B*), while protecting the median and ulnar nerves and their muscular branches. The anterior bundle of the medial collateral ligament must be preserved at the distal, deep aspect of the epicondyle. Once the epicondylar osteotomy is complete, mobilization of the muscle from the ulna continues until the bone fragment and muscle origin can be advanced to a point 5 to 8 cm proximal to the original position with the elbow acutely flexed to 130 degrees.

In the original Steindler technique, the tendon of origin was attached to the medial intermuscular septum and fascia. Mayer subsequently transferred the entire medial epicondyle and moved the attachment point to the anterior aspect of the humerus. This modification is preferred because (1) the attachment to bone is stronger than to fascia and (2) the more anterior position reduces the pronating tendency of the original transfer. Elbow flexion accompanied by marked pronation of the forearm compromises hand function.

In this technique it is helpful to predrill (and tap) the medial epicondyle before detachment. The median nerve and brachial artery are mobilized and retracted medially. The brachialis is split longitudinally to expose the humerus. It is prepared with

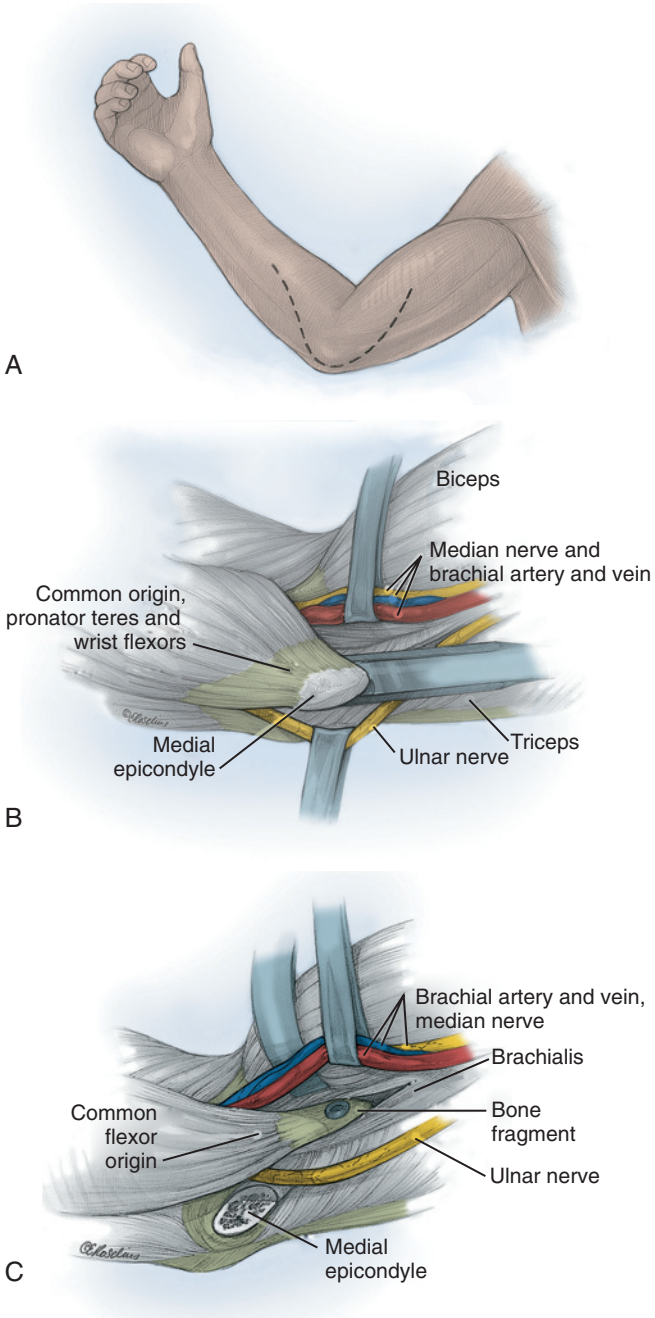

FIGURE 34.50 Authors' preferred Steindler procedure for reconstruction of elbow flexion. **A,** Skin incision. **B,** The common origin of the pronator and wrist flexor muscles is dissected and detached, along with a fragment of bone from the medial epicondyle with an osteotome while care is taken not to injure the ulnar and median nerves and brachial vessels. **C,** The bone fragment with the common origin of the pronator and wrist flexor muscles is fixed to the anterior surface of the humerus with a screw and suture anchors. (Copyright © Elizabeth Martin.)

a bur or osteotome, followed by fixation of the medial epicondyle and flexor-pronator group with a 3.5-mm screw to the anterior aspect of the humerus. We augment the screw fixation with two additional suture anchors inserted into the humerus around the drill hole. The anchor sutures are tied to the flexor pronator origin with the elbow flexed 130 degrees and the forearm supinated (see Figure 34.50, *C*). The proximal portion of the wound is closed and the dressing is applied.

Postoperative Protocol. The elbow is maintained in 100 degrees of flexion until union of the medial epicondyle fragment, generally by 6 to 8 weeks. Passive flexion of the elbow, wrist, and fingers commences just after the operation. Active flexion of the wrist and fingers with the elbow in full flexion is started in the third week. Extension of the elbow, wrist, and fingers is allowed from the seventh week after surgery. Postoperative rehabilitation and muscle reeducation take several months, with the goal of full active elbow flexion and a 30-degree elbow extension lag. The flexion contracture results in an increased mechanical advantage for initiation of flexion. The strength of the transferred muscles, the duration of immobilization, and the strength of the opposing triceps muscle all affect the outcome.[124]

Complications. The main complications of the Steindler transfer are pronation and flexion contractures. Pronation contractures are related to (1) preoperative absence of active supination and (2) an increased mechanical advantage of the pronator teres as a result of its proximal shift. Inserting the transfer more anteriorly and laterally on the humerus diminishes this tendency, but if no active supination is present, pronation deformity may remain a problem. The incidence in the literature varies from 28% to 50%.[38,72,122] A flexion contracture in excess of 30 degrees is uncommon and is usually treated by more intensive therapy, including passive range-of-motion exercises, stretching, and splinting.

Dutton and Dawson reported transient ulnar nerve paresthesias in two patients.[72] Lindholm and Einola reported two patients with postoperative ulnar nerve paresthesias, one of whom was still having symptoms at follow-up.[122]

Expected Outcomes. Published results of the Steindler flexorplasty reflect a high degree of success in achieving a functional range of elbow flexion against gravity, particularly when performed for poliomyelitis. Steindler achieved 79.5% good results (flexion against gravity of not less than 90 degrees) in 39 cases.[192] Using strict criteria for success, Mayer and Green recorded 11 excellent, 5 good, 4 fair, and 2 poor results in 22 flexorplasties.[137] Lindholm and Einola found that 50 of their 61 patients achieved a range of flexion of at least 90 degrees.[122] Eleven were able to lift a weight heavier than 1 kg at right angles. Dutton and Dawson noted that 20 patients had excellent or good function of the transferred muscles.[72] Eighteen could lift at least 1 to 2 kg through an arc of full elbow motion.

Monreal reported the results of 12 Steindler procedures performed in patients with incomplete C5-C7 brachial plexus palsy who had recovered elbow flexion of M2 or less.[148] Eleven patients were found to have good or very good outcomes based on the criteria established by Alnot and Abols,[6] and one patient had insufficient active flexion of the elbow. All underwent simultaneous wrist fusion. These results emphasize the role of late reconstruction by tendon transfer, when spontaneous recovery or nerve surgery results in insufficient strength. It should be noted that the strength of elbow flexion after a Steindler flexorplasty is limited.

CRITICAL POINTS *Flexor-Pronator Muscle Transfer (Steindler Procedure)*

Indications
- Inadequate active elbow flexion in upper (C5-C6 or C5-C7) brachial plexus palsy
- Elapsed time from injury of more than 6 to 9 months
- Normal or nearly normal power of the forearm flexor-pronator muscles
- Good shoulder control

Preoperative Evaluation
- Good strength of the forearm flexor-pronator muscles
- Positive Steindler effect

Pearls
- Use an anterior humeral fixation point and secure bony fixation.

Technical Points
- Longitudinal curved skin incision from the distal third of the upper part of the arm to the proximal third of the forearm
- Protection and mobilization of the ulnar nerve
- Identification of the median nerve, brachial artery, and veins
- Osteotomy of the medial epicondyle of the humerus, including the forearm flexor and pronator muscle origin, with predrilling of the medial epicondyle
- Longitudinal split of the brachialis muscle
- Subperiosteal dissection and shaving of the anterior cortex of the humerus
- Holes drilled in the humerus to accept the screws
- Fixation of the medial epicondyle with the forearm muscles to the humerus with a compression screw

Pitfall
- Pronation or flexion contracture of the elbow

Postoperative Care
- Immobilization of the elbow in 100 degrees of flexion for 6 weeks
- Passive flexion of the elbow, wrist, and fingers immediately after surgery
- Active flexion of the wrist and fingers 3 weeks postoperatively
- Active and passive extension of the elbow, wrist, and digits 7 weeks postoperatively

Triceps-to-Biceps Transfer. Use of the triceps muscle to replace the biceps is a technically straightforward method that produces reliable elbow flexion in patients with upper (C5-C6 or C5-C7) plexus palsy. It is considered undesirable by some because of the functional loss of active elbow extension that must necessarily result. It prevents overhead use of the arm should shoulder function recover, will adversely affect the ability to transfer from bed to wheelchair, and will prevent the use of a cane or crutch in others. There are instances, however, when its use is reasonable. In patients with poor elbow flexion and prominent cocontraction of a weak biceps and strong triceps, transfer of the triceps immediately solves both issues. The simplicity of the procedure and the relatively rapid postoperative recovery from it make it more desirable for many patients when other options are more complex.

Operative Procedure. The patient is positioned in a semisitting position with the extremity draped free. The incision

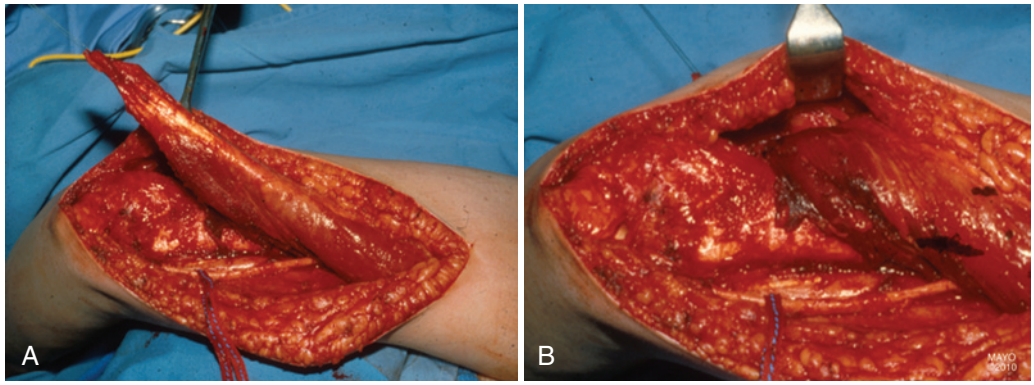

FIGURE 34.51 Triceps to biceps transfer. **A,** The triceps has been mobilized and the ulnar nerve protected. **B,** The triceps has been transferred to the biceps tendon via a lateral route after identifying and protecting the radial nerve. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

begins proximally in the posterior midline of the humerus and extends laterally and distally to the olecranon and along the subcutaneous border of the ulna for 5 cm (Figure 34.51). The ulnar nerve is exposed and protected medially and the triceps tendon is released, along with a tail of periosteum from the ulna. The medial head is mobilized while protecting the radial nerve in the spiral groove proximally. The medial and lateral edges of the tendon are brought together and tubed. The biceps tendon is exposed through a separate antecubital incision and the triceps tendon passed to it laterally through a subcutaneous tunnel. The distal end of the triceps tendon has a large nonabsorbable suture placed as a grasping suture with two long tails (Krackow-type suture). The radial insertion of the biceps tendon is identified and a bur hole is used to create a unicortical hole of 7 to 8 mm. Drill holes are placed through the opposite cortex with a 1-cm cortical bone bridge and the sutures are passed through the unicortical side through the drill holes and tied with the elbow in 90 degrees of flexion. Alternatively, a suture button technique can be employed or a Pulvertaft weave to the biceps tendon with nonabsorbable suture can be performed. If the triceps tendon is passed through a bone tunnel and secured to bone, the triceps and biceps tendon should be sewn together with large nonabsorbable, interrupted figure-of-eight sutures.

Postoperative Protocol. The elbow is maintained at 90 degrees with the forearm supinated for 6 weeks, followed by active exercises.

Complications. Complications are infrequent, with none reported in recent literature.

Expected Outcomes. Most authors report elbow flexion of between 116 and 125 degrees.[27,39] Little formal physiotherapy is required. An elbow flexion contracture will result but is generally less than 25 degrees. A contracture greater than 30 degrees can be treated by static or dynamic splinting and intensive physiotherapy.

Latissimus Dorsi Transfer. The latissimus dorsi is innervated by the thoracodorsal nerve (C6-C8) and may therefore be partially denervated in brachial plexus injuries requiring reconstruction of elbow flexion (C5-C6 pattern). Thus, assessment of latissimus strength is of critical importance. Because the latissimus dorsi generally works in concert with other shoulder internal rotators, such assessment can be difficult. The most accurate assessment is obtained by positioning the patient's arm over the buttocks, elbow extended, while grasping the patient's wrist with one hand. The patient is asked to maintain this position while the examiner pulls the arm laterally and anteriorly. It is helpful to use the other hand to palpate the strength of the contraction by grasping the latissimus at the posterior wall of the axilla. The fully contracting muscle must be able to strongly resist the examiner. Comparison with the opposite side is helpful.

Operative Procedure. Latissimus dorsi transfer has been described in two variations: moving the origin alone (unipolar) or moving both the origin and insertion (bipolar). Bipolar transplantation is preferable for several reasons. The mechanical efficiency of the transplant is increased by the more anterior placement of the origin onto the coracoid process, the proper length is easier to determine when the distal insertion is completed first, and there is less chance of the neurovascular pedicle kinking.

CRITICAL POINTS *Triceps-to-Biceps Transfer*

Indications
- C5-C6 or C5-C7 palsy

Preoperative Evaluation
- Grade 4 to 5 triceps
- Triceps/biceps cocontraction

Pearls
- Reliable method with rapid recovery

Technical Points
- Medial head mobilized, tubed, and passed from the lateral aspect to the antecubital fossa

Pitfalls
- Loss of active elbow extension will occur.

Postoperative Care
- Immobilization at 90 degrees is maintained for 6 weeks.

Bipolar transplantation. The operation is performed in four steps[216]:

1. Division of the origin and insertion of the latissimus dorsi muscle while preserving its neurovascular pedicle
2. Exposure of both ends of the biceps muscle through separate incisions
3. Transposition of the latissimus dorsi muscle beneath a cutaneous bridge in the axilla to the anterior aspect of the humerus; if necessary, resection of the biceps muscle to provide sufficient room for the latissimus dorsi
4. Fixation of the latissimus muscle to the coracoid process and biceps tendon

The technique described is the preferred approach used by Dr. Milan Stevanovic.[193] The patient is positioned in the lateral decubitus position, and the upper extremity is draped free. A longitudinal incision is made parallel to the lateral border of the latissimus dorsi muscle and extends from the posterior border of the axilla to the iliac crest, with incorporation of a skin paddle beginning 6 to 8 cm distal to the axillary fold. It should be 4 to 6 cm in width, with a length equal to that of the biceps muscle belly, elliptical in shape, and centered over the middle of the muscle. Dissection of the muscle is begun along its distal lateral border and proceeds medially and proximally. Initial dissection elevates the posterior and anterior skin flaps from the underlying fascia and muscle. With the muscle thus exposed, the arm is positioned in 180 degrees of abduction and forward flexion. The resting muscle length is marked with sutures at 5-cm intervals to facilitate later tensioning. Deep dissection proceeds from distal to proximal, with division of the origin and inclusion of the overlying fascial tissue. The dissection proceeds by mobilizing the vertebral border and separating the muscle at the inferior angle of the scapula from the deeper-lying rhomboid medially and the teres major and minor laterally. The thoracodorsal neurovascular pedicle is visualized on the deep muscle surface by developing the plane over the anterior border of the muscle. The lumbar fascial and posterior pelvic origins of the muscle are divided and the muscle is lifted off the chest wall with its attached neurovascular pedicle. The pedicle must be sufficiently mobilized to avoid kinking, which requires ligation of its serratus anterior branch and multiple (four to six) more proximal perforating branches. All fascia surrounding the pedicle must be completely released to maximize muscle mobility and minimize the potential for kinking of the pedicle. The tendon of insertion is sectioned at the humerus, and two Krackow 2-0 nonabsorbable sutures are placed.

A transverse incision 3 to 5 cm long is made at the coracoid, and an additional longitudinal incision is made along the more distal biceps muscle to the level of the antecubital fossa to completely expose the muscle belly and distal tendon. Four mattress sutures are placed in the biceps tendon, medial and lateral at the musculotendinous junction and medial and lateral more distally at the tendinous portion of the biceps, in preparation for securing the latissimus dorsi to the distal biceps tendon (Figure 34.52).

A subcutaneous pocket is created in the axilla to accommodate the latissimus by elevating the medial flap of the deltopectoral incision in a plane superficial to the axillary fascia, wide enough to admit four fingers. The muscle is tubularized by bringing the vertebral border to the lateral border and is secured with fascial sutures placed every 2 to 3 cm. The humeral insertion is moved proximally and anteriorly to the coracoid by blunt dissection below the tendon of the pectoralis major to create a tunnel for its passage.[187] Fixation is performed after the muscle is anchored distally.

The origin of the latissimus dorsi is passed under the axillary skin bridge into the deltopectoral incision while protecting its neurovascular pedicle from kinking or tension. The muscle is now stretched to restore the previously marked resting length. The elbow should be fully extended. Proximally, the tubularized latissimus should lay superficial to the biceps muscle. Distally, at the musculotendinous junction and biceps tendon, the latissimus dorsi is wrapped 360 degrees around the tendon and secured with the previously placed sutures. The proximal tendon is anchored to the coracoid process or the acromion with suture anchors and adjusted to maintain the elbow in approximately 100 degrees of flexion with full supination. Before skin closure, the pedicle should be checked both with a Doppler device and by direct visualization of the pedicle and skin. Any dark blood in the vein would indicate stretching or compression of the pedicle and requires inspection and correction. Two deep drains are placed and kept at the donor site until output is less than 5 mL in 24 hours to prevent seroma formation.

Postoperative Protocol. The arm is kept immobilized in a sling with an abduction pillow for 8 to 9 weeks. At 4 weeks we have the patient start isometric contraction of the transferred muscle while at 90 degrees. After 9 weeks, we have the patient begin working on slowly regaining extension at a rate of 10 to 20 degrees per week. Reeducation of the transferred latissimus dorsi muscle is accomplished initially by simultaneous shoulder extension and elbow flexion. Eventually, the patient will be able to flex the elbow in any shoulder position. Biofeedback by means of EMG is useful during postoperative reeducation of the transferred muscle. Later, exercise against resistance will produce powerful flexion of the elbow.

Complications. Weakness of elbow flexion may occur if the latissimus was partially denervated by the original plexus injury or if tensioning of the transfer was inadequate. Revision of the transfer tension may be performed at a later date.

Expected Outcomes. The outcomes reported are all from small patient series or case reports.[10,26,101] Zancolli and Mitre reported on eight patients who underwent bipolar transplantation of the latissimus dorsi.[216] The total arc of active flexion ranged from 105 to 140 degrees, and flexion strength varied from 0.7 to 5 kg. Flexion contractures of 10 degrees and 15 degrees occurred in two, and active supination of 20 to 50 degrees was achieved in six. Moneim and Omer achieved satisfactory flexion (100 degrees or more) in three of five patients.[147] The other two initially had paralysis of the latissimus dorsi and achieved only 65 to 70 degrees of flexion. Preoperative EMG evaluation of the muscle and the presence of normal (grade 5) strength were recommended. Botte and Wood noted satisfactory function in four of five patients treated by unipolar or bipolar latissimus dorsi transfer; flexion averaged 87 degrees (range, 35 to 130 degrees).[27]

Pectoralis Major Muscle Transfer. Both unipolar transfer and bipolar transfer of the pectoralis major have been reported. Our preference is the use of bipolar transfer without a fascial graft.[33,180]

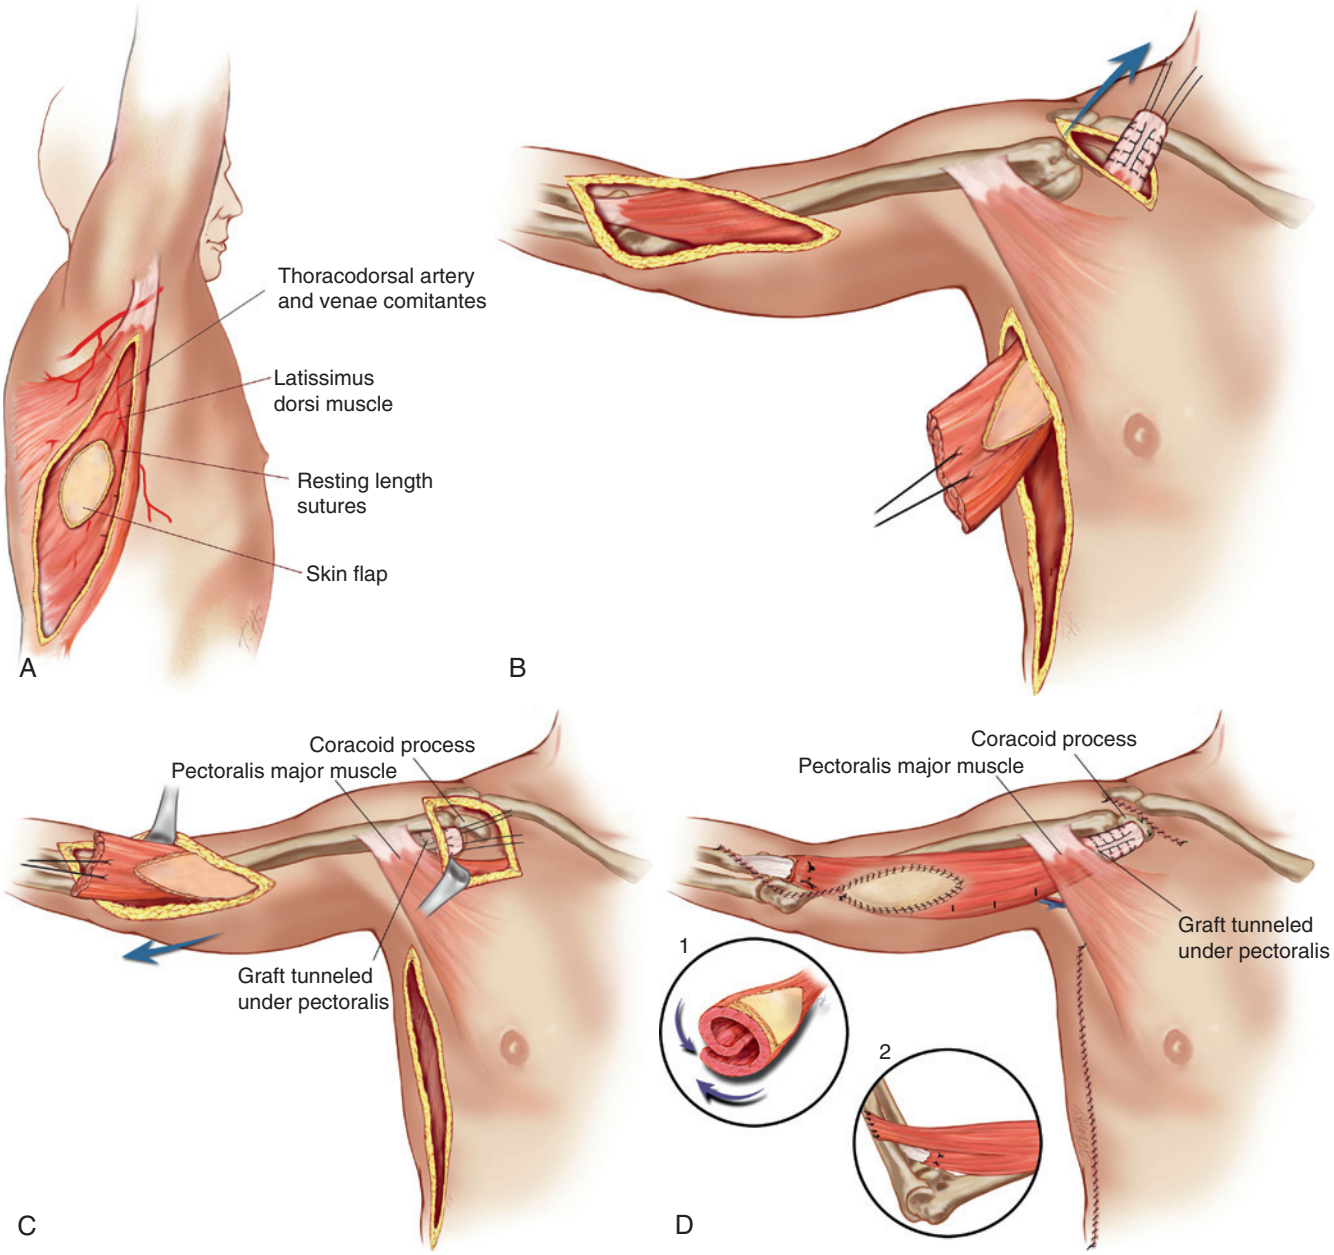

FIGURE 34.52 Pedicled bipolar latissimus transfer for elbow flexion. **A,** The latissimus is outlined, and an anteriorly based skin paddle is designed on the muscle. The flap is based on the thoracodorsal artery and vein and is innervated by the thoracodorsal nerve. With the arm abducted fully, sutures are placed in the muscle every 10 cm to assist in determining the resting length of the muscle. **B,** The latissimus is mobilized, the proximal origin is detached from the humerus, and the distal insertion is dissected free. Krackow-type sutures are placed in the proximal tendon. **C,** A tunnel is created under the pectoralis muscle large enough to pass the latissimus muscle. When passing the muscle, care must be taken not to twist or kink the vascular pedicle. The proximal latissimus tendon is sewn to the coracoid with heavy nonabsorbable sutures, and a tunnel (or open incision) is created on the anterior arm to the level of the biceps tendon attachment. **D,** The distal latissimus muscle is tubularized (1) and sewn into the biceps tendon and/or ulna (2). It is tensioned by using the previously placed sutures described in **A**. The skin paddle is used to assist in skin closure and as a monitor for the viability of the latissimus. (With permission of Milan Stevanovic.)

Operative Procedure. Prerequisites for this technique are that the sternocostal portion of the pectoralis major muscle be of normal strength and the elbow have full passive range of motion.[187]

Complete bipolar transplantation of the pectoralis major. The bipolar transfer was described by Carroll and Kleinman (Figures 34.53 and 34.54).[40] The patient is placed in the supine position with a flat bolster under the blade of the scapula and the upper extremity draped free. A long, curvilinear incision is made along the anterior thorax from the seventh sternocostal joint proximally to two fingerbreadths inferior to the clavicle. The incision continues laterally to the coracoid process and then distally along the anteromedial aspect of the arm to the level of the axilla. Alternatively, an inframammary incision may be used and extended proximally in the anterior axillary line. The muscle is exposed subcutaneously by elevating a large flap

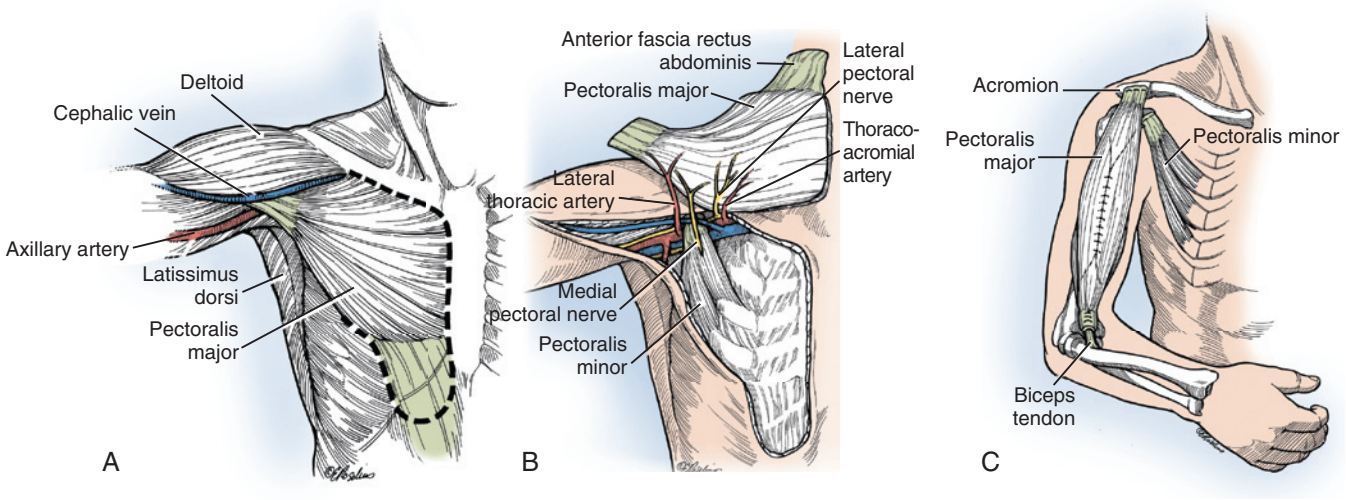

FIGURE 34.53 Authors' preferred method of transfer of the pectoralis major for elbow flexion. **A,** The entire mass of the pectoralis major muscle is detached from the clavicle, sternum, and ribs while taking a portion of the anterior rectus fascia. Note the *dashed line* indicating the border of the transplant. **B,** The pectoralis major muscle with the anterior fascia of the rectus is elevated based on branches of the thoracoacromial artery and veins and innervated by the medial and lateral pectoral nerves. **C,** The humeral attachment of the pectoralis major muscle is sutured to the acromion, and the origin of the pectoralis major along with the anterior rectus fascia is sutured to the biceps tendon. CRITICAL POINTS *Latissimus Dorsi Transfer for Elbow Flexion*

Indications
- Insufficient elbow flexion more than 6 to 9 months after Erb (C5-C6) paralysis
- Chronic, isolated paralysis of the musculocutaneous nerve
- Adequate latissimus dorsi strength

Preoperative Evaluation
- Assess the strength of the latissimus dorsi muscle.

Pearls
- During dissection, inclusion of superficial fascia with muscle facilitates fixation of the muscle origin. Ligation of multiple thoracodorsal perforators improves its mobility and helps prevent kinking.
- Appropriate tensioning and careful postoperative care optimize results.
- Reliable recovery and satisfactory power of elbow flexion are achieved when latissimus function is nearly normal.
- Flexion contractures of the elbow are unusual.

Technical Points
- Bipolar transfer is preferred.
- Use the lateral decubitus position with the extremity draped free.
- Harvest the entire latissimus dorsi from the fascial origin of the ilium to the humeral insertion through a longitudinal incision along the anterior muscle border.
- Dissect and protect the thoracodorsal neurovascular pedicle.
- Transfer the muscle subcutaneously beneath the axilla to the upper part of the arm through a deltopectoral incision.
- Pass the muscle beneath a subcutaneous skin bridge to the elbow. Suture the fascial origin of the muscle to the biceps tendon.
- Tension is adjusted by suturing the humeral attachment of the muscle to the coracoid process in 100 degrees of elbow flexion.
- Close the skin.

Pitfalls
- It is difficult to estimate the strength of the latissimus dorsi muscle.
- Distal repair and tensioning can be difficult.

Postoperative Care
- Immobilize the elbow in 100 degrees of flexion and the shoulder in 30 degrees of flexion and abduction with a shoulder pillow type of splint for 4 weeks, followed by a sling and gradual stretching/strengthening for an additional 4 to 5 weeks.

of skin and breast with either approach. Once the acromion and the entire pectoralis major muscle are exposed, a second curvilinear incision is made over the antecubital fossa with its transverse limb across the fossa and the longitudinal limb extending medially and distally for 6 cm. The entire pectoralis major muscle is detached from its origin along the medial half of the clavicle and its sternocostal border. A 12- by 6-cm strip of anterior rectus abdominis fascia is included and used to create a distal tendon of insertion. Care must be taken during dissection to avoid injury to both the lateral and medial pectoral neurovascular bundles, which are easily damaged.[187] The lateral pectoral nerve lies close to the costal margin of the muscle proximally and the deltopectoral groove laterally and passes in proximity to the thoracoacromial trunk. The medial pectoral nerve lies deep to the pectoralis minor muscle; it supplies small but powerful muscular branches that penetrate the pectoralis minor to reach the pectoralis major.

The entire muscle mass is carefully rotated 90 degrees on its two neurovascular pedicles. Distally, the rectus fascia with adjacent muscle is rolled into a tube and secured and reinforced with nonabsorbable suture. The muscular origin and attached rectus sheath are directed through the subcutaneous tunnel to the incision in the antecubital fossa. With the elbow flexed 135 degrees, the fascial tube is secured to the biceps tendon with

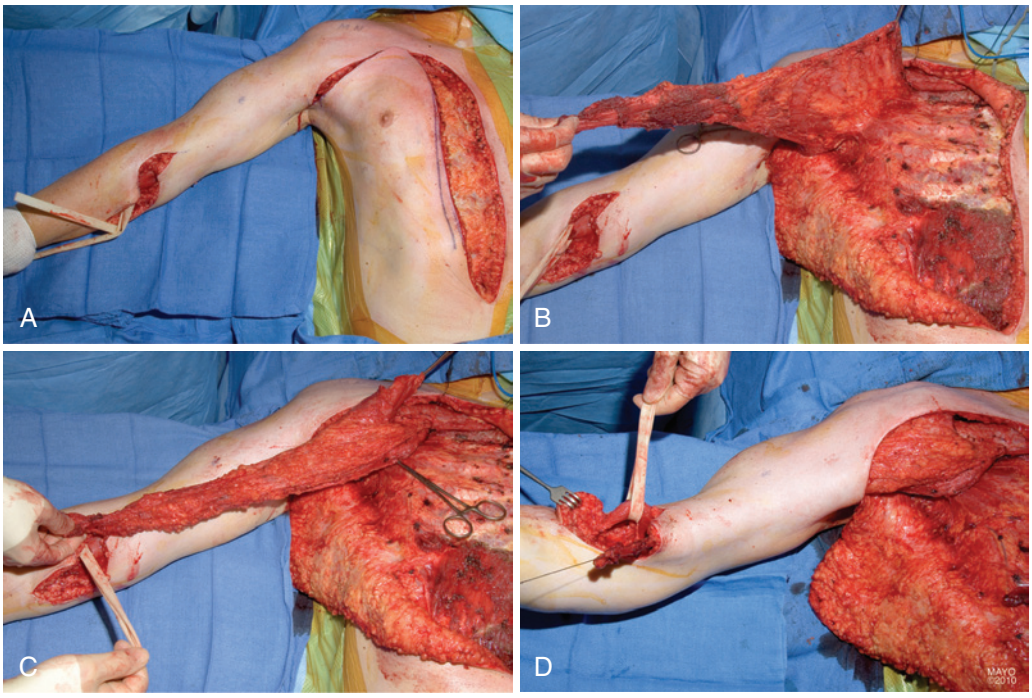

FIGURE 34.54 Transfer of the pectoralis major for elbow flexion. **A,** Skin incisions include an extensive incision that starts in the axilla, curves across the chest, and heads caudad to the level of the ipsilateral rectus abdominis. A second incision is made to expose the antecubital fossa and the biceps tendon. **B,** The two heads of the pectoralis major are carefully dissected while preserving the neurovascular bundles. Additionally, a long fascial strip from the rectus is taken to extend the transfer (held in the fingers of the surgeon's hand). **C,** The anterior rectus sheath is being entubulated before being sutured to the biceps tendon. The proximal humeral attachment is secured to the clavicle. **D,** A tunnel is created and the muscle is passed between the two incisions. The pectoralis major is then sutured distally to the biceps tendon. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

CRITICAL POINTS *Pectoralis Major Muscle Transfer for Elbow Flexion*

Indications
- Neglected cases or residual C5-C6 or musculocutaneous paralysis or paresis

Preoperative Evaluation
- Manual muscle testing of both the sternocostal head (innervated by the medial pectoral) and clavicular head (innervated by the lateral pectoral) of the pectoralis major

Pearls
- Inclusion of anterior rectus fascia simplifies connection to the biceps tendon of insertion.
- Results are dependent on normal function of the medial pectoral nerve.

Technical Points
- Supine position
- Curved longitudinal skin incision from the anterior aspect of the chest to the axilla and upper part of the arm
- Elevation of the entire clavicular, sternal, and costal origin with the anterior rectus sheath
- Protection of the medial and lateral pectoral nerves during mobilization
- Bipolar transfer of the origin to the elbow and the insertion to the acromion
- Suturing of the humeral attachment to the acromion under tension

Pitfalls
- Weak tension when suturing the muscle
- Relative cosmetic contraindication in women

Postoperative Care
- Immobilization of the elbow in 100 degrees of flexion and the shoulder in 60 degrees of flexion and abduction with a pillow for 4 weeks, followed by a sling and gradual extension for 4 to 5 weeks

nonabsorbable sutures. The tendon of insertion is directed proximally and anchored securely to the anterior acromion with nonabsorbable sutures through drill holes.

Postoperative Protocol. Postoperative immobilization and rehabilitation after pectoralis major muscle transfer are the same as for latissimus dorsi transfer.

Expected Outcomes. Botte and Wood reported satisfactory results in all five patients who underwent bipolar pectoralis major transfer but cautioned against using it in women because of the cosmetic disfigurement.[27] Matory and associates transferred the lower sternocostal segment of the pectoralis major in seven patients and achieved a functional range of elbow flexion (mean, 98 degrees) in all.[136] Loss of extension was just 15 to 25 degrees, and sustained flexion strength averaged 8 lb. Tsai and others performed a modified bipolar transplantation of the pectoralis major (with the lateral half of the clavicular origin

left intact), supplemented with a unipolar transfer of the pectoralis minor, in four patients.[203] Three of the four achieved excellent results (full extension with at least 60 degrees of flexion), and the other patient required a secondary Steindler flexorplasty.

Complications. Doyle and associates reported on two patients in whom transient nerve palsy developed after pectoralis major transfer, one median and one radial nerve palsy.[70] Both problems resolved completely after several weeks. Simultaneous contraction of the triceps, when the elbow is flexed, by the transposed pectoralis major has been reported.[180] All three patients had brachial plexus injuries and initially had paralysis of the triceps and elbow flexors. Axonal confusion after regeneration seems to be the probable explanation, but the complication cannot be predicted.

Free Muscle Transfer for Elbow Flexion in Delayed Cases

Indications. In the complete or upper type of brachial plexus injury, FFMT is indicated to restore elbow flexion when no local muscles of adequate strength are available for tendon transfer or when nerve transfer to the elbow flexors is inadvisable because of chronicity or muscle damage. The operation is technically more difficult in very young, small children and less successful in older individuals. Satisfactory results are not usually obtained in patients older than 65 years because of poor reinnervation of the transferred muscle. Other problems such as elbow joint damage, capsular contractures, vascular injury, poor soft tissues or skin coverage, and systemic injury or illness may limit the indications for this procedure, as well.

Vascular injuries to the subclavian artery, in particular to the thoracoacromial trunk, are a relative contraindication. Dissection through dense scar tissue in proximity to a subclavian artery injury or arterial reconstruction is technically challenging. If attempted at all, surgical confirmation of adequate vessels to permit microvascular anastomoses to the free functioning muscle is required before muscle harvest, and a vascular surgery team should be available in the operating theater if needed. If adequate arterial and venous sources cannot be identified, the muscle transfer should be aborted.

Donor Nerve Selection. Selection of the donor nerve depends on the availability of functioning nerves after the brachial plexus injury and any subsequent attempt at reconstruction. For late reconstruction of elbow flexion, the spinal accessory nerve is our donor motor nerve of choice (Figure 34.55). Proximal intercostal motor nerves (third to sixth ribs) are also commonly used because their position relative to the axilla permits direct transfer with sufficient length. We have found the results of these sources to be equivalent in ultimate strength and time to reinnervation of the muscle.[14] When these proximal intercostal nerves have already been used, more inferior intercostal nerves can be harvested. In C5-C6 or C5-C7 paralysis, the ulnar nerve offers an excellent option as a donor motor nerve for innervated muscle transfer.[94] In rare instances, other options may be considered, such as the use of a regenerated local nerve or contralateral C7 transfer.

Donor Muscle Selection. When selecting a functioning free muscle, one must consider its vascular and nerve innervation, cross-sectional area (a measure of ability to do work), and fiber length and excursion (to determine adequate excursion), all in comparison with the biceps brachii parameters.[60] The muscle must also be expendable, with minimal donor site morbidity. It

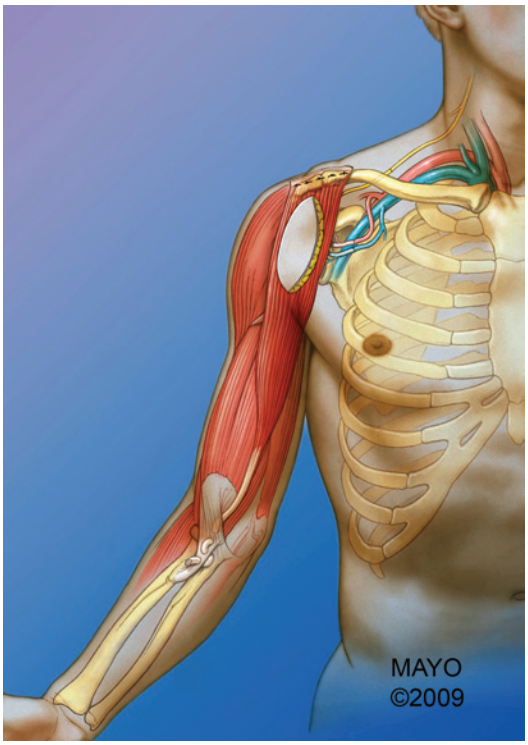

FIGURE 34.55 Free functioning muscle transfer for elbow flexion in a patient who was initially seen late after injury. In this illustration the spinal accessory nerve is transferred to the gracilis motor branch. Alternatively, intercostal nerves can be used, depending on the availability of nerve sources. The thoracoacromial vessels are used for the vascular repairs. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

can be expected to function best when used for a single purpose, but it may be used to both flex the elbow and extend the wrist, for example. A variety of muscles have been used as FFMTs, but the gracilis is certainly the most commonly used. The rectus femoris and latissimus dorsi are occasionally selected.

Operative Procedure. The technique is previously discussed in this chapter.

Expected Outcomes. More than 90% of patients who have undergone FFMT for elbow flexion have recovered more than 90 degrees of elbow flexion after transfer of the spinal accessory nerve or intercostal nerves.[45,64] Patients older than 40 years did not consistently recover comparable degrees of elbow flexion despite successful reinnervation to the transferred muscle. The final quantitative assessment of muscle strength showed 10% to 20% of the mean values of normal elbow flexion more than 2 years after surgery.

Wrist Arthrodesis. Nerve reconstruction for brachial plexus injury seldom restores function of the extrinsic wrist and finger motors. Recovery of grasp, whether spontaneous or the result of FFMT, may also be impaired by wrist extensor paralysis. When tendon transfer is not possible because of the lack of available motors (generally the case in adult traumatic plexus injury), the wrist may be supported with splintage. Long-term use of splints is often poorly tolerated and may result in skin breakdown over insensate skin. A wrist arthrodesis in these instances can be of benefit (see Chapter 12).

CRITICAL POINTS ***Free Muscle Transfer for Elbow Flexion***

Indications
- Delayed treatment (>6 to 9 months after injury)
- Failed cases after nerve grafting or nerve transfer
- Patients younger than 40 years

Preoperative Evaluation
- Available donor nerves and recipient vessels for vascular anastomosis
- Available expendable donor muscle
- Stable or reconstructible shoulder joint
- Supple elbow, adequate soft tissue envelope

Pearls
- Ischemic time should be kept to less than 60 minutes.
- Two teams (one for harvest and one for preparation of the recipient site) optimize surgical time.

Technical Points
- Minimization of ischemic time by ligating the muscle vascular pedicle only when the recipient site is fully prepared and the microscope is positioned for repair
- Proximal muscle fixation to the clavicle followed immediately by end-to-end or end-to-side microvascular anastomoses to the recipient artery and vein
- Direct transfer of the donor nerve to the FFMT motor nerve without an intervening graft
- Suture of the distal attachment of the muscle in its correct tension

Pitfalls
- Prolonged ischemia time
- Suture of tendons with incorrect tension

Postoperative Care
- Immobilization of the shoulder and elbow for 6 weeks. External rotation of the shoulder should be neutral with the elbow flexed 90 degrees.

NEUROPATHIC PAIN MANAGEMENT

Last, but not least, is the management of neuropathic pain in patients with traumatic brachial plexus injuries. Despite interventions to improve or restore function in the affected upper extremity, neuropathic pain may remain an important problem; the quality of life of patients with chronic neuropathic pain is significantly reduced. In patients with traumatic brachial plexus injury, the development of severe intractable neuropathic pain is highly variable. For example, intractable pain is very rarely reported to develop in Asian patients, whereas severe neuropathic pain develops in many American and European patients. Pain will develop in up to 80% of patients with a traumatic brachial plexus injury and will persist in 20%.[217] The pathogenesis of the pain is not well understood but may include postganglionic neuromas in some patients and central mechanisms of deafferentation pain attributed to segmental hyperactivity in the dorsal horn cells in patients with avulsion injuries.

Effective management of neuropathic pain in these patients requires (1) early recognition and treatment, (2) a multidisciplinary team, and (3) identification and targeting of physiologic as well as social and psychological factors. Nonsurgical options include psychosocial interventions (such as counseling, relaxation therapy, biofeedback, and support groups), rehabilitation (such as physical therapy and desensitization), and pharmacotherapy (combination of antidepressants, anticonvulsants, and analgesics). If the pain remains intractable over time despite aggressive nonsurgical management, surgical options should be considered. In some patients with postganglionic injury, neurolysis, neuroma resection, or nerve grafting of affected neural elements (or any combination of these therapies) may afford some relief of pain. Patients with root avulsions and chronic neuropathic pain may be candidates for radiofrequency destruction of the dorsal root entry zone (DREZ lesioning) of affected levels. With careful patient selection and adequate technique, the success rate can be as high as 66% to 90% at 4-year follow-up,[163,182] but it tends to decrease to 50% with longer follow-up.[44] Finally, central nervous system neuromodulation therapies such as spinal cord, motor cortex, or deep brain stimulation are increasingly being used by some groups to treat refractory neuropathic pain and can be considered.

Embryology of the Upper Extremity

Scott H. Kozin

Congenital anomalies affect 1 to 3% of newborns, and approximately 10% of these children have upper extremity abnormalities.[16,42] The incidence of congenital anomalies has not changed appreciably over the last decade. Congenital limb anomalies are second only to congenital heart disease in the incidence of birth malformations.[6] Most anomalies occur spontaneously or are inherited.[57] Few malformations are attributed to teratogens.[21,41,56] Limb anomalies can be produced in animal models; this has increased our knowledge of and insight into limb development.[34]

Recent advancements in understanding limb anomalies are directly related to our increased understanding of embryogenesis. Knowledge of hominoid limb development has been greatly expanded by the experimental embryologists. Animal models with limb patterning similar to that of humans have been used to dissect and manipulate crucial signaling centers that affect limb development and orientation.[48,49,55] Research on gene misexpression and loss of function has enhanced our understanding of limb formation.[6,48] There is intense work focusing on genotype-phenotype correlations that may have substantial clinical implications. The hand surgeon is uniquely positioned between clinical care and genetic research. He or she must possess a basic comprehension of embryogenesis and limb formation to comprehend congenital limb anomalies and to communicate relevant knowledge to the family of an affected child. Parents may initially bear a tremendous amount of guilt, and the role of disseminating information is the responsibility of the physician caring for the family.

EMBRYOGENESIS

Limb development begins during embryogenesis with events that affect the position and orientation of each limb and the number of limbs that appear (Table 35.1).[39] The limb bud is first visualized at 26 days after fertilization when the embryo is about 4 mm in length (crown-rump length), or about the size of a piece of rice.[62,66] The bud rapidly develops through 47 days of life until the embryo is close to 20 mm in length, or the size of a lima bean. Fifty-two to 53 days after gestation, the embryo is 22 to 24 mm long and the fingers are entirely separate.[30] Eight weeks after fertilization, embryogenesis is complete and all limb structures are present.[6,49,55] At this point, the joints form as condensation of the chondrogen creates dense plates between future bones.[11] Joint cavitation further forms the articulation, although proper joint development requires motion for modeling of the ultimate joint surface. Most upper extremity congenital anomalies occur during this 4- to 8-week period of rapid and fragile limb development. After 8 weeks' gestation, the fetal period commences, with differentiation, maturation, and enlargement of existing structures.

The limb bud represents an outgrowth of the mesoderm into the overlying ectoderm. Two sources of cells migrate from their origins into the limb bud.[6,11] The cells from the lateral plate mesoderm become bone, cartilage, and tendon. The cells from the somatic mesoderm form the muscular, nervous, and vascular elements of the limb bud (Figure 35.1).

In order to comprehend limb development and to explain it to families, the physician must appreciate the signaling centers that control the three spatial axes of limb development: proximodistal, anteroposterior, and dorsoventral.[11] Each of these limb growth axes contains a signaling center (i.e., a group of cells) that is responsible for establishing the corresponding axes; they are the apical ectodermal ridge (AER), the zone of polarizing activity (ZPA), and the Wingless type (Wnt) signaling centers (Table 35.2).[6,49,55] A coordinated effort between the AER, ZPA, and Wnt pathways is necessary for proper limb patterning and axes development.[11,22,36] The three signaling centers are interdependent, so that the loss of one signal results in compromise of the entire system.[44] There is considerable cross talk between these signaling pathways during limb development.

Programmed cell death plays an important part in limb development. Programmed cell death is an active process that is genetically controlled to eliminate unwanted cells during embryogenesis.[10] Apoptotic cells undergo a degeneration process with DNA fragmentation and are eventually engulfed by phagocytic cells. Genetic control of cell death is necessary during limb bud formation. For example, the digits initially develop as webbed fingers. Extraneous tissue between fingers must undergo apoptosis and interdigital necrosis for finger separation. Failure of interdigital apoptosis results in syndactyly.[65] Interestingly, bone morphogenetic proteins (BMPs), widely recognized for their role in chondrogenesis and osteogenesis, trigger apoptotic pathways of the interdigital mesenchyme to produce separated fingers.[10] BMP antagonist can

TABLE 35.1 Key Milestones in the Development of the Human Upper Limb*

Week	Day	Upper Limb	Lower Limb
4	24	Swelling appears in region of upper limb bud	
	28	Scattered blood vessels	Appearance of lower limb bud
5	32	Upper limb AER	
		Early marginal vessel	
		Early brachial plexus development	
	33	Hand plate appears	Lower limb AER
		Humeral mesenchymal condensations	
6	37	Humeral chondrification	Lumbosacral plexus
		Radial and ulnar mesenchymal condensations	
		Brachial plexus with radial, median, and ulnar nerves to the elbow	
		Early muscle masses	
	41	Finger rays (webbed)	Mesenchymal condensations of femur, tibia, fibula, and tarsus
		Radial, ulnar, and metacarpal chondrification	
7	44	Interdigital apoptosis	Chondrification of femur, tibia, and fibula
		Scapular and humeral head chondrification	
		Chondrification of carpals and proximal phalanges	
		Trapezius innervated (accessory nerve)	
		Major muscles distinguishable	
	48	Chondrification of middle phalanges	
		Shoulder and elbow interzones (joint cavity formation)	
8	51	Chondrification of distal phalanges	
	52	Ossification of humerus	
		Ossification of radius	
		All muscles distinguishable	
		Wrist and carpal interzones	
	54	Ulnar ossification	Ossification of femur and tibia
	57	Scapular ossification	Ossification of fibula
		Intramembranous ossification of distal tip of distal phalanges	Chondrification of tarsus and digits

AER, Apical ectodermal ridge.

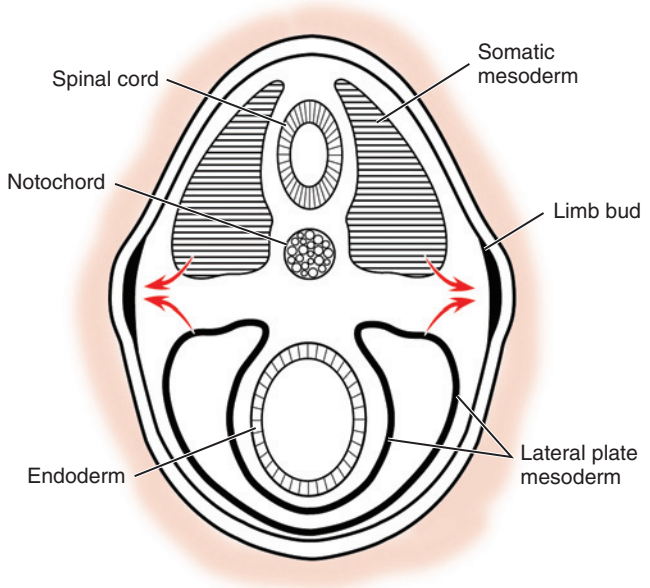

FIGURE 35.1 Axial view of an embryo. The lateral plate mesoderm forms the bone, cartilage, and tendon, and the somatic mesoderm forms the muscle, nerve, and vascular elements of the limb. (Adapted from Riddle RD, Tabin C: How limbs develop. *Sci Am* 280:74–79, 1999.)

block BMP signaling and prevent apoptosis and interdigital necrosis. For example, bats have web limbs, and BMP is blocked during their limb embryogenesis.[40] Similarly, altered signaling of fibroblast growth factors, such as occurs in Apert syndrome, can negate BMP-mediated apoptosis, resulting in syndactyly (Figure 35.2).

Spatial Axes of Limb Development and Their Signaling Centers

Proximodistal Limb Development

The limb develops in a proximal to distal direction, with the shoulder forming before the elbow and the elbow before the wrist. This progression is controlled by the AER, a thickened layer of ectoderm that condenses over the limb bud.[11] This signaling center guides the underlying mesoderm to differentiate into appropriate structures.[6,49] Removal of the AER results in limb truncation, and ectopic implantation of the AER causes additional limbs to form (Figures 35.3 and 35.4).[11,49,61,66] The secreted proteins within the AER that yield this effect are fibroblast growth factors.[28,37] In fact, removal of the AER can be overcome by application of fibroblast growth factors (Figure 35.5). Mice deficient in various fibroblast growth factors have complete transverse limb defects.[15,38,54]

When explaining this to a parent, we can say that we know the AER was not physically removed. However, we do have evidence to suggest that bleeding or ischemia within the AER resulted in its failure to work properly.[17]

Transverse deficiencies are usually sporadic without any underlying reason. Concern for teratogen exposure is raised when multiple limbs are involved, suggesting a widespread insult to all developing limb buds. Transverse differences are not inheritable, and future children are unlikely to be affected.

Anteroposterior Limb Development

The limb also develops in an anteroposterior (i.e., radioulnar or preaxial-postaxial) direction. The ZPA resides within the posterior margin of the limb bud and functions as a signaling center for anterior to posterior limb development.[6,48] This signaling pathway polarizes the limb into a radial margin and an ulnar border.[60] The signaling molecule within this pathway is the sonic hedgehog compound.[48] Transplantation of the ZPA or sonic hedgehog protein causes mirror duplication of the ulnar

TABLE 35.2 Signaling Pathways During Embryogenesis

Signaling Center	Responsible Substance	Action	Anomaly
Apical ectodermal ridge	Fibroblast growth factors	Proximal to distal limb development, interdigital necrosis	Transverse deficiency
Zone of polarizing activity	Sonic hedgehog protein	Radioulnar limb formation	Mirror hand
Wnt pathway	Transcription factor, Lmx-1	Ventral and dorsal limb axis	Nail patella syndrome, abnormal nail and pulp arrangement

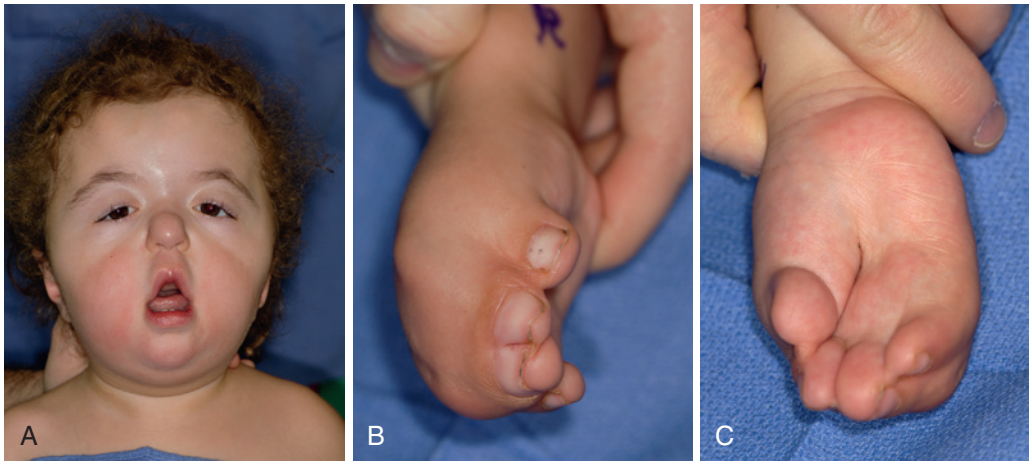

FIGURE 35.2 Two-year-old with Apert syndrome. **A,** Typical facies. **B,** Dorsal view of right hand with severe syndactyly, including web between thumb and index finger. **C,** Palmar view of right hand with deep crevasses. (Courtesy of Shriners Hospital for Children, Philadelphia.)

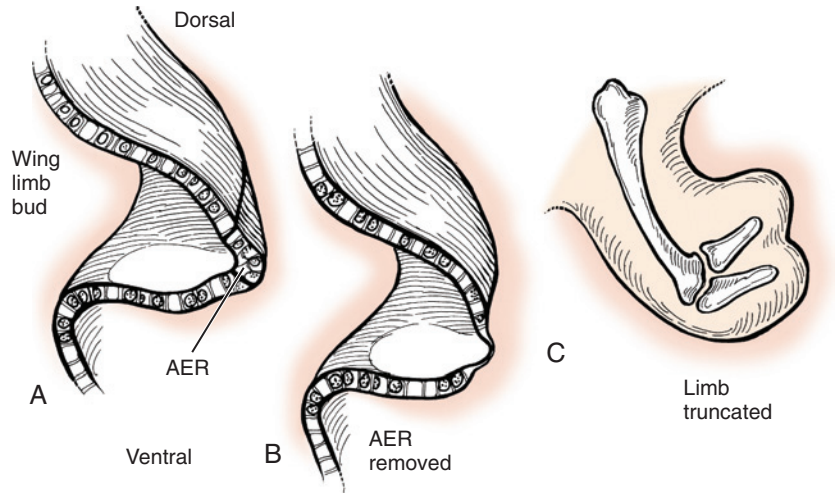

FIGURE 35.3 Removal of the apical ectodermal ridge (AER) from the developing limb bud results in limb truncation. (Adapted from Riddle RD, Tabin C: How limbs develop. *Sci Am* 280:74–79, 1999.)

aspect of the limb (Figure 35.6).[11] The extent of duplication is dose dependent, and greater transference results in more replication (Figure 35.7).[59] This explains the variable numbers of fingers and different phenotypes of mirror hands (Table 35.3).[3] Mutant mice that express sonic hedgehog protein in the anterior limb bud are polydactylous, with duplication of their ulnar digits.[29] Triphalangeal thumbs arise secondary to point mutations resulting in ectopic sonic hedgehog compound at the anterior margin of the limb bud.[23]

Sonic hedgehog compound is also expressed in a gradient fashion, and the duration of exposure of a digit to it determines the identity of the digit. The anterior digits (index and long fingers) are exposed for the shortest time, and the small digit is exposed for the longest time.[27,52]

FIGURE 35.4 Short below-the-elbow transverse deficiency with residual nubbins attributed to loss of apical ectodermal ridge function. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Dorsoventral Limb Development

Dorsoventral limb development, or the process of differentiation between the dorsum of the finger with a fingernail and the volar surface abundant with pulp tissue, is not as well understood.[11] The Wnt signaling pathway resides in the dorsal ectoderm and controls this spatial development. The pathway produces a transcription factor, Lmx-1, which induces the mesoderm to adopt dorsal characteristics.[47] In the ventral ectoderm, the Wnt pathway is blocked by a product of the gene Engrailed-1 (En-1). Mice lacking the Wnt pathway have ventralization of the dorsal surface (i.e., biventral limbs with palmar pads on both sides of the foot).[20,43] In contrast, mice lacking Engrailed-1 develop dorsalization of the volar surface (i.e., bidorsal limbs).[25]

Differences affecting this pathway are relatively rare. Loss of Lmx-1 is associated with nail patella syndrome.[14] Occasionally, children will present with anomalies that have an extraneous nail or abnormal pulp development. These abnormalities are related to the Wnt signaling pathway and occur sporadically without any definable cause.[2]

Musculoskeletal System Development

The muscular blastema and the chondrogenic blastema form the muscles and bones, respectively.[4] The chondrogenic blastema is located in the central portions, where the oxygen tension is relatively low. The muscular blastema resides in the periphery, where the oxygen tension is higher. The muscles form sequentially from proximal to distal, separating from the muscular blastema. The chondrogenic blastema also forms from proximal to distal, with the cartilage undergoing ossification to form bones.

The joints form in interzones between the ends of two blastemas. A joint capsule surrounds the interzone, and the intervening blastemas undergo cavitation within the center of the interzone to produce a joint space. Joint fluid is produced within this space and cartilage caps the two ends of the bones. Failure of this process results in synostosis across the intended joint, such as a proximal radioulnar joint or an ulnohumeral

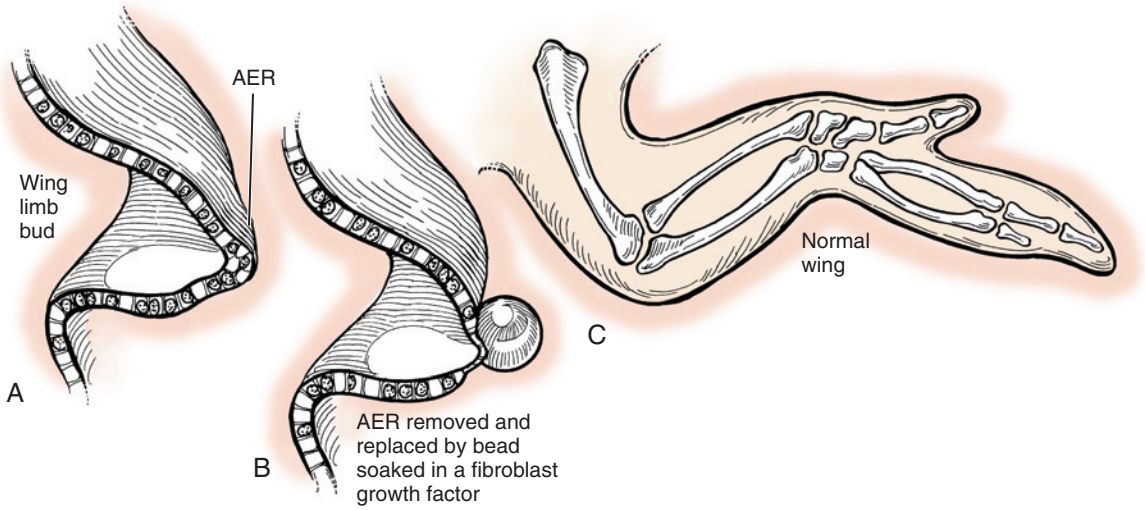

FIGURE 35.5 Removal of the apical ectodermal ridge (AER) and replacement with fibroblast growth factors can result in normal limb formation. (Adapted from Riddle RD, Tabin C: How limbs develop. *Sci Am* 280:74–79, 1999.)

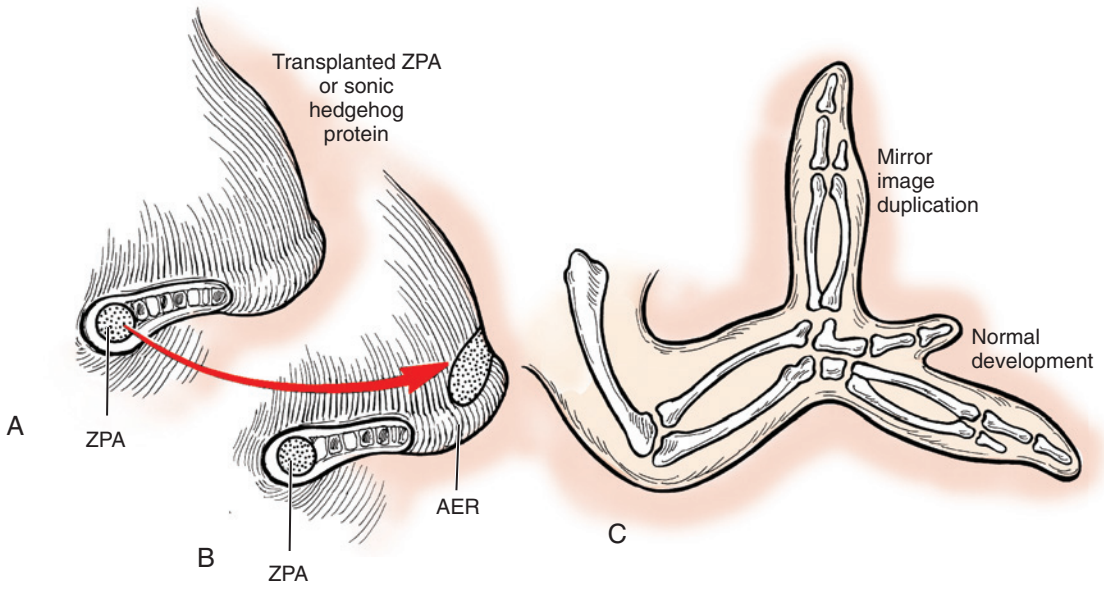

FIGURE 35.6 Transplantation of the zone of polarizing activity (ZPA) or sonic hedgehog protein causes mirror image duplication of the ulnar aspect of the limb. *AER,* Apical ectodermal ridge. (Adapted from Riddle RD, Tabin C: How limbs develop. *Sci Am* 280:74–79, 1999.)

FIGURE 35.7 Mirror hand with seven fingers explained by transplantation of the zone of polarizing activity or sonic hedgehog protein. (Courtesy of Shriners Hospital for Children, Philadelphia.)

joint (Figure 35.8). Motion is necessary to form a mobile functioning joint. In the absence of movement, such as arthrogryposis, the joint space is infiltrated by fibrous tissue, yielding an immobile joint (Figure 35.9).

Genes and Molecular Abnormalities

The spatial axis of limb development is only one aspect of limb formation. Mutations encoding signaling proteins, receptor molecules, and transcription factors can alter the normal limb arrangement and yield anomalies. The number of congenital anomalies seen by the practicing hand surgeon identifiable at the molecular level increases each year. Despite the accelerated pace of discovery, only a small number of limb anomalies have been mapped to specific chromosomal segments and are less defined at the molecular level.[6] Many of these differences, however, are genetically linked with variable patterns of inheritance. Accurate diagnosis is mandatory, and referral for genetic consultation warranted. Parents need appropriate counseling regarding the different expressions and phenotypes across the spectrum of a particular mutation. A continuing misconception is that an affected parent with a mild phenotype feels that his or her anomaly (heart and/or hand) is "not so bad and, therefore, my children will be fine like me." Based on this misperception, he or she proceeds with pregnancy, naïve to the concept of variable expression and inconsistent phenotypes. Subsequently, the affected child may be considerably more affected and the parents are not prepared to handle such

CRITICAL POINTS *Limb Bud Formation*

- Limb bud formation commences approximately 4 weeks after gestation begins and is complete by 8 weeks. The majority of limb anomalies occur within this time of rapid and fragile limb development.

Signaling Centers

- Three signaling centers control the spatial axes of limb development. The apical ectodermal ridge (AER) governs proximodistal limb formation, the zone of polarizing activity (ZPA) manages anteroposterior (i.e., radioulnar) limb formation, and the Wingless type (Wnt) signaling center directs dorsoventral limb formation.

Molecular Abnormalities

- The HOX and T-box genes encode transcription factors crucial for limb formation. Mutations within the HOX gene locus have been identified as the causes of synpolydactyly, hand-foot-genital syndrome, and Madelung deformity associated with Leri-Weill dyschondrosteosis. T-box gene abnormalities have been linked to Holt-Oram syndrome and ulnar-mammary syndrome.
- Cartilage-derived morphogenetic protein appears paramount to digital length; deficiencies have been associated with various forms of brachydactyly, such as Grebe and Hunter-Thompson chondrodysplasias.

involvement. Appropriate counseling prior to pregnancy can alleviate this misconception and educate the parents as to the facts surrounding inheritance rates and possible clinical findings.

The HOX and T-box genes encode transcription factors crucial for limb formation and exhibit some control over upper limb formation.[6,19,32,35,50,63] Abnormalities in HOX and T-box gene production alter limb constitution. The extent of malformation is related to the number and extent of gene irregularities.[6,13] HOX genes are important for the patterning of many tissues in the developing embryo. Mutations within the HOX gene locus have been identified as the cause of several types of human differences. Synpolydactyly and hand-foot-genital syndrome have been related to mutations within the HOX genes (Figures 35.10 and 35.11).[18,31,33,64] Madelung deformity associated with Leri-Weill dyschondrosteosis has also been connected

FIGURE 35.11 X-ray reveals concealed ring finger duplication with angular deformities. (Courtesy of Shriners Hospital for Children, Philadelphia.)

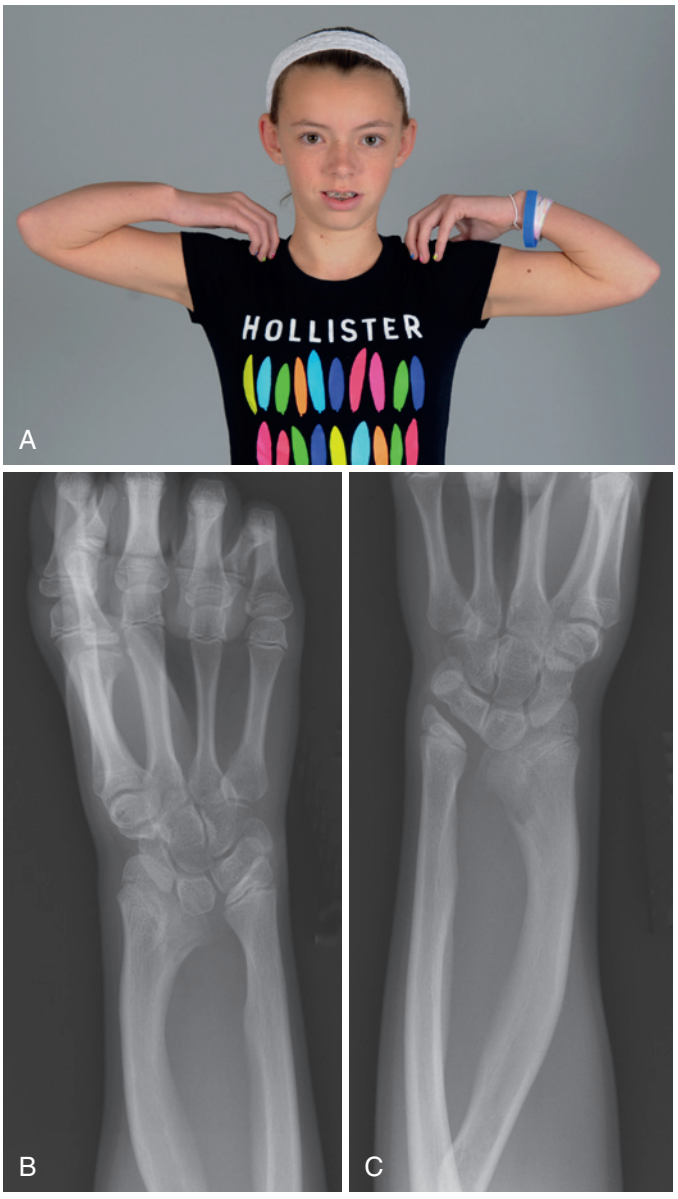

FIGURE 35.12 Twelve-year-old with short stature, bilateral shortened forearms, and Leri-Weill dyschondrosteosis. **A,** Clinical appearance of bilateral Madelung deformity. **B,** Left wrist radiograph with classic findings associated with Madelung deformity. **C,** Right wrist x-ray with similar findings. (Courtesy of Shriners Hospital for Children, Philadelphia.)

to HOX gene defects (Figure 35.12).[51] These three entities are autosomal dominant conditions, although Leri-Weill dyschondrosteosis affects females more severely. This information is critical to relay to affected families and justifies genetic counseling.

The T-box genes are a highly conserved family of transcription factors that govern both limb and organ system development.[1,9] Altered expression of T-box products can affect the anteroposterior (i.e., radioulnar) development of the limb. The combination of a cardiac defect and radial deficiency (e.g., Holt-Oram syndrome) has been specifically linked to the production of transcription factor Tbx5.[7,8,24] Holt-Oram syndrome is an autosomal dominant trait with variable phenotypes, and affected families would benefit from genetic counseling. T-box gene mutations have also been linked to limb anomalies associated with a variety of systemic syndromes, including ulnar-mammary syndrome (Tbx3 mutation), which is associated with postaxial limb anomalies.[5,6,46]

The family of BMPs are expressed in the developing limb.[11] Cartilage-derived morphogenetic protein appears paramount to digital length during embryogenesis. Deficiencies in a cartilage-derived morphogenetic protein are associated with various forms of brachydactyly. Grebe and Hunter-Thompson chondrodysplasias are associated with severe brachydactyly and have been directly related to a cartilage-derived morphogenetic protein deficiency (Figure 35.13).[45,58]

Systemic Considerations

During the period of embryogenesis, other organ systems are also developing and maturing. Errors affecting limb formation can also disturb formation of these systems. Certain upper limb anomalies are associated with concomitant systemic disorders (e.g., radial deficiency).[12,26] Other limb anomalies occur in isolation or are combined with other musculoskeletal problems (e.g., ulnar deficiency).[53] Some limb anomalies, such as central deficiency, can be associated with a systemic condition (EEC syndrome: triad of ectrodactyly, ectodermal dysplasia, and facial clefting) or can be linked to other musculoskeletal anomalies, such as lower limb hemimelia. Identifying anomalies that occur in isolation and anomalies associated with systemic ailments is mandatory. Many of the systemic illnesses are more important than the limb anomaly and require accurate evaluation to prevent life-threatening consequences.

The basic molecular events of hand formation are being discovered at a rapid rate. The complex interaction between signaling centers, genes, and molecular events complicates direct linkage between an abnormality and a particular limb

FIGURE 35.13 Hands of a child with Grebe chondrodysplasia and severe brachydactyly associated with a cartilage-derived morphogenetic protein deficiency. (Courtesy of Shriners Hospital for Children, Philadelphia.)

difference. In addition, variable amounts of gene and molecular damage result in innumerable different phenotypes. Application of this basic science knowledge to the clinical setting is a necessary linkage. The National Institutes of Health website provides a mechanism for keeping abreast of current knowledge. Links to the Online Mendelian Inheritance in Man database offer valuable information regarding genes and disease. This information is readily available, frequently updated, and invaluable when evaluating children with congenital deficiencies.

SYNDACTYLY

Syndactyly describes a variable fusion of the soft tissue or skeletal elements or both of adjacent digits, and it occurs when the normal processes of digital separation and web space formation fail to some degree. During normal development, the digits form as condensations of mesoderm within the terminal paddle of the embryonic upper limb. Spaces form between the fingers in a distal to proximal direction to the level of the normal web space by a process of regulated apoptosis.[140] This process is dependent on the apical ectodermal ridge and the molecular signaling of several cytokines, including bone morphogenetic proteins, transforming growth factor-β, fibroblast growth factors, and retinoic acid.[51,52,75,107,115] The normal web space slopes 45 degrees in a dorsal to palmar direction from the metacarpal heads to the midproximal phalanx (Figure 36.1). The second and fourth webs are wider than the third web, allowing greater abduction of the index and small fingers. The first web space is a broader diamond-shaped expanse of skin composed of the glabrous skin of the palm and thinner mobile skin dorsally.

General Considerations

Epidemiologic Findings

Isolated syndactyly is a common congenital anomaly of the hand, with an incidence of approximately 1 in 2000. It occurs bilaterally in 50% of cases. Between 10 and 40% of cases demonstrate a positive family history that is inherited as an autosomal dominant trait. Variable expressivity and incomplete penetrance account for the male predominance (2:1) and the variable phenotype that is often seen within a family pedigree. Syndactyly is also seen with other deformities, such as polydactyly, clinodactyly, brachydactyly, symphalangism, and synostosis, as part of a broader anomaly of a child's hand, either as a sporadic occurrence or as part of a syndromic association. In isolated syndactyly, the long finger/ring finger web space is most commonly affected (57%), followed by the ring finger/small finger web space (27%). Thumb/index finger and index finger/long finger web syndactylies are the least common. In syndromic cases, the thumb/index finger and index finger/long finger web spaces are relatively more frequently affected.

Pathologic Findings and Classification

The conjoined digits may show abnormalities of the nails, the digital neurovascular bundles, the skeleton, and the tendon systems. The skin envelope of the fused digits is inadequate to resurface the circumference of each independent digit. The abnormal underlying fascia has a continuous thickened, lateral digital sheet that spans the length of the syndactyly across the potential interdigital web space. Syndactyly is described as *complete* if the web space extends to include the fingertip and *incomplete* when the web space occurs anywhere between the normal commissure and the fingertips. *Simple syndactyly* has only skin or soft tissue connections (Figure 36.2). The joints are usually normal, and the flexor tendon and extensor tendon mechanisms are usually independent. The digital neurovascular anatomy is usually normal, although the bifurcation of the common digital structures may be distal to the level of a normal web. *Complex syndactyly* is marked by skeletal anomalies. The most common form of complex syndactyly is a side-to-side fusion at the distal phalangeal tuft level (Figure 36.3). This distal synostosis is usually reflected in a synonychia with loss of the paronychial fold and flattening of the nail matrix across the bony mass. *Complex complicated syndactylies* are those with accessory phalanges or digits interposed within the abnormal web space. The incidence of tendon and neurovascular abnormalities increases with the complexity of the syndactyly.

Preoperative Evaluation

When evaluating a patient with syndactyly, the important features to consider are which web space(s) is involved, the extent of the syndactyly, the involvement of the nail, and the presence of other anomalies. Lack of differential motion between the digits may indicate bony fusion or an extra digit, or both, concealed within the conjoined digits. Examination should include the entire upper limb, the contralateral hand, the chest wall, and the feet. Radiographs may reveal skeletal fusion, a concealed extra digit (synpolydactyly), or other bony or articular deformities. Further imaging with ultrasound or magnetic resonance imaging can be useful in determining the flexor tendon and vascular anatomy in complex cases.

Management Considerations

Syndactyly can have cosmetic, functional, or developmental impacts on the growing child. The appearance of the hand is

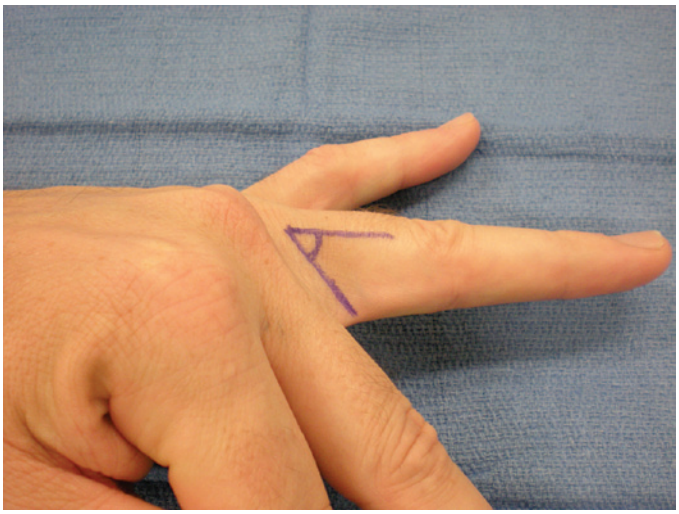

FIGURE 36.1 The normal web of skin slopes 45 degrees in a dorsal to palmar direction from the metacarpal heads to the level of the midproximal phalanx.

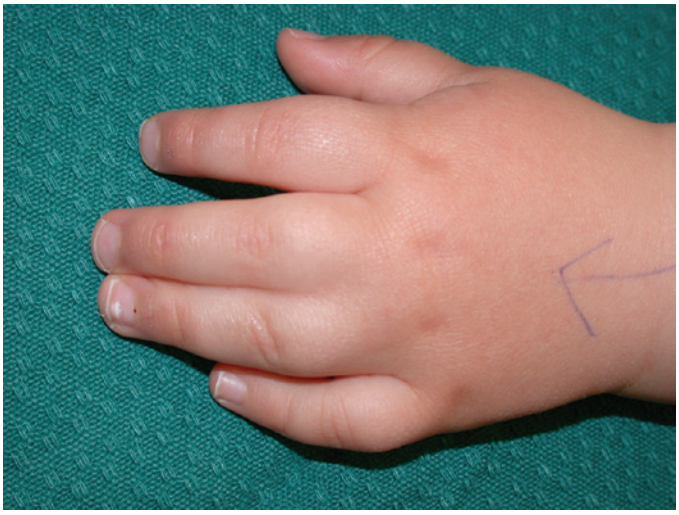

FIGURE 36.2 Simple and complete syndactyly between the third and fourth rays.

altered, more so with complete complicated forms of syndactyly. Syndactyly of the first web space hampers grasp and the development of pinch. Syndactyly of the second, third, and fourth web spaces inhibits independent digital motion, particularly abduction, and therefore reduces the span of the hand. Syndactyly between digits of unequal length causes tethering of the longer digit, which deviates toward the shorter digits and may also cause a flexion contracture at the proximal interphalangeal joint (PIP) that progresses with growth (Figures 36.4 and 36.5).

Surgery is indicated for most cases, but contraindications include mild incomplete syndactyly without functional impairment, medical conditions that preclude surgery, or complex syndactylies that risk further functional impairment with attempted separation. On occasion, there are insufficient components in the fused mass to produce independent, stable, and mobile digits (Figures 36.6 and 36.7). This situation typically arises in central brachysyndactyly or synpolydactyly, and separation risks reducing function.

FIGURE 36.3 Radiograph of complex syndactyly with distal skeletal fusion.

FIGURE 36.7 X-ray of complex syndactyly with fusion of adjacent phalanges that prohibits separation. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Several important surgical principles apply to the correction of syndactyly, including the timing of the procedure or procedures, staging the releases of multiple web space syndactylies, creation of a commissure, techniques of separation and resurfacing of the digits, and postoperative dressing and aftercare.

Timing of Surgery

Syndactyly release has been performed in the neonatal period[89] or during infancy, or it has been delayed until childhood. Long-term reviews by Flatt[63] and Ger[71] have shown better outcomes with release after 18 months, although early surgery may be dictated by progressive skeletal deviation or deformity.[97] The goal is to complete all the releases by school age. Syndactyly involving multiple web spaces requires staging of the release procedures because only one side of an affected digit should be released at a time to avoid vascular compromise of the skin flaps or digits. Syndactyly of all web spaces is usually treated in two stages. The first procedure separates the thumb/index finger and long finger/ring finger web spaces. Three months later, a second procedure separates the index finger/long finger and ring finger/small finger web spaces. In addition, the first procedure can be combined with isolated release of the fingertips and distal phalangeal fusions of all the digits to reduce the tethering effect between surgical procedures.

FIGURE 36.8 A proximally based rectangular flap from the dorsum of the syndactyly is the most frequently used method to reconstruct the commissure. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Commissure Reconstruction

A basic tenet of syndactyly release is reconstruction of the interdigital commissure with a local skin flap. The most frequently used methods incorporate a proximally based rectangular flap raised from the dorsum of the syndactyly (Figure 36.8).[18] Several modifications have been proposed, including a trapezoid-shaped dorsal flap or a dorsal flap supplemented with lateral wings used to resurface the digits adjacent to the commissure.[55,69,122,150] Alternative choices for commissure skin are available. Skin from the dorsum of the hand raised as an island flap can be advanced in a "V-Y" fashion into the web space.[40,147,161] The palmar surface of the syndactyly alone or in combination with the dorsal surfaces of the syndactyly can be introduced into the web space as opposing triangular flaps. Where the syndactyly is incomplete and restricted to the proximal digit, the web may be repositioned by deepening or lengthening the

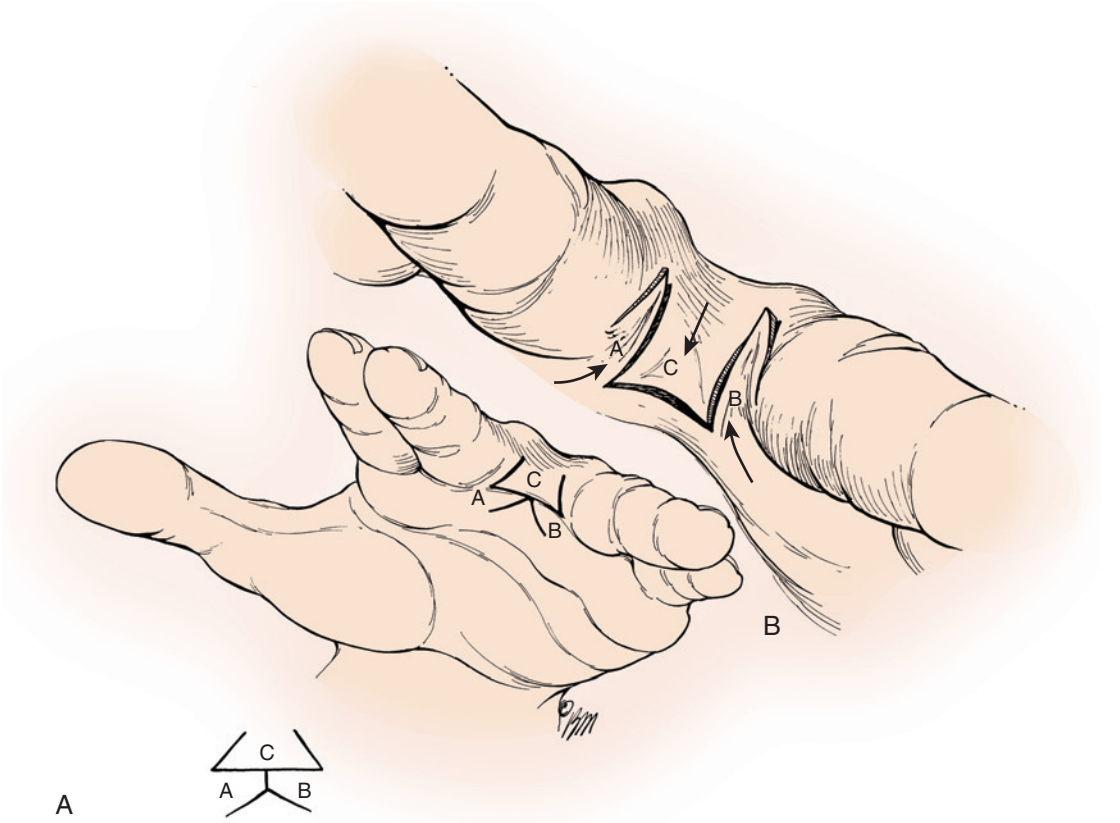

FIGURE 36.9 The double-opposing "Z"-plasty or butterfly flap is occasionally useful for mild degrees of web deepening. **A,** The palmar "V" of this flap may be given a stem to convert it to a "Y." **B,** The classic double-opposing "Z"-plasty and the flap transfers after mobilization. (Copyright © Elizabeth Martin.)

existing web alone by a simple "Z"-plasty, a four-flap "Z"-plasty, or a double-opposing "Z"-plasty (butterfly flap) (Figure 36.9). Other methods in this situation include combinations of local flaps, such as the three-flap web-plasty or an "X-M"-plasty.[53] Incomplete syndactyly can be deceptive, as there often appears to be an abundance of local skin available. However, following commissure reconstruction and transposition of the local flaps, a skin defect is common in the proximal digital surface, with excess skin located distally. Brennan has described a technique to address this situation by raising the distal skin as island flaps that are advanced in a proximal direction and combined with triangular flaps for commissure reconstruction.[29]

Syndactyly of the first web space presents a special problem and varies in extent. First web syndactyly is more common in syndromic disorders such as Apert syndrome and is often associated with a thumb deformity. It hampers hand function more severely than does syndactyly of the other web spaces. Mild to moderate first web space syndactyly can be treated with a local flap, such as a four-flap "Z"-plasty (Figure 36.10). Other options include a transposition flap from the index finger, a combination of transposition flaps from the radial and ulnar borders of the index and thumb, respectively, or a "V-to-Y" advancement of the central web.[42]

Severe syndactyly with marked thumb/index web narrowing may require more skin than is available in local flaps. In this situation, skin may be imported from the dorsum of the hand after tissue expansion[41] or as a rotation advancement flap (Figure 36.11).[40] Pedicled flaps such as the radial forearm[77] or free flaps from distant sites such as the groin can also be used.[84] Despite the complexity, free flaps import skin of excellent quality to the hand in cases of severe skin deficiency associated with syndromic syndactyly.

Separation and Resurfacing of the Digits

Release of syndactyly requires careful planning to optimize use of the available skin and to allow surgical exposure for separation of digits and structures. Incision design must be placed such that inevitable scar contraction will avoid joint or web space contracture. Numerous patterns of skin incisions have evolved, including laterally based triangular and rectangular flaps. Cronin's technique of a combination of palmar and dorsal triangular flaps with matched zigzag incisions on both surfaces of the conjoined digits remains the basis of most techniques (Figure 36.12).[44] Modifications of this pattern have been proposed to redistribute the available skin in an unequal manner to avoid skin grafting on both sides of the commissure (Figure 36.13). Syndactyly release has also been performed with straight-line midlateral incisions closed with skin grafts, which are splinted to prevent contracture and subsequently serially excised to leave an acceptable midlateral scar,[142] or with direct closure after defatting of the skin flaps.[145] This is a departure from the traditional technique but may be of benefit when grafts and scars are at risk of pigmentation and hypertrophy. Another alternative approach is the "open finger" technique of Sommerlad, where the residual skin defects resulting from separation of the digits are left open to heal by secondary intention.[154]

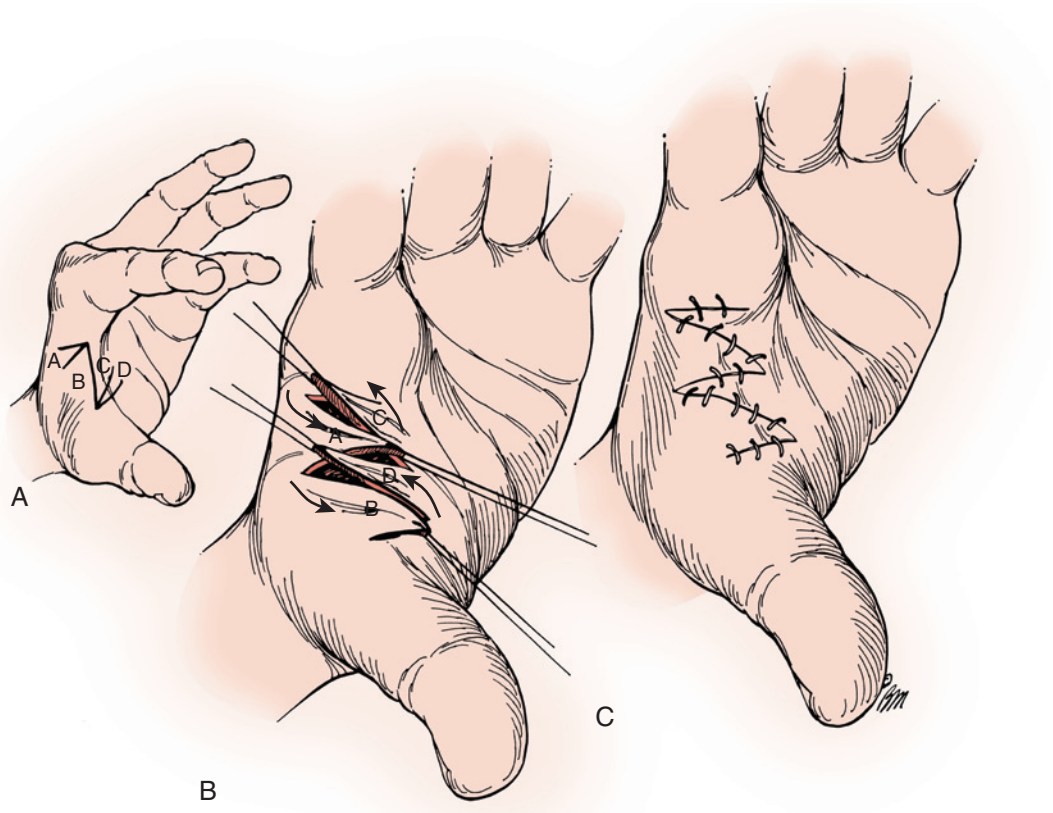

FIGURE 36.10 The standard four-flap "Z"-plasty often used for deepening broader webs such as the thumb web. **A,** The incisions are outlined. **B,** The flaps have been mobilized and crossed. **C,** Closure. (Copyright © Elizabeth Martin.)

However, most surgeons fear the secondary cicatrix formation with scar contracture and hypertrophic scarring and so are reluctant to endorse this method.

Separation of the digits requires division or excision of fascial interconnections between the digits, with care taken to identify and preserve the individual neurovascular bundles and the venous plexus on the dorsum of the digits and of the commissure flap (Figures 36.14 and 36.15). Bifurcation of the common digital nerve and artery may be distal to the planned position of the web space. In this situation, the digital artery can be ligated provided the other side of the digit is unoperated or the contralateral digital artery is known to be intact. Otherwise the web release is limited to the level of the arterial bifurcation or the artery is extended with a vein graft (very rarely necessary). When multiple digits are released, each digit must have at least one digital artery remaining; hence, the importance of precise operative records in such cases. Distal bifurcation of the digital nerve is managed by interfascicular dissection and proximal separation.

Resurfacing the digits is achieved with the palmar and dorsal flaps raised from the conjoined digits supplemented with skin grafts. Full-thickness skin grafts are preferred over split-thickness skin grafts to lessen secondary graft contracture. Skin grafts are usually obtained from the inguinal donor site.[99] Alternative donor sites include the antecubital fossa, the hypothenar border of the hand (Figure 36.16), the forearm/wrist (Figures 36.17 and 36.18), and the skin of an accessory digit. The foreskin has been used,[124] although it tends to take poorly and develop pigmentation. The authors favor the medial upper arm, believing skin from this area is less likely to manifest unpredicted hair growth at maturity and is less likely to develop pigmentation than the inguinal grafts. Regardless of the chosen donor site, a careful explanation and consent are mandatory because the scar may hypertrophy.

Resurfacing the digits without skin graft has been performed to improve overall skin match and to avoid the risk of contracture associated with graft loss.[74] This technique may require some reduction of digital diameter by excising the subcutaneous fat of the digit while preserving the dorsal venous system. Extensive defatting, however, carries the risk of vascular or nerve injury and may lead to a thin finger after the involution of the fat of infancy. Another option to avoid skin grafting is to import skin from the dorsum of the hand and/or adjacent digits (Figure 36.19). The authors favor a dorsal flap from each adjacent finger as part of a trilobed commissural flap. In theory, more skin can be generated with tissue expanders, although this technique has limited success in syndactyly.[9] Tissue expansion has also been achieved with transverse soft tissue stretching through the use of a distraction frame. Neither of these techniques has been widely adopted.

Paronychial Fold Formation

Release of a complete syndactyly, particularly when associated with distal phalangeal fusion, requires the formation of a paronychial fold. The distal phalangeal tufts may be covered using the technique described by Buck-Gramcko. Laterally based long narrow triangular flaps are raised from the hyponychium of the conjoined digital mass and folded around to form the lateral

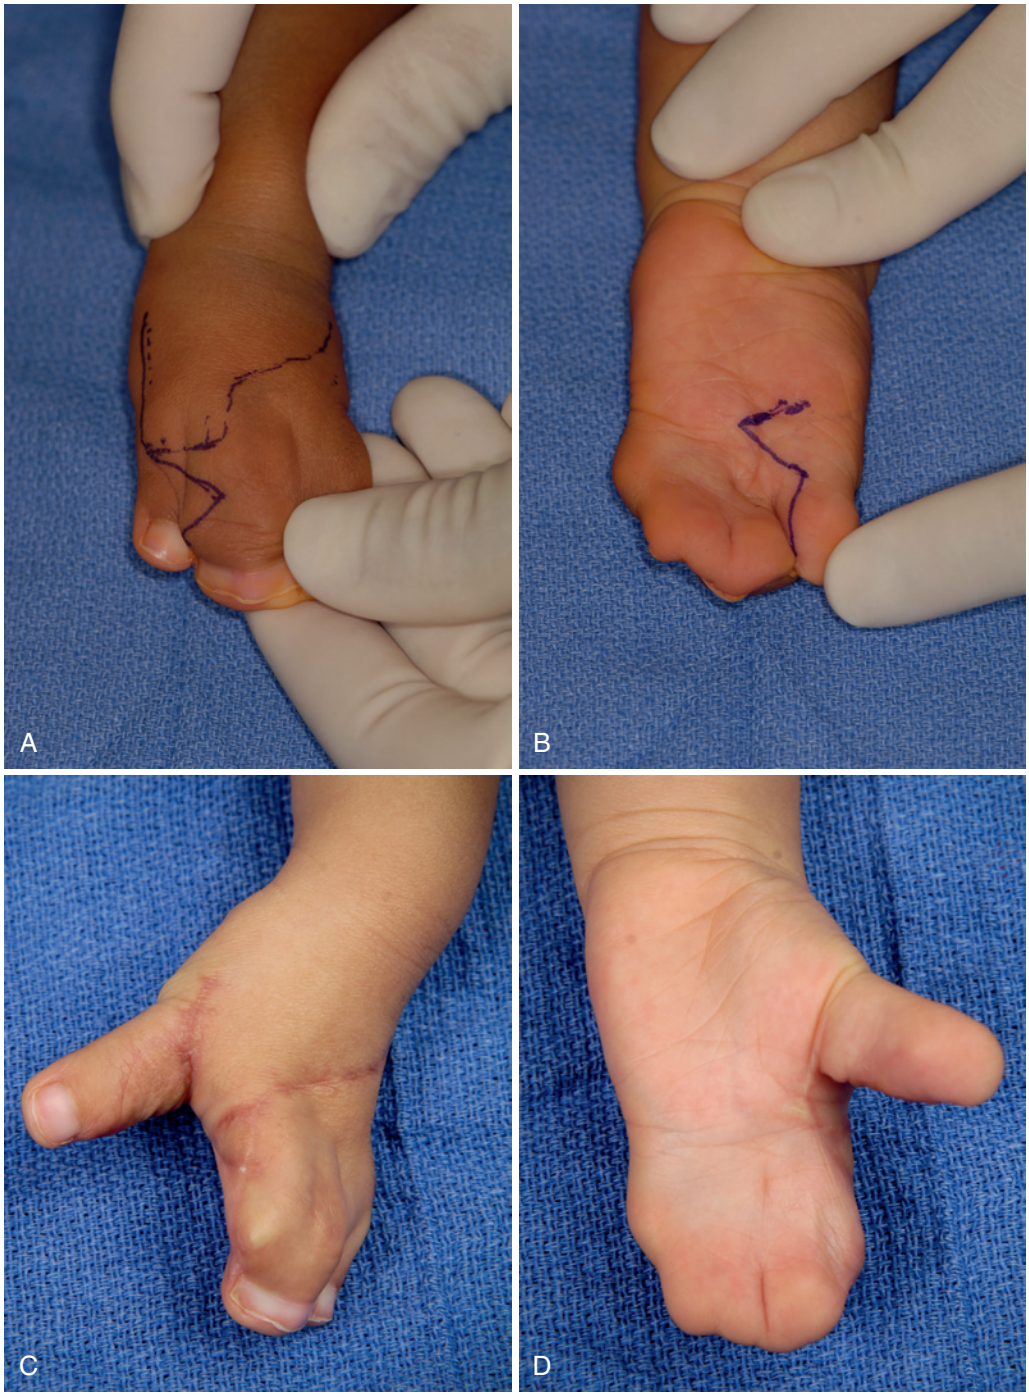

FIGURE 36.11 Three-year-old with severe syndactyly and marked thumb/index finger web narrowing. **A,** First web space reconstruction using dorsal flap. **B,** Palmar view with intended level of commissure. **C,** Postoperative appearance of thumb/index finger web space. **D,** Palmar view with thumb out of the palm. (Courtesy of Shriners Hospital for Children, Philadelphia.)

nail fold (Figure 36.20). Alternatively, the defect may be resurfaced with a skin flap from the conjoined pulp for one of the nail folds and a subcutaneous fat flap from the conjoined pulp covered with a graft for the other nail fold. Distant skin flaps including a thenar flap have been used,[88] but this technique requires delayed division and a second surgical procedure and in all but the youngest child, risks a PIP joint contracture. A composite graft of skin and subcutaneous fat harvested from the toe can also be used to reconstruct the fingertip.[153]

Outcome

The complexity and technical demands of syndactyly release are often underestimated. What appears to be simple surgery requires careful three-dimensional planning, careful technique, and meticulous wound closure. The procedure is often time consuming and demands patience. An acceptable outcome with independent digits that are freely mobile is usually achieved with simple syndactyly separation. In contrast, the outcome after complex syndactyly separation is often limited

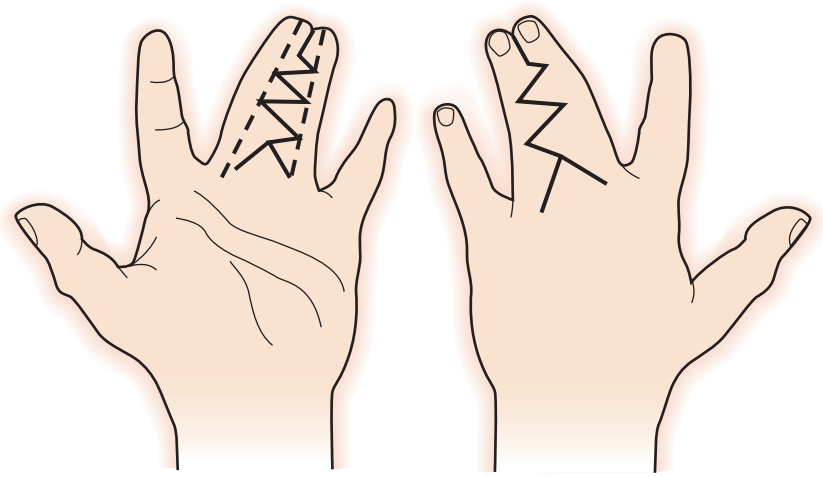

FIGURE 36.12 Cronin technique of a combination of palmar and dorsal triangular flaps with matched zigzag incisions on both surfaces of the conjoined digits. (From Cronin TD: Syndactylism: results of zig-zag incision to prevent postoperative contracture. *Plast Reconstr Surg* 18:460–468, 1956.)

by associated anomalies and severe skin shortage, which result in increased scarring and diminished mobility.[73]

Complications

Early complications include vascular compromise, infection, wound dehiscence, and graft loss. Tension-free wound closure is mandatory to prevent dehiscence and may require judicious defatting or skin grafts or both. Over time, the commissure may be drawn in a distal direction (web creep) by scar contraction (Figure 36.21). Poor flap design with placement of longitudinal scars at the base of the finger can precipitate web creep.[11] Web creep is also associated with areas of skin graft loss that heal by secondary intention, the use of split-thickness grafts, or the dehiscence of the commissure flap. Joint contractures are a result of contracture of scars on the palmar surface of the interphalangeal (IP) joint. This complication may require scar revision with further skin grafting or, where there is adequate skin, a "Z"-plasty to reorient and lengthen the scar. In the fingertip, inadequate soft tissue bulk and scarring can produce a beaked nail deformity or an inadequate paronychial fold.[34] Lastly, joint instability may occur after separation of complex syndactyly owing to insufficient collateral ligaments.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

In simple syndactyly, the preferred technique depends on the specifics of the deformity. Where the syndactyly is incomplete or loose and resurfacing without skin graft is feasible, that is our preferred method. Because incisions differ between techniques, the decision of whether a graft will be needed must be made prior to surgery.

Release of syndactyly is performed with the patient under general anesthesia using a tourniquet and loupe magnification.

If release will involve skin grafts, an hourglass-shaped dorsal flap is preferred for commissure reconstruction (see Figure 36.8). The flap begins at the level of the metacarpal heads and extends for two thirds of the length of the proximal phalanx. On the palmar surface of the dorsal commissure flap, a rectangular flap is fashioned to resurface the proximal area of a digit adjacent to the commissure (see Figure 36.13). The proximal transverse incision represents the palmar level of commissure reconstruction, and the distal transverse edge equals the length of the dorsal commissure flap. Subsequently, interdigitating zigzag dorsal and palmar flaps are constructed distal to the dorsal commissure and palmar rectangular flap. The dorsal zigzag incision begins at one distal corner of the commissure flap, whereas the palmar incision starts at the opposite corner of the rectangular flap (see Figures 36.8 and 36.13). The dorsal incision extends to the midline of the PIP joint of the adjacent finger and back across to the midline of the distal interphalangeal (DIP) joint. At this level, the incision

FIGURE 36.19 Fifteen-month-old with isolated left long finger/ring finger syndactyly and substantial coronal skin. **A,** Dorsal view. **B,** Palmar view. **C,** Triangular lateral extension (seagull flap) can allow direct closure over the dorsum of the finger and spare the amount of tissue required in the transverse direction. **D,** Volar incision. **E,** Identification of neurovascular bifurcation. **F,** Commissure flap inset and lateral wings closed. **G,** Volar view following complete closure without skin graft. **H,** Dorsal view of the same completed procedure. (Courtesy of Shriners Hospital for Children, Philadelphia.)

extends distally between the tips of the interconnected digits. The palmar flaps are based opposite the dorsal flaps (mirror images) with the base centered over the opposite PIP and DIP joints to allow for interdigitation. It can be helpful to mark the level of the peak of each flap with encircling ink-stained suture material to facilitate accurate apposition of the peak on one digit with the trough of the opposite digit. This orientation minimizes the tendency for formation of a flexion scar contracture and maximizes coverage potential. The palmar rectangular flap (opposite the dorsal commissure flap) and zigzag construction is often biased to cover one digit entirely, leaving residual bare areas on the adjacent digit that requires skin grafting. This has an advantage in requiring fewer grafts and a shorter operative time.

The flaps are elevated by sharp dissection with hemostasis using bipolar electrocautery. Dorsal flaps are elevated first, preserving the paratenon surrounding the extensor tendon. Next, the palmar flaps are raised and the underlying neurovascular bundles identified distally. The digits are separated from distal to proximal while protecting the neurovascular bundles. Manual spreading of the digits places the intervening tissue under tension, which facilitates digital separation (see Figure 36.14). The sturdy transverse fascial bands are incised to allow for sufficient proximal placement of the commissure. The bifurcation between the common and proper neurovascular structures is identified during proximal dissection (see Figure 36.15). A distal split of the digital nerves is easily separated by microdissection. The surgical options when the arterial bifurcation is

FIGURE 36.20 Laterally based triangular flaps from the hyponychium of the conjoined digital mass are folded around to form the lateral nail fold. (Courtesy of Shriners Hospital for Children, Philadelphia.)

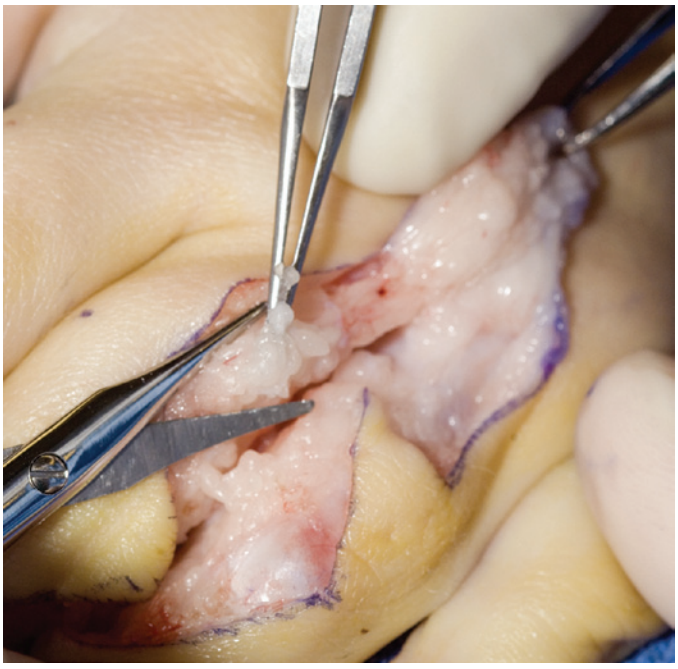

FIGURE 36.22 The adjacent sides of the separated digits are defatted before insetting the flaps. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 36.21 Web creep and angulatory deformity after separation of syndactyly. (Courtesy of Shriners Hospital for Children, Philadelphia.)

distal to the desired web position are described in the text above. Ligation of a proper digital artery for an acceptable commissure placement is usually required. Selection of the proper digital artery to ligate depends on the status of the proper digital artery on the adjacent sides of the digits being separated. If both digits have intact proper digital arteries on both sides, the smaller artery is usually ligated. However, if one of the digits still requires additional surgery (e.g., staged syndactyly release), then ligation of the larger artery may be considered. If the status of the opposite digital artery is unclear, microvascular clamps are applied to the digital arteries and the tourniquet is deflated to ensure adequate perfusion of each digit.

Before insetting of the flaps, the adjacent sides of the separated digits are defatted (Figure 36.22). Defatting decreases the tension across the flaps and improves the overall appearance of the separated digits. Abnormal or contracted fascial structures may be encountered and are also released or excised at the time of this defatting. The commissure flap is sutured first to assess placement and configuration of the web space. Subsequently, the interdigitating flaps are approximated, avoiding excessive tension. An absorbable 5-0 or 6-0 suture is used for closure, and sutures are placed very close to the skin edges to avoid cross-hatched scarring. The remaining skin defects are covered with full-thickness skin graft (Figures 36.23 and 36.24).

In select cases, an experienced surgeon may decide that skin grafts may be avoided with a trilobed dorsal flap for construction of the commissure. This design requires the harvesting of skin from the dorsum of the adjacent digits, and so, in return for a potentially more pliable web and no pigmented skin grafts, a less discrete dorsal scar is formed.

Proper postoperative dressings are an essential part of the operation. The dressings must apply gentle compression across the skin graft sites and protect the separated digits. Nonadherent dressings and moist cotton are placed into the web spaces and reinforced with large amounts of soft gauze. In young children, the compressive hand dressing is reinforced by above-the-elbow plaster or a soft cast (Scotchcast, 3M, St. Paul, MN) to prevent inadvertent removal. The elbow is positioned in at least 90 degrees of flexion to minimize the chances of the cast sliding off the arm. The dressings are removed 3 weeks after surgery, and then gentle washing and wound care are needed. The wounds are protected until they are dry and healed. Normal hand use is allowed after the dressing has been removed.

FIGURE 36.23 Dorsal appearance after flap closure and full-thickness skin grafting. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 36.24 Volar appearance after flap closure and full-thickness skin grafting. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Physiotherapy is usually not required. Once healing has taken place, an elasticized compression glove may be fitted and worn for up to 3 months for scar management. Scar massage, silicone gel sheets, or elastomere products can be used to treat areas of hypertrophic scarring.

FIGURE 36.25 Acrosyndactyly in amniotic disruption sequence with a sinus tract or cleft from the dorsal to the palmar surface of the conjoined digits.

SPECIAL CASES OF SYNDACTYLY

Acrosyndactyly

Acrosyndactyly is a syndactyly with a fenestration between the digits proximal to the distal fusion and is characteristic of constriction ring syndrome (amniotic disruption sequence) (Figure 36.25). It is bilateral in 50% of cases and is associated with absent digits in 50% of patients. The syndactyly can vary from a simple syndactyly to a complex anomaly with distal fusion of multiple digits producing a jumble of fingertips. The sinus is variable in size (from the size of a pin tract to a broad passage) and is usually distal to the normal commissure level (Figure 36.26). The digits distal to the constriction ring may be edematous, atrophic, or skeletally disrupted.

Management is dependent on the severity of the distal deformity and the position and size of the sinus. Mild deformities with well-preserved distal digits can be released with the standard techniques as described previously. The sinus may be incorporated during resurfacing of the digits or excised. For more complex deformities, staged release of the fingertips followed by delayed commissure reconstruction is recommended. Staging allows unimpeded growth of the digits. In severe deformities, amputation of disorganized or atrophic fingertips may be preferred because the potential for reuniting them with the parent digit is limited. In addition to the syndactyly release, associated constriction rings can be managed by excision and "V-Y" plasty.

Apert Syndrome

Apert syndrome describes the combination of bicoronal craniosynostosis and midfacial hypoplasia with severe complex syndactyly of the hands and feet.[60] It is due to a mutation of the fibroblast growth factor receptor type 2 gene (FGFR2), which

TABLE 36.1 Classification of Apert Hand Deformities

Type	First Web	Central Mass	Fourth Web
Type I Obstetrician hand or spade hand	Incomplete simple syndactyly	Digital mass flat in palmar plane. Good metacarpophalangeal joints with variable degree of symphalangism at interphalangeal joints	Incomplete simple syndactyly
Type II Mitten hand or spoon hand	Complete simple syndactyly	Digital mass forms palmar concavity with splaying of metacarpals proximally and tight fusion of fingertips distally with synonychia of central digital mass	Complete simple syndactyly
Type III Hoof hand or rosebud hand	Complete complex syndactyly	Thumb incorporated into mass, which is tightly cupped; synonychia of all digits apart from the small finger; skeletal abnormalities of index ray; Complicated by paronychial infections and maceration of palmar skin	Simple syndactyly, usually with metacarpal synostosis of fourth and fifth metacarpals

Blauth W, Schneider-Sickert F: Symbrachydactylies. In Blauth W, Schneider-Sickert F, editors: *Congenital deformities of the hand*, Berlin, 1981, Springer-Verlag, pp 249–271; Upton J: Apert syndrome: classification and pathologic anatomy of limb anomalies. *Clin Plast Surg* 18:321–355, 1991.

is located on chromosome 10q.[184] Several other acrocephalosyndactyly syndromes have been identified; however, the hand deformities are typically less complex than those of Apert syndrome. In addition to the characteristic hand deformity, upper limb manifestations include abnormalities of the shoulder and elbow. The development of the glenohumeral joint is asymmetric, with relative overgrowth of the greater tuberosity and a hypoplastic glenoid fossa. Shoulder movements become more restricted with growth. Elbow anomalies most commonly involve the radiocapitellar articulation.[7,119,128]

The hand deformities in Apert syndrome include complex syndactyly of the index, long, and ring fingers and a simple syndactyly between the ring and small fingers. Varying degrees of first web space syndactyly prevent useful prehension, which is exacerbated by radial clinodactyly of the thumb (Figure 36.27). The fingers are short, and IP joints are stiff in the central rays. In the most severe cases, the distal phalanges of all of the fingers are fused to each other and growth of the fingers results in a rosebud or bunched appearance with a deep hollow in the palm caused by the tethering distally.[171] Frequently, nail fold infections result from overlapping and ingrowth of the tightly adjacent nail plates. A capitohamate coalition and synostosis between the ring and small metacarpals is frequent (Figure 36.28). This finding is clinically important because it prevents opposition of the fifth digit toward an already restricted thumb. There is an inverse relationship between the severity of the hand and craniofacial deformities. The hand deformity has been classified according to the involvement of the first web space and conformation of the central mass (Table 36.1).

The management of hand anomalies in patients with Apert syndrome must be performed in concert with the management of the craniofacial and other associated anomalies. In practice, this is complex surgery requiring careful coordination between hand surgeons and the craniofacial service. The goal of surgery is to complete separation of the digits and correct the thumb deformity before 2 years of age to allow for growth and the development of function. Surgery to mobilize the small finger by release of the ring and small metacarpals' synostosis may be beneficial because it allows cupping of the palm and some function between the often better articulated fifth finger and the thumb. Surgery is rarely performed about the shoulder and elbow.

Separation of the digits requires careful planning. Reconstruction of an adequate first web space is the first priority. Sequential single-stage release of the skin and fascia, intrinsic muscle lengthening, and capsulotomy of the carpometacarpal (CMC) joint allow the thumb ray to be positioned in 45 degrees of abduction (Figure 36.29). Minor first web space narrowing can be addressed with local flaps such as a four-flap "Z"-plasty. Considerable narrowing with deficient skin requires a dorsal advancement rotation flap[61] or preliminary tissue expansion on the dorsum of the hand.[41] We prefer to use a transposition flap from the radial border of the index finger for incomplete thumb/index finger syndactyly. The index finger flap can

FIGURE 36.31 Restoration of substantial soft tissue within the first web space after a free groin flap.

lengthen the first web space and be positioned into the thenar crease to correct any associated flexion-adduction contracture. For severe contracture of the first web space, Buck-Gramcko has described successful release with a large dorsal rotation flap,[32] but our preference is to import new skin to the very deficient hand integument. A free groin is used (Figure 36.30), and this allows the import of large areas of pliable skin while minimizing the donor defect. The groin donor has the potential disadvantage of future pigmentation and hair growth, but the vessels lie within the territory of the flap and appose themselves to the recipient vessels accurately. Substantial tissue is placed within the first web space (Figures 36.31 and 36.32). Contrary to prevalent belief, the vessels within the first web space and the flap are adequate for microvascular anastomosis. However, this is daunting microsurgery, requiring highly specialized anesthesia, and should only be contemplated in units with the resources and experience to perform this surgery. The least disfiguring alternative is probably the dorsal rotation advancement flap; we eschew the pedicled forearm flaps because of the scarring that results and the division of a major axial vessel.

FIGURE 36.32 Another view of restoration of substantial soft tissue within the first web space after a free groin flap.

The thumb clinodactyly must be corrected with an osteotomy of the phalanx. An opening wedge osteotomy and a bone graft are preferred to lengthen the shortened thumb. This is best done at the same stage, so that the fixation of the thumb web space release is combined with fixation of the bone graft. The bone graft can be taken from the division of the synostosis between the fourth and fifth metacarpals. Usually, there is a resultant skin shortage on the radial aspect of the thumb that can be addressed with "Z"-plasty.

Release of the finger syndactylies is usually staged,[173] though release of the syndactyly in a single stage has been reported.[80] Anomalies of the neurovascular bundles are common. The surgical plan is influenced by the extent of the first web space reconstruction and the status of the index finger. A severely deformed index finger may be sacrificed if it is unlikely to yield a stable finger of adequate length, though our preference is to preserve all digits. More information about the skeletal abnormality can be assessed with three-dimensional computed tomography, which may be combined with the craniofacial imaging.[82]

When the thumb is released, the opportunity may be taken in the tightly bunched or rosebud hand to release the distal osseous unions via a simple linear incision and to line the raw lateral surfaces with skin grafts, thereby converting the tight bunched hand into the flat "spade" of the type I deformity.[171] This simple maneuver prevents growth distortion, buys time to allow other surgeries, and also serves to prevent the recurrent nail infections that can dominate the early months of hand care in these children. Subsequent releases of the multiple syndactylies are staged to avoid surgery to both sides of the digit at the same sitting.

In this way, we have staged the release of the severely deformed hand by releasing the distal osseous fusion and dividing the common nail plate through dorsal incisions between the distal digits. This converts the complex syndactyly to a simple syndactyly and releases the digits from the osseous tether. The interdigital defects are resurfaced with full-thickness grafts to allow some differential motion between the digits. The grafts generate enough pulp skin to provide adequate pulp and

paronychial flaps for the release of the fingers at a later stage. The digits in the Apert hand are stiff in extension, and therefore the release of the proximal part of the syndactyly can be achieved with a straight-line incision, as there is not the same risk of IP joint contracture with longitudinal scars in these digits. The defects are resurfaced with full-thickness grafts, which may need to be harvested as a lower abdominal ellipse rather than from the groin because of the extensive area of graft required. Emphasis does need to be given to the commissure reconstruction to allow freedom of independent metacarpophalangeal joint movement. A dorsal commissure flap is usually used.

Surgery to free the small finger may be required if the finger is functional. Release of the synostosis between the ring and small metacarpals should include fascia or fat interposition to prevent recurrence. Upton's experience suggests that this procedure is best delayed until 5 years of age to decrease the incidence of recurrence, although we like to use the bone resected as a graft for the thumb clinodactyly. Therefore, we accept the risk of recurrence requiring an additional release. The position of the fifth ray may be improved by release of the CMC joint to allow flexion of the metacarpal.

Symbrachydactyly

Symbrachydactyly is from the Greek for "short webbed digits." Symbrachydactyly occurs sporadically but may be a feature of Poland syndrome. The anomaly is almost always unilateral, and the severity varies from almost complete absence of digits to relatively well-formed short fingers. When the digits are well formed, the syndactyly component requires intervention. The technique may be modified to include division of the transverse metacarpal ligament to increase the mobility and apparent length of the fingers, though the commissure should not be placed in such a proximal position between the metacarpal heads that there is a risk of producing a narrowed, "V"-shaped web space.

Poland Syndrome

Poland syndrome has been attributed to disruption of the blood flow in the subclavian artery in the embryo (hence, it is also called subclavian artery disruption sequence); a spectrum of hypoplastic anomalies in the upper limb is produced. The syndrome consists of absence of a shoulder girdle muscle and abnormalities in the hand, which may be very minor. In fact, there is no correlation between the severity of each component of the deficiencies. Commonly seen conditions are aplasia of the sternocostal head of the pectoralis major (although the clavicular head may also be absent); brachydactyly affecting the index, long, and ring fingers; hypoplasia of the hand; and syndactyly of the digits. The chest wall anomalies may be extensive and include hypoplasia of the breast, aplasia of the pectoralis minor and latissimus dorsi, and skeletal thoracic wall anomalies (Figure 36.33). The hand deformity is variable, but the central digits are most commonly affected and are generally shortened secondary to an undersized middle phalanx. The syndactyly is usually simple and either complete or incomplete. Surgical separation follows the timing and technique described previously. In our service we like to set up a treatment schedule extending from infancy to sexual maturity that combines the management of the thoracic deformity (usually, by ipsilateral muscle transfer) with staged reconstruction of the female breast.

FIGURE 36.33 Poland syndrome with considerable breast underdevelopment and an absent nipple. (Courtesy of Shriners Hospital for Children, Philadelphia.)

The hand surgery should be integrated into this treatment schedule.

Dystrophic Epidermolysis Bullosa

Syndactyly in dystrophic epidermolysis bullosa is not truly a congenital anomaly but rather a consequence of the scarring from this blistering condition of the squamous epithelial surfaces. Epidermolysis bullosa encompasses a rare heterogeneous group of congenital blistering conditions.[143] The skin structure is disrupted by a loss of the normal adhesion between the various lamina of the skin. The variants are classified according to the level and cause of blistering. Epidermolysis bullosa simplex variants blister at the basal keratinocyte level, junctional epidermolysis bullosa blisters within the lamina lucida of the basement membrane, and dystrophic epidermolysis bullosa blisters because of abnormal anchoring collagen VII fibrils within the papillary dermis. Dystrophic epidermolysis bullosa is associated with repeated dermal injury. The inevitable scarring produces syndactyly and contracture in the hands. Autosomal dominant and recessive forms of dystrophic epidermolysis bullosa have been recognized, with the recessive form being the most severe. Typically, the hand deformity progresses toward flexion contractures of the digits that become cocooned into a common mass (Figure 36.34). The thumb can be included within the cocoon. The hand problem, however, is only part of a complex condition that requires a multidisciplinary approach to management. These patients should be managed in specialized multidisciplinary centers with experts in treating the skin, gastrointestinal, ocular, oral, oncologic, psychological, and

FIGURE 36.34 The hand deformity in dystrophic epidermolysis bullosa with flexion contractures of the digits, which have become cocooned into a common mass.

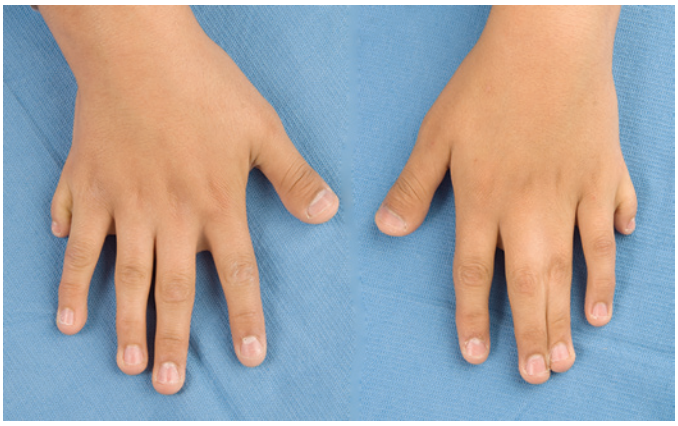

FIGURE 36.35 Twelve-year-old with bilateral postaxial polydactyly. The left hand also has long finger/ring finger syndactyly. (Courtesy of Shriners Hospital for Children, Philadelphia.)

anesthetic aspects of the disease. The hand surgery is based around release and resurfacing of the syndactyly and contractures. Radical release, particularly of the first web space, is recommended to maintain some hand function.[162] The syndactyly (also named pseudosyndactyly) in this condition is usually caused by adhesion between digits and can be achieved with blunt dissection after removal of the encasing membrane of scar. The dermal scarring generally produces flexion contractures of the digits or first web contractures. We believe that the maintenance of the first web space is the key to useful hand function in these children. For this reason, we consider free tissue transfer from an unscarred flexion area of the body (such as the groin) to be desirable where other considerations permit. Local flaps are usually impossible because of the extensive scarring and cocooning in these highly abnormal hands. The skin deficits can be allowed to heal by secondary intention or by using the skin of the cocoon, skin flaps from filleted fingers, or grafts. Split-thickness skin grafts are preferred, although we have successfully used free groin flaps to resurface the vital first web space. Despite initially satisfactory results, recurrence is common, with reoperation rates of over 50%.[162]

Expected Outcomes

The expected outcome of syndactyly release in children with simple syndactyly is a natural-appearing web commissure with pliable skin, unrestricted function, and no distal creep of the web with time; however, it may be complicated by contracture or hypertrophy of the scars associated with surgery and lead to distal creep of the web position. This may require further surgery to reposition the web. The outcomes in complex or complicated cases depend on the extent of the osseous syndactyly and associated anomalies, which often lead to stiffness or deformity of the digit or digits.

CRITICAL POINTS *Syndactyly*

- Syndactyly may involve only the soft tissue (simple) or include bony connections (complex).
- Atypical forms of syndactyly are labeled *complicated* and involve either convoluted soft tissue abnormalities or a hodgepodge of abnormal bones. Many atypical configurations occur in conjunction with a variety of syndromes.
- Mild incomplete syndactyly that does not interfere with function does not require treatment. In contrast, simple syndactyly of any considerable degree warrants surgical reconstruction of the web space for improved function and appearance.
- Border digits (thumb/index finger and ring/small finger web spaces) have marked differences in their respective lengths and should be separated within the first few months of life. This prevents tethering of the longer digit, which results in a flexion contracture and rotational deformity.
- Syndactyly that combines digits of relatively equal length (e.g., long/ring finger web space) negates the development of deformity. Separation may be delayed until the child is older and the hand larger to facilitate surgical reconstruction.
- Surgical reconstruction should only include one side of an affected digit at a time to avoid vascular compromise of the skin flaps or digit, or both.
- Surgical reconstruction of the commissure must be free of skin graft. Creation of a flap to recreate the commissure avoids interdigital contracture.
- Complex syndactyly is more challenging to treat, especially as the degree of bony union increases.

POLYDACTYLY

Ulnar Polydactyly

Epidemiologic Findings

Polydactyly can occur on the preaxial (radial) and postaxial (ulnar) sides of the limb. Postaxial polydactyly is frequently inherited via an autosomal dominant pattern but has a variable penetrance pattern. Postaxial polydactyly is more common in Africans and African-Americans. The polydactyly can be bilateral (Figure 36.35). Preaxial polydactyly is more frequent in Caucasians. The prevalence of postaxial polydactyly in African-Americans is estimated to be 1 in 143 live births. In comparison, the prevalence of postaxial polydactyly in Caucasians is estimated to be 1 in 1339 live births.[177] Postaxial polydactyly in a Caucasian individual is sometimes indicative of an underlying syndrome (e.g., chondroectodermal dysplasia or Ellis–van Creveld syndrome) (Figure 36.36).

FIGURE 36.36 Postaxial polydactyly in chondroectodermal dysplasia or Ellis–van Creveld syndrome. The dorsal view demonstrates the characteristic nail dysplasia. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 36.37 One-year-old with bilateral postaxial polydactyly. A ligature clip has been placed at the base for amputation. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Classification and Treatment

The supranumerary digit is either well developed (type A) or rudimentary and pedunculated (type B). A small nubbin or scrawny postaxial element (type B) can be removed by ligating the base in the nursery or using local anesthesia with epinephrine and electrocautery in the office (Figure 36.37). Suture or vessel clips can be applied to the base of the digit. The digit will turn gangrenous and fall from the hand. A residual bump or nubbin is the most common complication (Figure 36.38), though other complications have been reported.[81,129]

FIGURE 36.38 Residual nubbin after suture ligation of postaxial polydactyly. (Courtesy of Shriners Hospital for Children, Philadelphia.)

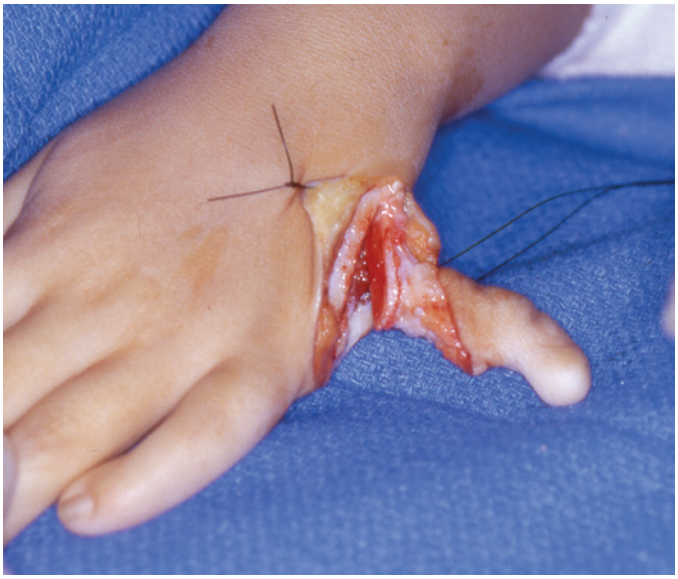

FIGURE 36.39 Elliptical incision around a postaxial digit extended in a proximal direction to allow adequate exposure and removal of the extra digit. (Courtesy of Shriners Hospital for Children, Philadelphia.)

A well-developed or nearly normal digit (type A) requires operative ablation. The extra digit is removed, and any important functional parts (e.g., ulnar collateral ligament and abductor digiti quinti) are transferred to the adjacent finger.

Surgical Technique

An elliptical incision around the digit is outlined (Figure 36.39). The incision is extended in a proximal direction to allow adequate exposure. Anomalous tendons are removed with the extra digit. The digital nerves are incised and the digital arteries coagulated. If the ablated digit contains the abductor digiti quinti, the muscle and tendon to the adjacent digit are transferred to

restore digital abduction. The skin is closed with absorbable suture and the limb immobilized in a long-arm cast for 3 weeks to protect any ligament and/or muscle-tendon transfer.

CRITICAL POINTS *Postaxial Polydactyly*

- Postaxial polydactyly is frequently inherited in an autosomal dominant pattern but has a variable penetrance pattern. Postaxial polydactyly is more common in African-Americans and preaxial polydactyly is more frequent in white individuals.
- A small nubbin or rudimentary postaxial element can be removed safely by tying the base in the nursery or using local anesthesia and electrocautery in the office.
- Well-developed postaxial polydactyly requires operative ablation with transfer of any important parts (e.g., ulnar collateral ligament and abductor digiti quinti) to the adjacent finger.

Central Polydactyly

Epidemiologic Findings

Central polydactyly is an extra digit within the hand as opposed to along its borders. Central polydactyly is uncommon in comparison with border polydactyly. The ring digit is the most common duplication, followed by the long finger and finally the index digit. Central polydactyly occurs in isolation or as part of a syndrome, such as Grebe chondrodysplasia (Figure 36.40). The central polydactyly may be hidden within a concomitant syndactyly (i.e., synpolydactyly) (Figures 36.41 and 36.42). Identification of synpolydactyly requires careful examination supplemented by radiographic verification (Figure 36.43). Central polydactyly (ring finger duplication) combined with syndactyly has a familial inheritance pattern and has been linked to a gene mutation (HOXD13 gene) on chromosome 2.[126]

FIGURE 36.44 One-year-old with central polydactyly consisting of five fingers with full motion and function. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Treatment

Treatment depends on the status and extent of the extra digit and the presence or absence of concurrent anomalies, such as syndactyly. A central polydactyly that has a fully formed digit and normal function does not require removal to restore the normal complement of digits (Figure 36.44). An isolated central polydactyly with limited motion is treated by resection of the ray. The span of the hand is maintained by transposition of the adjacent digits or intermetacarpal ligament reconstruction (or both). Synpolydactyly is treated by separation of the syndactyly and reduction of the concealed polydactyly. Surgery is

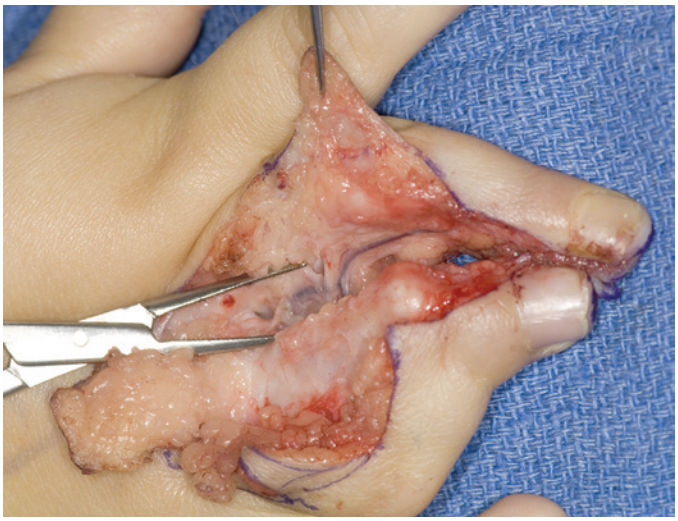

FIGURE 36.45 Child depicted in Figure 36.1 treated with a wide dorsal exposure to isolate the underlying bony elements and neurovascular structures. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 36.46 Abnormal bony elements are treated by a combination of resection and osteotomy to improve alignment. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 36.47 Postoperative results with improved alignment and structure. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 36.48 Partial index finger polydactyly with concomitant thumb duplication. (Courtesy of Shriners Hospital for Children, Philadelphia.)

quite difficult and is unlikely to restore normal motion and alignment. Complete removal of the redundant bones is difficult to accomplish without jeopardizing joint structure or digital circulation. Wide surgical exposure is necessary. Flaps are designed for extensive exposure of the underlying bony elements and isolation of the neurovascular structures (Figure 36.45). Creativity and intraoperative flexibility may be required to restore the best functioning digit with components from each part (Figure 36.46). A combination of resection and osteotomy is often necessary to obtain the best digit possible (Figure 36.47). The result is often incomplete resection of the surplus bones, which enhances appearance but does not improve motion. Partial central polydactyly is treated with principles similar to those used for reconstruction of the duplicated thumb (Figure 36.48). Multiple surgeries may be required for central polydactyly, and the outcome may still be disappointing. Similar to complex syndactyly, duplicated digits with complicated connections may be better left untreated rather than separated into individual digits with limited motion and instability.

MIRROR HAND

Mirror hand is a rare congenital anomaly characterized by symmetric duplication of the limb in the midline. Typically, there is a central digit with three digits on each side that represent the middle, ring, and small digits in mirrored symmetry (Figure 36.49).[15] Despite the seven digits, the thumb is absent. Within the forearm, there are two ulnas but no radius is present. The ulnas support duplicated ulnar carpal elements (Figure 36.50); hence the term *ulnar dimelia*. The preaxial ulna is often short, and the hand is positioned in radial deviation. The soft tissue anatomy is bizarre and complicated. Unpredictable anatomic variations are commonplace. Varying degrees of the deformity complicate the classification and treatment strategies.

The theory that mirror hand is part of a spectrum that culminates in the exceedingly rare anomaly of multiple hands has been presented (Table 36.2).[4]

CRITICAL POINTS *Central Polydactyly*

- Central polydactyly is uncommon in comparison with border polydactyly.
- Central polydactyly may be hidden within a concomitant syndactyly (i.e., synpolydactyly).
- Synpolydactyly is difficult to treat. Separation of the syndactyly and reduction of the concealed polydactyly often result in incomplete resection of the extra bones without an increase in motion.
- Central synpolydactyly with complicated connections may better be left untreated than separated into individual digits with limited motion and instability.

Etiologic Findings

The etiologic findings have been attributed to replication of the signaling center that controls radioulnar development. The zone of polarizing activity (ZPA) within the posterior margin of the limb bud polarizes the limb into a radioulnar axis and governs preaxial-postaxial limb development.[45] Transplantation of the ZPA or its signaling molecule, sonic hedgehog protein, causes mirror duplication of the ulnar aspect of the limb (see Embryology section).

Examination of the mirror hand begins with an inventory of the number and function of the digits. The amount of wrist,

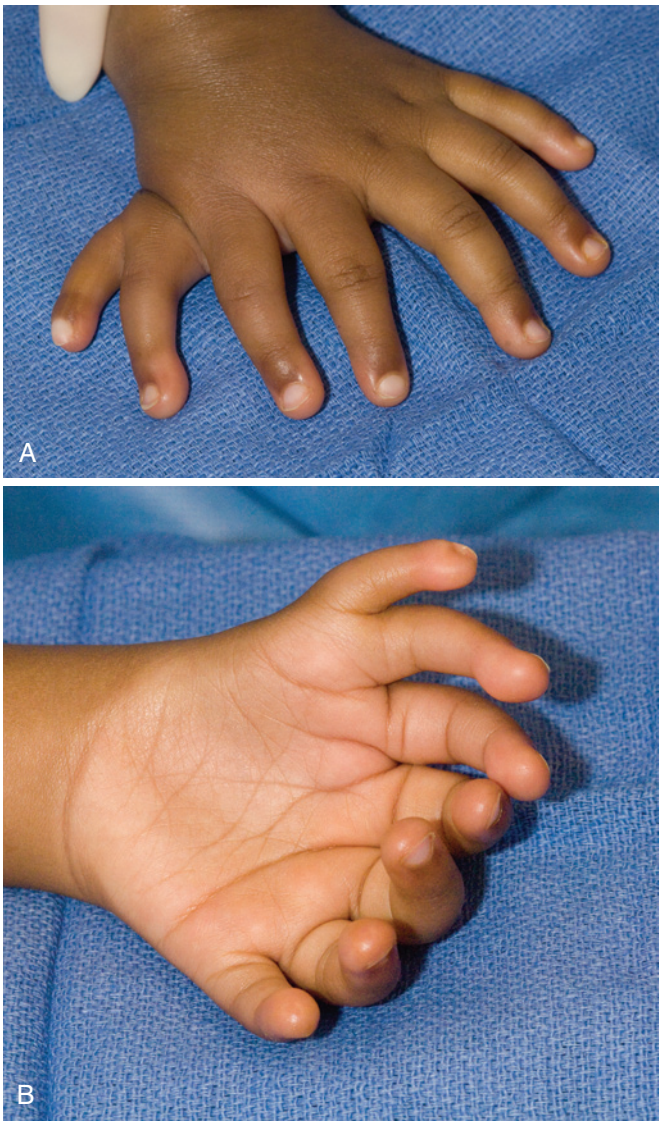

FIGURE 36.49 **A** and **B,** One-year-old girl with a left mirror hand and seven digits. (Courtesy of Shriners Hospital for Children, Philadelphia.)

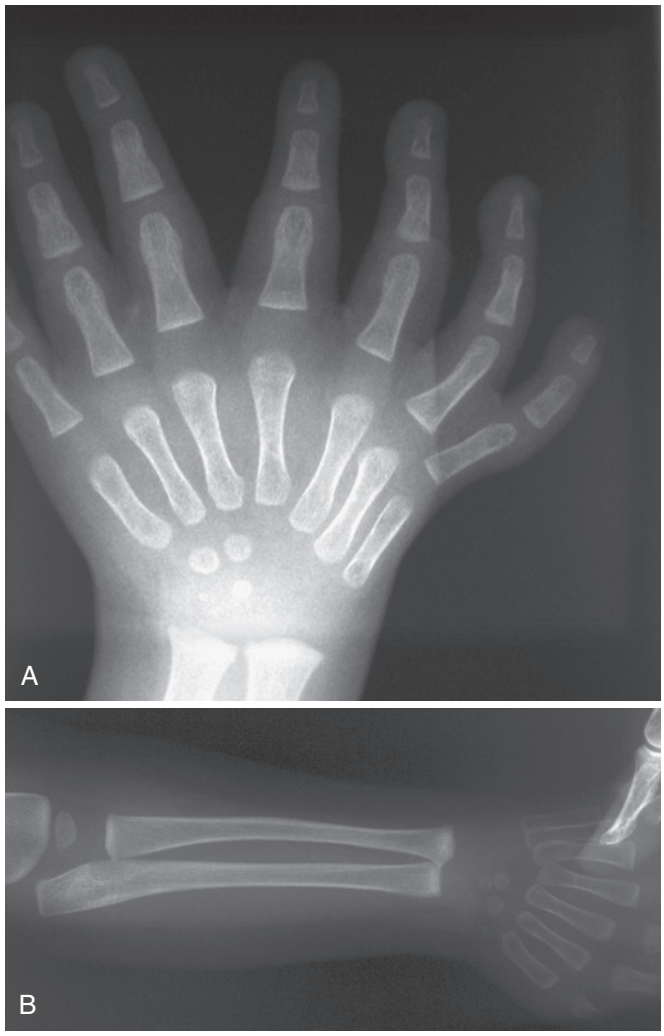

FIGURE 36.50 Two-year-old girl with a left mirror hand. **A,** Hand x-ray showing seven rays and early ossification of the ulnar carpus. **B,** Forearm x-ray showing two ulnas and no true radius. (Courtesy of Shriners Hospital for Children, Philadelphia.)

forearm, and elbow motion is recorded. Limited wrist extension is common secondary to concomitant deficiency of the wrist extensor tendons. There is limited forearm and elbow motion because the presence of two ulnas prevents normal movement. The amount of elbow flexion present is variable and is related to the degree of abnormal elbow anatomy.

TABLE 36.2 Classification of Mirror Hands

Type	Name	Clinical Features
1	Ulnar dimelia	Multiple fingers with two ulnas Type A: Each ulna well formed Type B: Preaxial ulna hypoplastic
2	Intermediate form	Multiple fingers with two ulnas and one radius
3	Intermediate form	Multiple fingers with one ulna and one radius Type A: Radius well formed Type B: Hypoplastic radius
4	Syndromic form	Bilateral, mirror feet and nasal defects characteristic Type A: Sandrow syndrome: two ulnas Type B: Martin syndrome: one ulna and one radius
5	Multiple hand	Complete duplication of the hand, including the thumb; forearm normal

Treatment

Treatment is designed to reduce the number of digits to four and reconstruct a thumb from the deleted digits. Selective ablation of the supernumerary digits and thumb reconstruction are the mainstays of surgery. The procedure must reconstruct the first web space and augment the motor function of the preserved thumb via tendon transfer (Figure 36.51). The principles of pollicization and the use of "spare parts" guide construction of the thumb (Figure 36.52).[6,16] We select the most mobile radial digit for pollicization and remove the stiffer radial digits (Figure 36.53). The skin forming the ablated digits is used to augment the first web space (Figure 36.54).

CRITICAL POINTS *Mirror Hand*

- Mirror hand is rare and characterized by symmetric duplication of the limb in the midline. Typically, there is a central digit with three digits on each side and absence of the thumb.
- The forearm often has two ulnas but no radius is present.
- The etiologic findings have been attributed to transplantation or replication of the ZPA from the posterior margin of the limb bud into the anterior region.
- Treatment consists of reduction of the number of digits to four and reconstruction of a thumb from the deleted digits.

BRACHYDACTYLY

The term *brachydactyly* describes a short finger in which the elements of the digital skeleton are present but one or more are

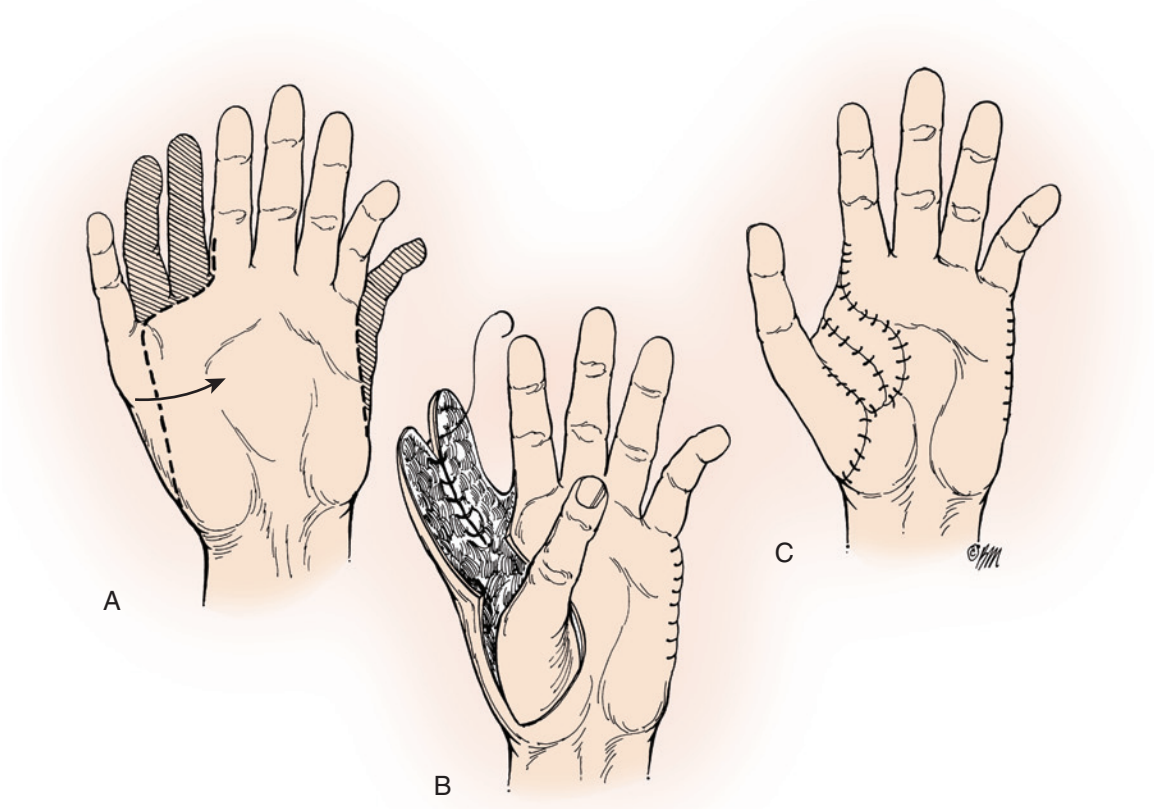

FIGURE 36.51 A to **C,** When eight digits are present, the most preaxial digit may be retained and undergo pollicization, whereas the second and third digits are filleted to surface the first web space. Amputation of the most postaxial digit improves the cascade alignment of the four residual fingers.

reduced in size. The description can be extended by specification of the bone involved. *Brachytelephalangy, brachymesophalangy*, and *brachybasophalangy* refer to short distal, middle, and proximal phalanges, respectively. *Brachymetacarpia* refers to shortening of the metacarpal. These specific terms are rarely used anymore, because *brachydactyly* has become the preferred term. Brachydactyly may occur in isolation, as part of a complex hand anomaly, as a constituent of a generalized syndrome, or as a consequence of trauma (Table 36.3). The functional and aesthetic aspects of brachydactyly can range from minimal to considerable, depending on the degree of shortening and the status of the remaining digits. The diagnostic aspects and genetic implications are pertinent to the patient and family.

Epidemiologic Findings

Brachydactyly, as a feature of congenital hand anomalies, is quite common. Anomalies in which brachydactyly is the dominant feature are rare and are typically inherited anomalies with an autosomal dominant pattern of inheritance. These have been classified by Bell into brachydactyly types A to E based on phenotypes expressed within pedigrees. Following the initial description in 1951, the classification has been modified by numerous authors, with additions of variants and subclassifications (Table 36.4).[19] Brachydactyly may also occur as a sporadic anomaly or may be part of a systemic syndrome that does not conform to the classification (Figure 36.55). For example, short metacarpals are seen with pseudohypoparathyroidism or pseudopseudohypoparathyroidism. Lastly, noncongenital brachydactyly can occur after growth plate injury from trauma, infection, or frostbite.

Pathologic Findings

Recent research has identified candidate genes for some forms of brachydactyly through pedigree analysis and DNA examination. Various mutations have been identified that affect digital length. Brachydactyly E[158] has been linked to a Glypican 1 gene mutation on Ch2q; brachydactyly B[144] has been associated with mutations of *ROR2*, a tyrosine kinase receptor gene at Ch9q22; brachydactyly A1[68] has been related to nucleotide mutations

within the Indian hedgehog gene; and brachydactyly C[59] has been associated with mutations in the gene for growth differentiation factor-5. Deficiencies in a cartilage-derived morphogenetic protein have also been associated with various forms of brachydactyly. The Grebe and Hunter-Thompson chondrodysplasias are associated with severe brachydactyly and have been directly related to a cartilage-derived morphogenetic protein deficiency (see Figure 36.40).[10] These mutations account for some forms of brachydactyly; however, a variety of additional genetic mutations have yet to be determined to explain the numerous phenotypes.

TABLE 36.4 Modified Bell Classification of Brachydactyly

Type A	A1: Farabee brachydactyly	Principal feature: Short middle phalanges (sometimes fused to distal phalanges). Associated feature: short proximal phalanges of thumbs and great toes.
	A2: Mohr-Wriedt brachydactyly[114]	Principal feature: Short delta phalanx deformity of middle phalanges, index fingers, and second toes.
	A3: Bauer brachydactyly–clinodactyly (brachymesophalangy V)	Principal feature: Short rhomboid or delta middle phalanx of the small finger.
	A4: Temtamy brachydactyly[160]	Principal feature: Short middle phalanges of index and small fingers. Associated features: Ring finger middle phalanx short, middle phalanges of toes short, and talipes calcaneovalgus.
	A5: Bass brachydactyly[17]	Principal feature: Absent middle phalanges, hypoplastic nails in fingers and toes. Associated feature: Hypoplastic distal phalanges.
Type B	Mackinder brachydactyly	Principal feature: Hypoplastic distal phalanges with absent nails. Associated features: Thumbs and great toes may be normal or duplication of distal phalanges may occur; symphalangism. Syndactyly.
Type C	Drinkwater brachydactyly[49]	Principal feature: Short middle phalanx of index and middle fingers. Short delta middle phalanx of small finger. Hyperphalangism of index and middle fingers, with ulnar deviation of these digits. Associated features: Short metacarpals. Symphalangism.
Type D	Breitenbecker brachydactyly (stub thumb)	Principal feature: Short distal phalanx of thumb.
Type E	Bell brachydactyly (brachymetacarpia/ brachymetatarsia)[19]	Principal feature: Short metacarpals and metatarsals with phalanges of normal length. Associated features: Short stature.
	Subclassified by Hertzog	Joint laxity.
	Type E1	Short fourth metacarpals and metatarsals.
	Type E2	Variable combinations of short metacarpals and phalanges.
	Type E3	Variable combinations of short metacarpals and normal phalanges.
Other types	Pitt-Williams brachydactyly[130]	Short distal phalanges of ulnar digits, short metacarpals, and normal stature.
	Sugarman brachydactyly[156]	Short proximal phalanges with symphalangism.
	Smorgasbord brachydactyly	Combination of types A2 and D brachydactyly.

Clinical Features

The severity of the digital shortening is variable. Mild shortening may be apparent only because the normal cascade of the digits is disrupted. The most commonly affected phalanx is the middle phalanx, which is the last component of the digital skeleton to ossify. The small finger and the index finger are the most commonly affected digits. Associated anomalies, such as syndactyly, clinodactyly, and/or symphalangism, also exist and often create a greater functional problem than the brachydactyly (Figure 36.56). Careful examination of the remainder of the upper limb, the pectoral girdle, the contralateral upper limb, and the lower limbs is a requisite. Additional limb or chest wall involvement may lead to a diagnosis of a specific form of brachydactyly or a more inclusive anomaly, such as Poland syndrome. Examination of parents and siblings may reveal further evidence of an inherited anomaly, although the phenotype may not be uniform throughout the affected family members because of variable expression. Traumatic brachydactyly is usually identified via a history of injury and subsequent radiographs that reveal physeal arrest.

Management

The management of brachydactyly depends on the degree of shortening, associated anomalies, and status of the remaining digits. In a complex anomaly, brachydactyly may be a relatively minor component compared with the syndactyly, clinodactyly, or symphalangism (or any combination of these abnormalities). As an isolated deformity, the indications for intervention are aesthetic and functional. The appearance of the hand is most affected when there is disruption of the normal hand cascade, particularly the central digits. A short central metacarpal head may be palpable in the palm and interfere with power grip.

Isolated shortening of one metacarpal (brachymetacarpia) is a common finding and commonly affects the ring finger metacarpal in girls. Enthusiasm for surgery on the part of the parents, patient, or surgeon must be tempered by potential problems of lengthening, including joint stiffness, contracture, and loss of hand function. Lengthening of the shortened digital skeleton requires subperiosteal osteotomy of the shortened element, distraction to the desired length, and either bone grafting or

FIGURE 36.56 X-ray of brachydactyly (shortened middle phalanges) combined with clinodactyly and variably shaped phalanges.

fixation until the intercalated subperiosteal defect has ossified (callatosis) or waiting for the bone of the lengthened skeleton to regenerate. The technique varies with regard to the approach, configuration of the osteotomy, and method of bone lengthening (i.e., immediate lengthening versus gradual distraction osteogenesis).

The majority of lengthening techniques have used a dorsal approach to the phalanx or metacarpal. Saito and colleagues[139] described a palmar approach for lengthening short central metacarpals to avoid the dorsal scar, although care is required to preserve the deep branch of the ulnar nerve. Most authors achieve lengthening using a simple transverse osteotomy and a distraction frame for lengthening. Single-stage lengthening has been performed using a variety of bony cuts to achieve stability, including a step-cut osteotomy, chevron osteotomy (Figure 36.57), or dowel-shaped osteotomy. Immediate lengthening of the metacarpal may require soft tissue release, reconstruction of the transverse metacarpal ligaments, and/or advancement of the origins of the interosseous muscles (Figure 36.58). Intercalary bone graft is not usually required in young children but may be required in teenagers, and the callatosis is stabilized with the distraction frame until the skeleton is consolidated. The alternative approach is distraction osteogenesis with osteotomy and gradual lengthening using a distraction frame.[127] Alignment is best maintained with two fixation pins on each side of the osteotomy to prevent palmar or dorsal angulation. Dhalla and colleagues[47] described a technique suited to small bones

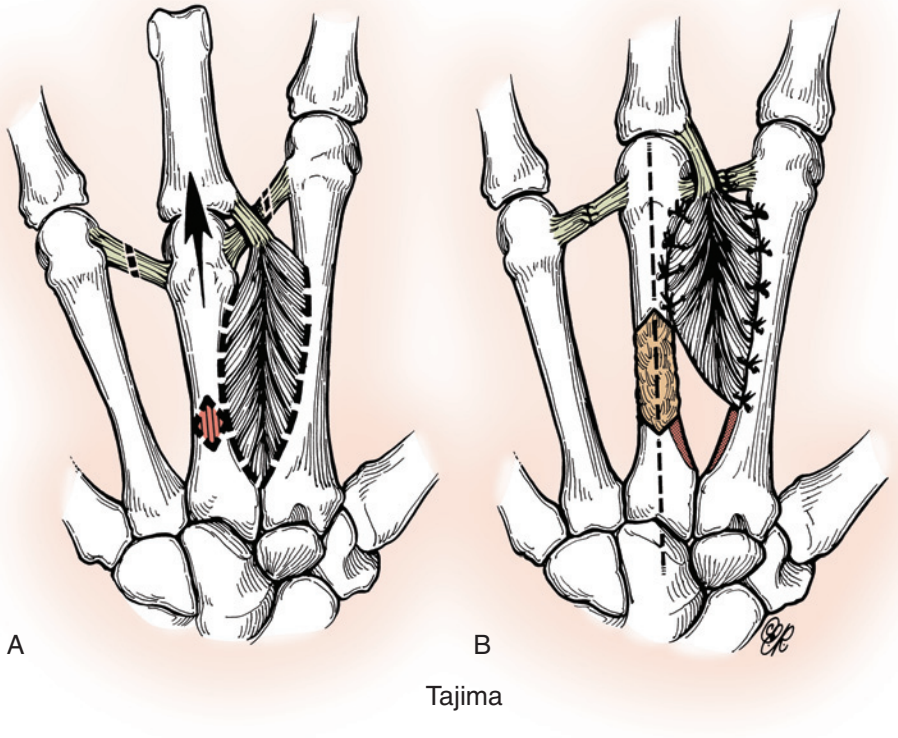

FIGURE 36.57 **A** and **B,** Chevron-type slot graft used to lengthen the metacarpal, as described by Tajima. (Copyright © Elizabeth Martin.)

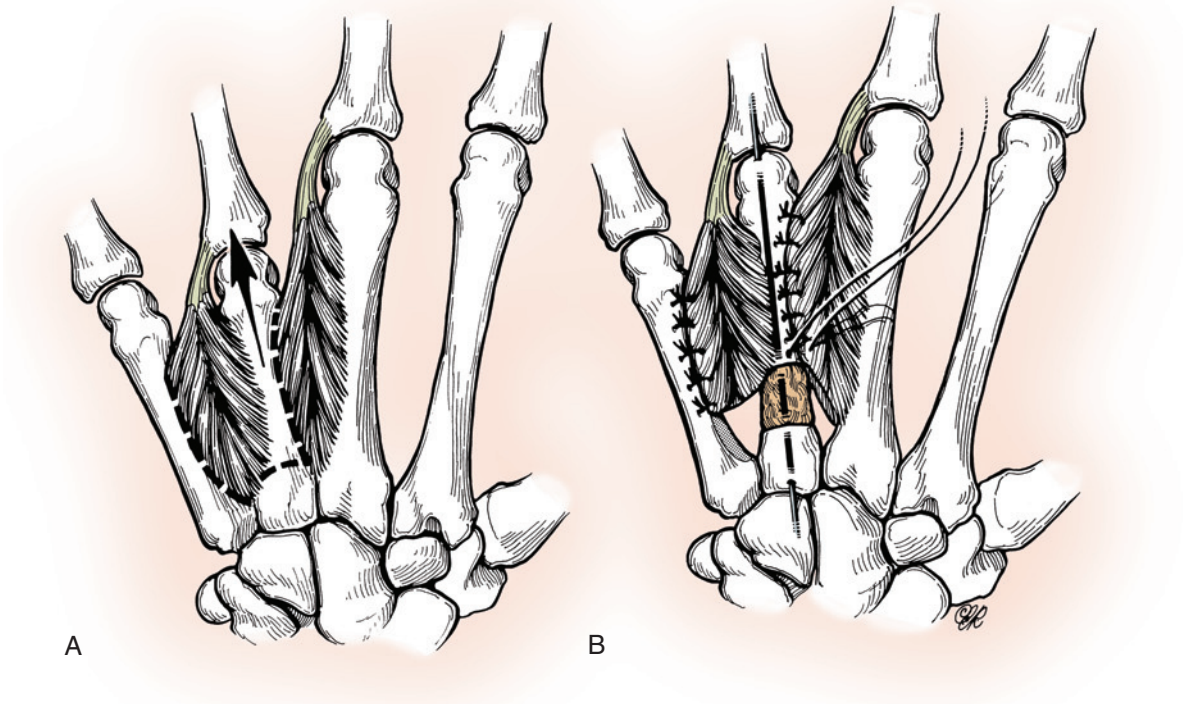

FIGURE 36.58 **A** and **B,** Buck-Gramcko technique for lengthening a short metacarpal. (Copyright © Elizabeth Martin.)

using only one pin on each side of the osteotomy, supplemented with an intramedullary Kirschner wire to maintain alignment. Advantages of distraction callatosis are concomitant soft tissue lengthening, limiting contracture and stiffness, and the formation of regenerate bone that can negate the need for bone graft. Published results of distraction lengthening for congenital short digits and metacarpals are positive, with mean gains in length of up to 15 mm without the need for bone grafting.[8,47,92] Distraction osteogenesis, however, is time consuming and requires cooperation of the patient and parents. The external fixation frame is often in place for more than 4 months to achieve consolidation of the skeleton. Pin loosening and pin site infections can complicate the process, and skeletal lengthening may exceed the soft tissue envelope capacity, producing tender bony prominence of the fingertip.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

The authors' treatment preference for brachydactyly secondary to short phalanges is to avoid surgery. Hand function is often normal in patients with brachydactyly, and lengthening is complex; it often produces a stiff or contracted digit, and the aesthetic result may be disappointing. Distraction lengthening of the phalanges has been used in selected cases of shortening combined with an associated deformity, such as angulation. Immediate lengthening combined with angulatory correction is the preferred approach for brachydactyly combined with angulation. An opening wedge osteotomy and insertion of a trapezoidal bone graft restore alignment and achieve length in a single setting. A closing wedge osteotomy should be avoided in a short digit. On occasion, a single flail shortened hypoplastic digit within an otherwise normal or nearly normal hand is treated by ray amputation.

For brachydactyly secondary to a short metacarpal, lengthening is often recommended to restore the hand contour, particularly if a central metacarpal is involved, as is often the case. The authors' preference is distraction lengthening using a uniaxial distractor. The first stage requires application of the external fixator and osteotomy. Two open or percutaneous pins are placed into the metacarpal on each side of the planned osteotomy site. A dorsal approach is used with the aid of an image intensifier to ensure accurate placement. A distraction frame is applied across the metacarpal. The metacarpal is exposed at the site of osteotomy with retraction of the extensor tendon(s) and cutaneous nerves. A longitudinal incision is made in the periosteum, and subperiosteal dissection is performed to expose the osteotomy site while preserving a sleeve of periosteum. A transverse osteotomy is performed using an osteotome or fine-bladed saw, and the wound is closed. Distraction of the osteotomy site is begun between 4 and 7 days after surgery at a rate of 0.25 to 0.5 mm twice a day. Distraction continues until the desired length is achieved. The frame is not removed until consolidation of the metacarpal (i.e., three cortices visualized on the anteroposterior and lateral films) is apparent radiographically. In some cases, secondary bone grafting may be required. Throughout the period of distraction and consolidation, the patient requires close supervision by the surgeon and hand therapist to ensure that digital range of motion is maintained. Regular radiographs are required to assess the progress of the distraction and identify potential complications of pin displacement and/or failure of the apparatus.

CRITICAL POINTS *Brachydactyly*

- Brachydactyly refers to shortening of the digit or ray within the hand. It can occur sporadically or as part of a syndrome, including a number of inherited anomalies with specific patterns of skeletal anomaly.
- The functional and aesthetic impact of brachydactyly varies according to the extent of shortening, the number of digits involved, and whether associated anomalies such as syndactyly, clinodactyly, or symphalangism are present as well.
- The most commonly affected bone is the middle phalanx, which is the last component of the digital skeleton to ossify.
- Short bones may be lengthened either by bone grafting or by distraction osteogenesis. This may be of specific functional benefit for restoration of pinch function or, in the case of brachymetacarpia, for restoration of the normal cascade of the hand.
- The potential complications of lengthening in a congenitally shortened skeleton relate to the associated soft tissues. Joint contracture or stiffness can develop in the lengthened digit and, in some cases, in adjacent normal digits. Enthusiasm for lengthening, particularly of the markedly shortened digit, must be tempered by this consideration.

CENTRAL HAND DEFICIENCIES

Central deficiency of the hand or cleft hand has been considered a longitudinal deficiency affecting the central digits, and in the past it was grouped with radial and ulnar longitudinal deficiencies, though its position in the classification of congenital hand anomalies is controversial. The hallmark of central longitudinal deficiency is a "V"-shaped cleft in the center of the hand, which may or may not be associated with the absence of one or more digits. Historically, central deficiency was subdivided into typical and atypical types (Figure 36.60), although the latter has long been recognized as symbrachydactyly,[103] which is considered a transverse rather than a longitudinal deficiency. Maisel[102a] proposed that the clinical spectrum of central deficiencies was a progression from a central soft tissue defect to complete absence of all digits. Digital suppression progresses in a radial direction so that in the monodactylous form, the most ulnar finger is preserved (Figure 36.59). This observation is not based on embryogenesis but does represent the clinical findings. Reviews of the clinical findings[113,126,168] in combination with animal models have led to the proposal that because cleft hand is commonly found in association with syndactyly, both simple and osseous, and central polydactyly (Figure 36.61), the disorder is related to a failure of induction of the central digital rays rather than a suppression. A modified International Federation of Societies for Surgery of the Hand (IFSSH) classification has been proposed to include a "failure of finger ray induction group" that includes typical cleft hand, central polydactyly, and (bony) syndactyly.[46]

FIGURE 36.59 Bilateral central deficiency with considerable suppression of the central rays. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Etiologic Findings

The cause of the cleft hand anomaly has been deduced from animal models, particularly the *dactylaplasia* mouse, which expresses a cleft phenotype in its heterozygote form. In this model, the central segment of the apical ectodermal ridge degenerates, leaving the radial and ulnar segments intact. Ogino and colleagues[120,126] have produced rats with cleft hand/foot deformity and central polydactyly and/or osseous syndactyly with teratogen exposure. Fetal studies in this model have identified a combined ectodermal and mesodermal injury in the developing limb bud with disruption of normal signaling. It is proposed that this disruption leads to failure of normal digital ray induction.

A cleft hand is commonly inherited as an autosomal dominant trait and is associated with a number of syndromes (Table 36.5). The most common syndromes are split-hand/split-foot (SHSF) and EEC syndrome (ectrodactyly, ectodermal dysplasia, and cleft lip/palate).[35,76,85,131] SHSF is usually inherited as an autosomal dominant pattern with variable penetrance. Five gene mutation loci have been identified to date and the phenotype can vary substantially between and within individuals, though some characteristics such as preaxial involvement appear to relate to specific mutations.[57] The variable expressivity and reduced penetrance cause difficulty in predicting future phenotypes in an affected family.

TABLE 36.6 Characteristics of Cleft Hand

Typical Cleft Hand	Atypical Cleft Hand (Symbrachydactyly)
Autosomal dominant	Sporadic
Limbs are involved	No limbs are involved (no feet)
"V"-shaped cleft	"U"-shaped cleft
Finger nubbins are not present	Finger nubbins may be present
Syndactyly (especially of first web)	

TABLE 36.7 Classification of Central Deficiency

Type	Description	Characteristics
I	Normal web	Thumb web space is not narrowed
IIA	Mildly narrowed web	Thumb web space is mildly narrowed
IIB	Severely narrowed web	Thumb web space is severely narrowed
III	Syndactylized web	Thumb and index rays are syndactylized; web space is obliterated
IV	Merged web	Index ray is suppressed; thumb web space is merged with the cleft
V	Absent web	Thumb elements are suppressed; ulnar rays remain; thumb web space no longer present

Clinical Features

The condition may be unilateral or bilateral and may or may not involve the feet. The extent of cleft hand varies from generation to generation, and the characteristics are described in Table 36.6. The manifestations of cleft hand may vary from only a very minor cutaneous cleft without absence of the finger to a severe form in which only the little finger remains. Syndactyly between the digits bordering the cleft is common: the first web space is often narrowed. Duplications can also occur adjacent to the cleft. Within the cleft, metacarpals may or may not be present, and transverse tubular bones may be present and may further widen the cleft as they grow. Phalangeal anomalies often coexist, including longitudinally bracketed epiphyses or double phalanges. The metacarpal anomalies are variable, including absence within the cleft, bifid metacarpals supporting one finger, and duplication. The anomaly is often bilateral, and in the SHSF phenotype it is associated with comparable defects in the feet. Although proximal enabling structures such as muscle-tendon units and nerves are frequently absent, some structures are present to variable degrees.

Classification

Many classifications exist[13,23,31,46,62,141,176]: in our experience, the most useful is that of Manske and Halikis, which concentrates on the status of the first web space (Table 36.7).[104] This classification acknowledges that more extensive clefts merge with the first web space and produce a wide and competent web. More extensive cleft formation, however, can involve the thumb, which is hypoplastic or even absent.

Surgical Treatment

Indications for Surgery

Flatt memorably described the cleft hand as a "functional triumph, but a social disaster" because many cleft hands, although stigmatizing the child, function well.[63] A family with one or more generations of cleft hands may avoid surgery for their children because they perceive function as excellent and aesthetic improvement as marginal. Such opinions require sensitive handling when outlining the indications for surgery and the surgical plan. Surgery should improve both appearance and function but should never downgrade either. Many authors have attested to the psychological consequences of cleft hand, and the moving account of Walker in Flatt's text[63] highlights the psychosocial complexities faced by families with this condition. It is surely axiomatic that no physician should add to the misery

of these patients and their families by the outdated practice of using animalistic comparators such as *lobster claw* or *pincer*.

Several broad indications for surgery are recognized: (1) progressive deformity (caused by deforming syndactyly or transverse bones); (2) deficient first web space; (3) deformity of the cleft; (4) the absent thumb; or (5) the feet. The deformity comes as a shock in a family previously unaffected, and it may be inappropriate and unnecessary to propose early surgery to parents still adjusting to these unexpected circumstances.[27,93] Most parents, however, will accept surgery to prevent worsening of the deformity. Indications for early surgery include the separation of syndactyly between digits of unequal length (especially the thumb and index finger) and the removal of transverse bones that result in widening of the cleft during growth and progressive deformity. Most of the other surgical procedures are less urgent and may be reserved until the child is between 1 and 2 years of age.

Surgical Management of the Progressive Deformity

Removal of Transverse Bones. Removal of transverse bones from within the cleft can prevent progression of deformity and serve as a prerequisite for closure of the cleft. The transverse bone may originate and insert from either the metacarpal or proximal phalanx.[3] The bone may join the metacarpophalangeal (MCP) joints, and removal requires preservation or reconstruction of the collateral ligaments about the joint or joints. Articular surface sculpting of the remaining joint may be required.

Syndactyly Release. Syndactyly may affect the border rays of the hand. Early release is indicated to prevent progressive deviation of the longer ray (see Figure 36.61). Release of the syndactyly is performed according to the principles detailed above, with specific attention paid to the digital artery anatomy, which may be abnormal, particularly for digits adjacent to the cleft where the common digital artery is likely to be deficient.

Surgical Management of the Cleft Deformity

Release of the First Web Space and Closure of the Cleft. The classification proposed by Manske and Halikis[104] has focused attention on the importance of the first web space morphologic condition in dictating surgical treatment of the cleft hand (Figure 36.62). In type IIA cases, the first web space is mildly narrowed and a cleft is present between the index finger and the

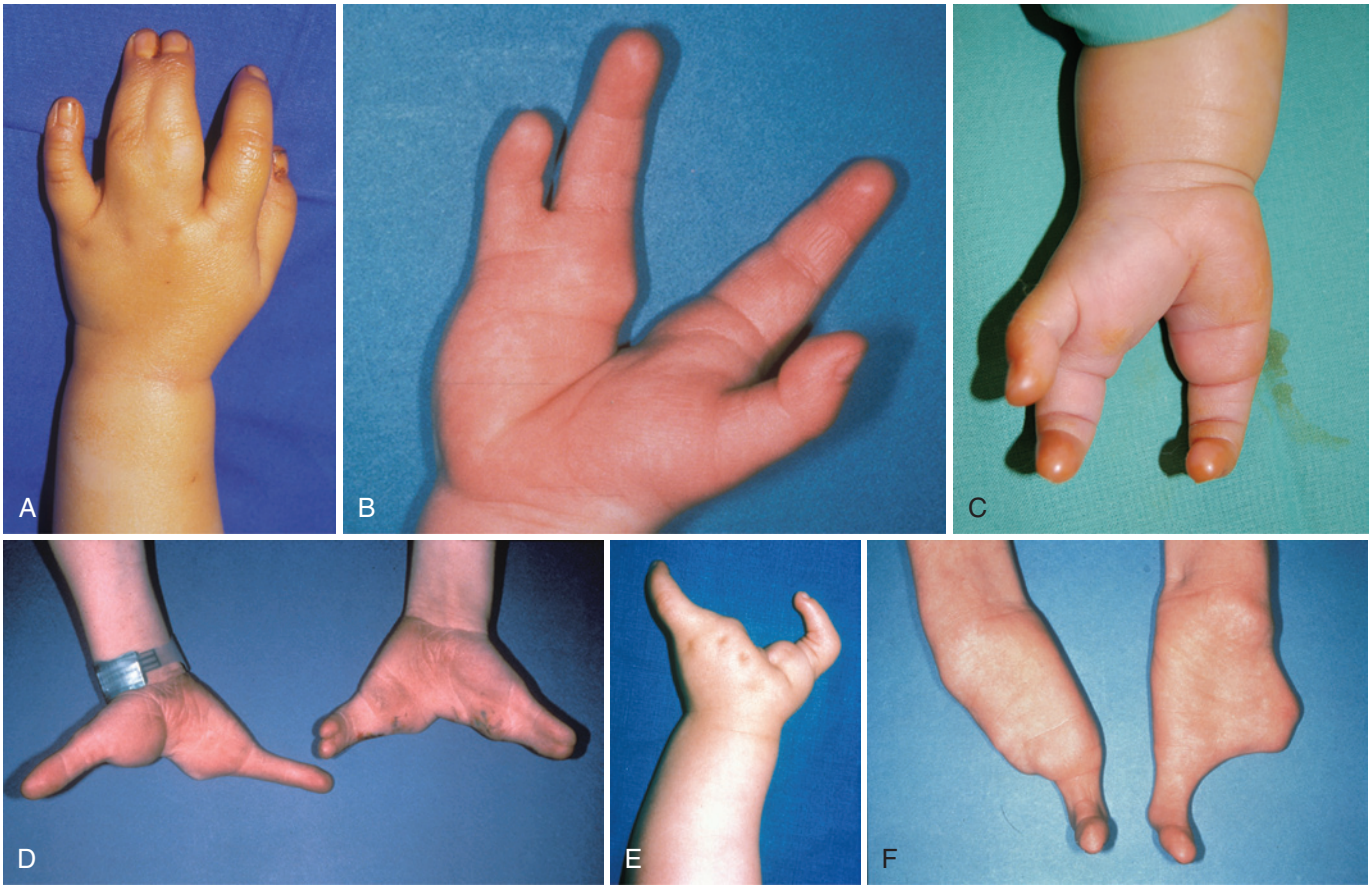

FIGURE 36.62 **A** to **F,** These images illustrate the Manske and Halikis classification and also some aspects of the teratologic sequence in cleft hand. **A,** Type I hand with a normal web space between the thumb and index finger. A very minor cleft is present between the second and third rays and syndactyly between the third and fourth rays. **B,** Type IIa hand in which the thumb web space is mildly narrowed. Note the suppression of the central ray with a deep cleft and minor syndactyly between the ring finger and little finger. **C,** Type IIb cleft hand with a severely narrowed first web space and deletion of the third and fourth rays. **D,** Type III cleft hand (untreated) on the right side and type IV cleft hand on the left. On the right side the thumb and index fingers have untreated syndactyly that completely obliterates the first web space. The central ray is absent, and the fourth and fifth rays are also syndactylized. **E,** Type IV cleft hand with a merged web space. The two border rays are present, but the index ray and other central rays are suppressed, and the first web space merges with the cleft. **F,** Bilateral type V cleft hands. The thumb web space and the thumb are absent, and only the ulnar digit remains.

ring finger, with complete absence of the central ray. Concomitant syndactyly of the ulnar digits is often present. In type IIB hands, the first web space is more severely constricted and the cleft element more variable. Type III cleft hands have a complete syndactyly between the thumb and index finger. Type IV cleft hands possess a thumb web space that is merged with the cleft. Type V cleft hands have suppression of the thumb elements without a thumb web space.

Release of a slightly narrow first web space may require simple skin release from volar to dorsal across the narrowed first web space. Release of complete first web space syndactyly may require formal separation, with release of the thick fascia or muscles within the abnormal web space. In these cases, it will also be necessary to import new skin into the web space. In cases of index finger/thumb syndactyly, the thumb may be rotated into the plane of the other digits and a metacarpal rotation osteotomy may be required to realign the thumb. Such an osteotomy is not simply a matter of transverse division of the tubular bone and rotation with fixation: unless longitudinal soft tissue structures, including tendons, intrinsic muscles, and the periosteum, are freed and given new vectors of force, the digit will progressively derotate, returning to the original form. Frequently, a short disc of bone must be removed during rotation osteotomy to avoid imparting undue torsion on the tissues as rotation occurs.

The cleft incision is designed to re-create the commissure after the cleft is narrowed. For this purpose, a small commissural flap is prepared on one border of the cleft and a recipient defect planned on the other border of the cleft (Figure 36.63). Closure of the cleft can free skin to be used for resurfacing of the widened first web space. Snow and Littler described an elegant but complex technique[152] that has been elaborated on by Flatt (Figure 36.64 and Video 36.1). The cleft skin is raised as a palmar-based flap and designed to transpose into the first web space (Figure 36.65). The position and dimensions of the first web space will change after translocation of the index ray. The viability of this palmar flap depends on preservation of the intrinsic blood supply, and dissection must maintain the

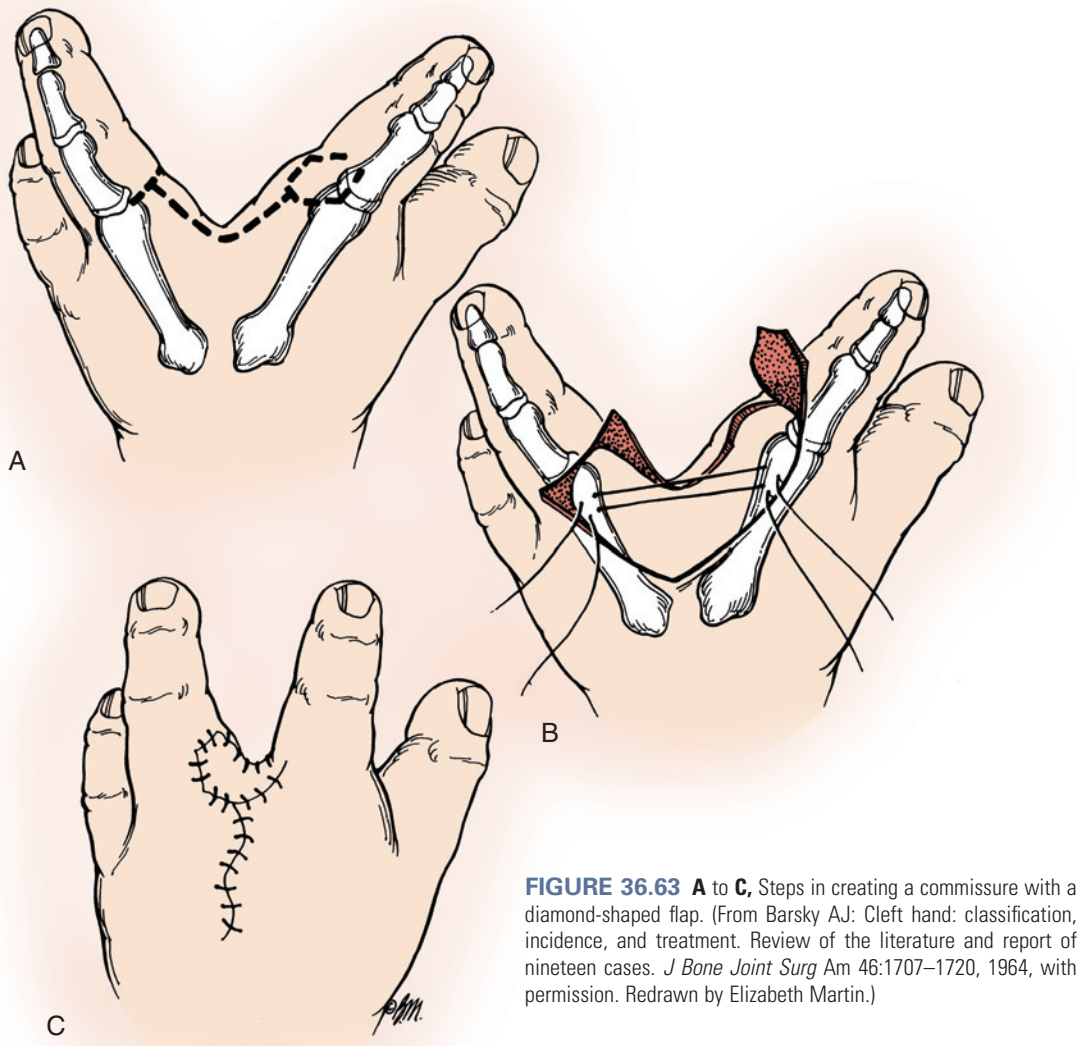

FIGURE 36.63 **A** to **C,** Steps in creating a commissure with a diamond-shaped flap. (From Barsky AJ: Cleft hand: classification, incidence, and treatment. Review of the literature and report of nineteen cases. *J Bone Joint Surg* Am 46:1707–1720, 1964, with permission. Redrawn by Elizabeth Martin.)

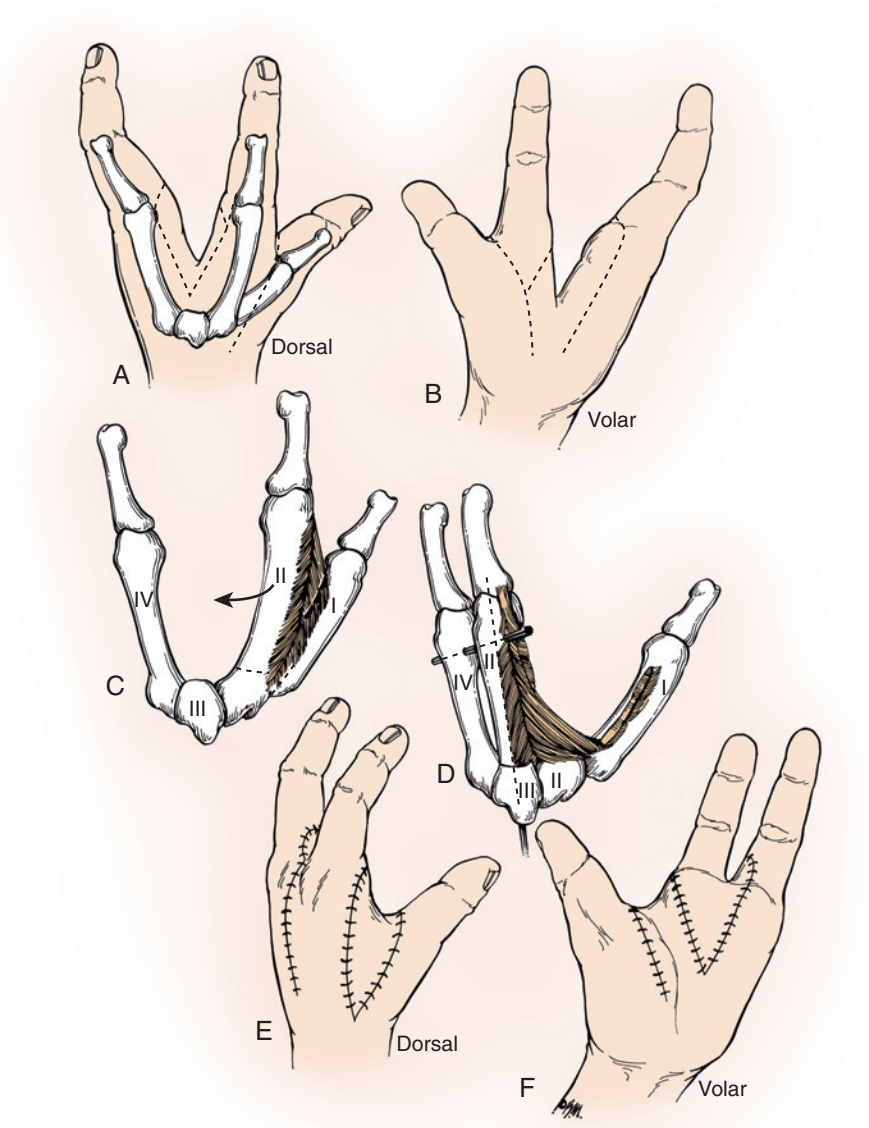

FIGURE 36.64 **A** to **F,** The Snow-Littler procedure. The cleft is raised as a palmar-based flap, with a small radial flap preserved for recreation of the commissure. The first web space is released, which may require division of the first dorsal interosseous origin and surrounding fascia. The second metacarpal is transposed and fixed to the remnant of the base of the third metacarpal if present. Fixation is achieved with axial and transverse wires, and careful attention must be given to correction of rotation at this point. The palmar flap is transferred, and the new commissure between the second and fourth rays is re-created.

subdermal plexus. If possible, a digital artery should be included with the flap to transform its blood supply from random to axial.

Relocation of the index finger to the base of the third metacarpal widens the first web space and decreases the amount of flap transposition. The index finger must be carefully positioned to prevent malrotation and scissoring during finger flexion. The osteosynthesis at the base of the metacarpal is usually performed with a Kirschner wire or interosseous sutures (or both), although miniplate fixation is now preferred by the authors. In those cases without a base of the third metacarpal to receive the index transposition, the cleft may be closed by wedge excision of the index metacarpal or within the carpus to widen the thumb-index web and realign the fingers.

Foucher and coauthors[66] reported a series where carpal osteotomies were used to relocate the ulnar digits centrally to close deep and wide clefts. Reconstruction of the intermetacarpal ligament should be used to reinforce the cleft closure and to prevent splaying of the digits, as in the technique of Saito and colleagues or Ogino, which uses the A1 pulleys from the digits (Figure 36.66) unfolded toward each other and overlapped. The final stage in cleft closure is creation of a commissure across the cleft. The commissure flap previously outlined is raised and inset (see Figure 36.64).[13] The Snow-Littler procedure is far from a simple procedure: the planning and execution can be difficult, and the transposed flap may not inset into the correct position. Supplementary skin grafts may be necessary. In addition, the flap may undergo partial necrosis because its length substantially exceeds its breadth. Rider and coworkers[135] have reported a low rate of flap necrosis, but a third of patients required revision, and supplementary skin grafting was required in tight first web spaces.

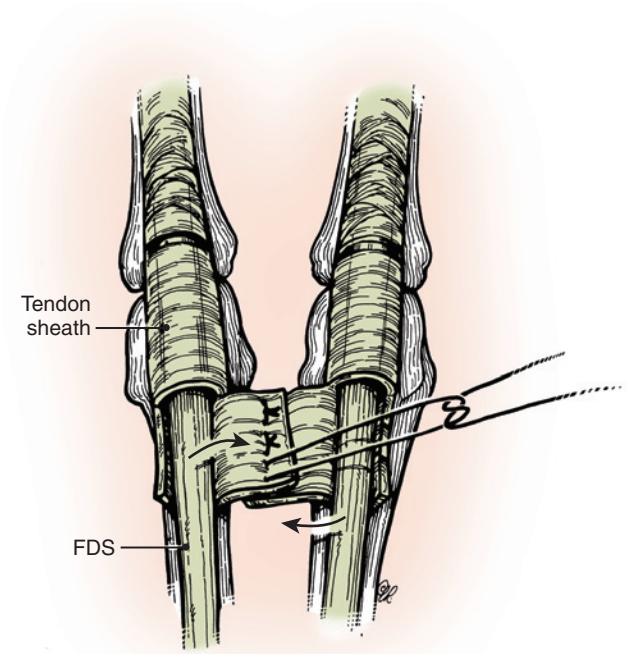

FIGURE 36.66 The deep transverse metacarpal ligament is reconstructed by using the flexor sheaths (part of the A1 or A2 pulleys) of the index and ring fingers. *FDS,* Flexor digitorum superficialis.

Miura and Komada[110] and more recently Upton[172] have described techniques that allow the transposition of the index finger into the central position and redrape the palmar and dorsal skin as separate flaps to create the first web (Figure 36.67). The cleft is incised from side to side across its leading edge. The index finger is raised on its neurovascular bundles and transposed by osteosynthesis with the third metacarpal or by angulation osteotomy.

Ueba[170] also describes a less complicated procedure using transverse flaps from either border of the cleft and transposition of the index digit (Figure 36.68). The flaps from either side of the cleft are used to resurface the palm, the dorsal aspect of the metacarpal head of the transposed digit, and the ulnar part of the first web space. Ueba also used slips of tendon material to connect the common extensor tendons of the digits bordering the cleft to prevent digital separation during extension. This technique allows a simpler approach to cleft closure but has the aesthetic disadvantage of transferring palmar skin to dorsal and dorsal skin to palmar.

In reality, the surgeon versed in congenital hand surgery will treat type IIB and type III cleft hands on an individual basis, borrowing elements of the above technique(s). In cases in which there is a small digital remnant within the cleft, the use of a bilobed flap technique may also transport a large amount of pliable, vascularized skin into the first web space (Figure 36.69). Rarely, when a tight or narrow first web space is associated with a small, narrow, or shallow cleft, a distant flap to import skin may be needed. Again, this will follow standard plastic surgical techniques and attempts to codify treatment break down in these unique circumstances.

An acceptable outcome is ensured by adherence to the principles of adequate first web release, resurfacing of the first web with enough vascularized pliable tissue, transposition of the most radial finger, re-creation of an intermetacarpal ligament, and recreation of a commissure about the cleft.

In the type IV cleft hands, the first web space is merged with the cleft and function does not require creation of a first web space. Surgical effort is usually directed toward mobility and/or position of the thumb or ulnar digit to promote pinch and grasp.

In type V cleft hands, there is no cleft or web space and the thumb is very deficient. Surgery for this group is considered in the next section.

Surgical Management of the Absent Thumb Deformity

Creation of a radial digit is the priority in the management of the type V cleft hand. In some cleft hands, a digit or digits may be positioned on the radial side of the hand albeit in the plane of the ulnar digit. Separation and rotation of this radial ray may re-create a functional and useful hand but require distant flap cover for the first web space. Options include free or pedicled flaps from the forearm and groin.

An absent radial ray can only be replaced by free toe transfer. In contrast to microsurgical toe transfer in children for other indications, transfer for cleft hand is fraught with problems.[95,96,175] Not only is the hand anatomy highly abnormal, with suppression of many of the proximal longitudinal structures that might be expected to drive a transferred toe, but the feet themselves are often abnormal. In the bifid foot with a tibial and fibular ray, it is the fibular ray that bears weight, and the angulated and abnormal tibial ray may be harvested, and is often ablated to enable shoe fitting. Experience with such free toe transfers is limited. A child who underwent transfer of the tibial rays of the foot to the hands is shown in Figure 36.70. A number of interesting clinical and anatomic findings were found. First, flexor and extensor tendons were connected around the distal part of the limb and had adequate excursion after division. Second, vessels and cutaneous nerves were readily found on exploration aided by 10-mHz Doppler examination (angiography was not performed in either the foot or hand). Last, useful function was achieved despite limited power and range of motion. Prehension provided useful holding and manipulative abilities otherwise unachievable in a hand with a single inflexible digit.

Surgical Management of the Feet

The foot deformity in cleft hand often parallels the hand deformity.[1,146,185] The hand surgeon may or may not also be involved in the feet, but his or her opinion will often be sought at the time of consultation. Blauth and Borisch[22a] have classified the foot deformities that occur with cleft formation into six types. Types I and II have only minor abnormalities without absence of metatarsals, whereas the metatarsals are progressively absent in the remaining types. Type VI is the monodactylous cleft foot in which the fibula ray is always the last remaining ray.

The status of the great toe ray or tibial ray presents a challenge in surgical decision making in the foot. It is fairly common to see patients with great toe polydactyly and deviation in whom the decision about preservation and correction of the tibial ray is required. In our experience, the fibular ray is always the more important and the tibial ray may be present but may not participate in weight bearing. In those rare cases in which a microsurgical transfer is considered from the feet, it is likely

FIGURE 36.67 Two-year-old with cleft hand. **A,** Dorsal view. **B,** Palmar view. **C,** Upton skin design with Barsky flap for commissure reconstruction. that the feet will also be severely afflicted, with perhaps only two rays remaining. In these cases, reluctance to sacrifice the tibial ray is understandable. Nonetheless, this ray can be transferred, although waiting until the child is of an age to undergo gait analysis is wise.

Rarely is surgery indicated for cleft foot. When it is, it is usually because of difficulty in fitting footwear because of either duplication or deviation of the border digits. This may be corrected either by osteotomy or excision of trapezoidal phalanges. Occasionally, as in the hand, resection of a transverse bone may be necessary. The common experience is that despite a quite bizarre appearance in the feet, function is remarkably good and gait is rarely considerably impaired.

In summary, surgical treatment for children with central deficiency is challenging but can provide good functional and aesthetic results. In more severe forms, ingenuity of the surgeon is required. In these cases, the surgeon must discuss with parents how experience over generations shows that despite the adverse appearance, children will adapt and learn to use their hands in a way that might have been considered impossible when they were born. Surgery should improve appearance and function, or both, but should never downgrade either. Surgical correction should be planned according to a schedule that recognizes the urgency of some aspects of treatment and the discretionary nature of others. The overriding determinant of hand function is the first web space, and this structure is the basis of the most

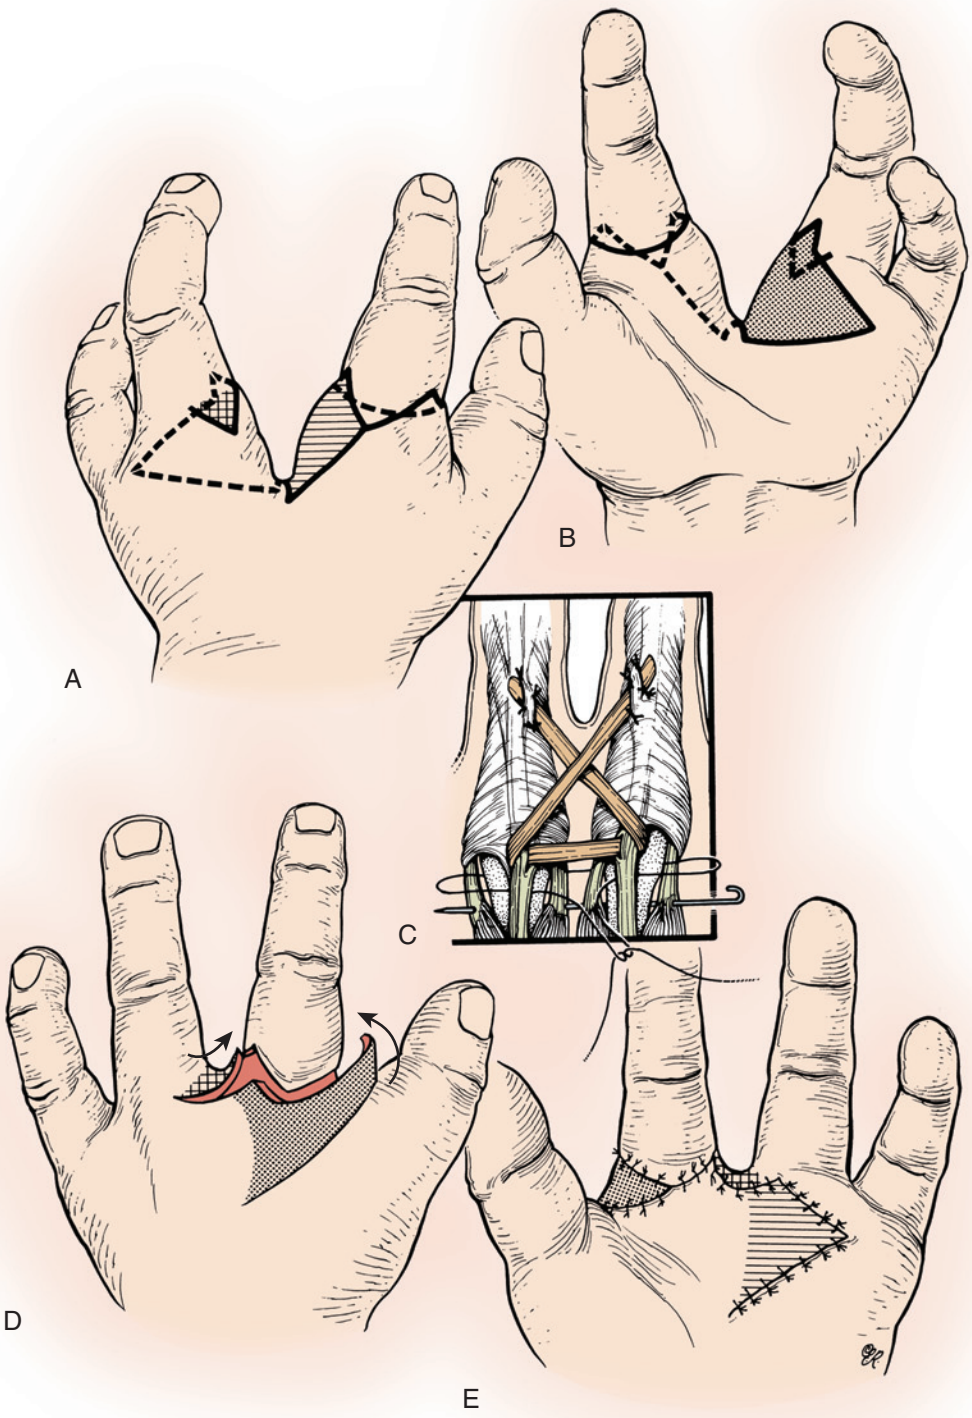

FIGURE 36.68 **A** to **E,** Ueba technique for treatment of a typical cleft hand with one ray suppressed. Ueba used a tendon graft between the extensor tendons of the border digits **(C)**, but this is not an essential component of the procedure, and the Ogino method of creation of a transverse palmar ligament is used (see Figure 36.66). The disadvantage of this technique lies in the transfer of palmar skin dorsally or radially in the cleft, and vice versa. (Copyright © Elizabeth Martin.)

useful classification. Microvascular transfers from the foot can be useful in highly selected cases. If amputation in the foot is being contemplated, use of the part in the hand should be considered.

CRITICAL POINTS *Central Hand Deficiencies*

- True cleft hand is distinct from atypical cleft hand, which is recognized as part of the teratologic sequence of symbrachydactyly.
- Cleft hand is commonly inherited as an autosomal dominant trait and is associated with SHSF and EEC syndrome (ectrodactyly, ectodermal dysplasia, and cleft lip/palate).
- Surgery is considered for a variety of indications, including progressive widening of the cleft secondary to transverse lying bones, a narrowed first web space, and the widened cleft.
- Indications for early surgery are separation of syndactyly between digits of unequal length, especially the thumb and index finger, and removal of the transverse bones that result in progressive widening of the cleft.
- In cases of thumb/index finger syndactyly, the first web space requires reconstruction. The technique depends on the severity of the syndactyly. Complete syndactyly can be released and the cleft closed in a single setting. The skin from the cleft is rotated into the first web space to create supple tissue.

Expected Outcomes

The expected outcome from surgery will vary, as expected, according to the degree of deformity. For children with a preserved thumb, good function can usually be achieved by repositioning of the digital rays and reconstruction of a first web space. Children without a thumb present a substantial challenge for thumb reconstruction in a hand with abnormal proximal anatomy.

ABSENCE OF FINGERS OR THUMB

When considering absence of digits, the absence may be in either a transverse or longitudinal direction. In a transverse deficiency, the digit(s) is absent but the proximal supporting structures required to support digital function are present albeit to a variable extent. Examples of transverse absence include ring constriction syndrome, symbrachydactyly, and idiopathic transverse absence. In longitudinal deficiency, the supporting structures are severely deficient or absent. Examples are thumb absence in radial deficiency, absence of ulnar digits in ulnar dysplasia, and central absences in central deficiency or true cleft hand.

Reconstruction of transverse absence may be achievable by replacing the absent distal part (e.g., by microvascular toe transfer), which is then enabled by the proximal neurovascular and musculotendinous structures. Reconstruction of longitudinal absence requires replacement of the absent part and most of the enabling proximal structures, as in pollicization of the index finger for thumb absence.

Constriction Ring Syndrome (Amniotic Disruption Sequence or Amniotic Band Syndrome)

Amniotic disruption sequence is characterized by partial or complete circumferential constrictions around limbs, digits, or other body parts.[78] Consequences include acrosyndactyly of digits, terminal absence or amputation, and localized swelling with digital edema distal to constrictions (Figure 36.71).

Etiologic Findings

Streeter, in 1930, and others have proposed that this syndrome was caused by vascular disruption in the embryo. Others believe that it is due to amniotic disruption with release of amniotic bands that encircle and strangulate limbs or parts of limbs in utero. It is also postulated that the limb may become entrapped within the ruptures of the amniotic wall.[165] The most prevalent theory is amniotic disruption with release of amniotic bands, based on the appearance of the circumferential constrictions strangling the digit or other body parts and also upon the recovery of amputated digits from within the womb.

Clinical Features

The constrictions may be completely or incompletely circumferential and may occur anywhere on the body but are most commonly seen on the limbs. A consequence of these constrictions may be amputation or near amputation with distal edema. In severe cases, the limb viability is threatened. The constriction may also produce fusion of the digits to adjacent or nonadjacent digits, producing either a complicated syndactyly (see Figure 36.71, *C*) and/or acrosyndactyly with a distal fusion of the digits and a proximal sinus between them. From the hand surgeon's perspective, the most important thing about the transverse absence in amniotic disruption sequence is that the proximal structures of the hand are almost normal (Figure 36.72). Amputations or absences may occur at any level of the limb and have even been described in the head and neck. Lesser constrictions may be responsible for some rare cases of facial clefting. The digital stumps may exhibit tapering skeletal elements with tight skin cover. Where the distal limb is present, the skin distal to the constriction ring may be hard and swollen with an uncompressible edema. Nerve palsies have been associated with constriction ring sequelae and are present from birth (Figure 36.73).[169] The authors have found that these palsies, if explored surgically, are associated with absence of the nerve distally, further confusing the ideas on pathogenesis. Heterotopic reimplantation of amputated digits rarely occurs and is managed individually.[163]

Classification

Constriction syndromes are classified as a whole entity and subclassified according to limb manifestations (Table 36.8). These classifications are not useful for directing treatment but may assist in collaborative research.

Management

Treatment of the Digit or Limb Threatened at Birth. The condition is increasingly diagnosed in utero,[12] and the hand surgeon may be called upon to offer a clinical opinion to the parents. It is wise to confine this opinion to generalities prior to term. On rare occasions, a proximal ring may cause overt distal ischemia. Surgical release of the constriction may be appropriate. Survival of the limb is often questionable, and amputation is usually required. In utero release of lower limb constriction rings has been performed successfully with preservation of the limb[136] and is worth considering in proximal severe constrictions identified on antenatal ultrasound. However, the risks to the mother

and child must be considered. Currently, fetoscopic band release is limited to progressive edema and loss of circulation that most likely will result in loss of the limb. The place for fetoscopic surgery is still emerging,[87] and the physician must tell the family that the risk of spontaneous abortion is 6% to 10% following global fetoscopic procedures.

Treatment of Nerve Palsies. A peripheral nerve palsy may occur underlying a constriction ring. The value of electrodiagnostic evaluation is questionable.[182] Successful outcomes following decompression of the nerve compression have been described, although the authors and others have seen cases with limited nerve continuity and no improvement after surgery.[48,169]

Treatment of the Constriction Ring. Treatment is aimed at both functional and aesthetic improvement. The mainstays are excision of the ring and subcutaneous tissue combined with "Z"-plasty or "W"-plasty. This technique elongates and reorients the scar to allow relaxation and concealing of the constriction. Mutaf and Sunay[119a] have recently reported on a rectangular flap

FIGURE 36.72 Normal structures are present proximal to the constriction ring. The intrinsic muscles, flexor tendons, and neurovascular structures are identifiable.

technique that focuses on correction of the contour with interposing dermofat flaps raised from the cleft, without lengthening the skin scar. The importance of correcting the contracture within the subcutaneous layer has been emphasized by Upton. Previously, circumferential surgery was not recommended at a single setting; however, complete circumferential excision may be performed safely.[79] An exception to circumferential surgery is two rings that are closely adjacent. In this case, it is prudent to release the rings one at a time.

Treatment of Acrosyndactyly. Acrosyndactyly secondary to amniotic disruption sequence is separated according to the principles of syndactyly reconstruction (see Syndactyly). Separation requires attention to the commissure, resurfacing of the digital surfaces, and attention to the nail and pulp. The sinus is usually too distal to incorporate into the commissural skin flaps and so it is often excised and the skin yielded used as a full-thickness graft. Additional attention may be directed toward release of concomitant constriction rings. The timing of separation is important because connected but nonadjacent digits are often of unequal length, which creates angulatory deformities during growth. Release of the distal connection is often enough to resolve this tethering effect, and definitive separation and commissure reconstruction may be deferred until the child is older.

Treatment of Skin Protuberances. Skin protuberances are often present in amniotic disruption sequence. These lumps are present on the dorsum of the fingers and appear firm and edematous. These protuberances may be treated via numerous techniques. "Z"-plasty is often unsatisfactory, and excision is preferred with resurfacing using full-thickness skin grafts (Figure 36.74).

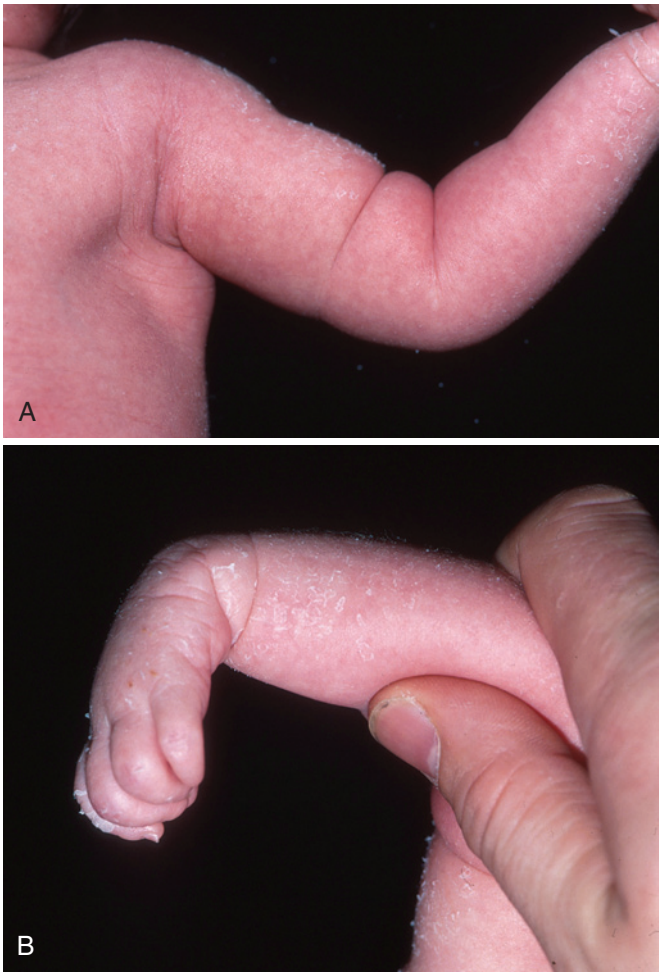

FIGURE 36.73 **A,** A constriction ring around the arm in a newborn child. **B,** Associated radial nerve palsy.

FIGURE 36.74 Dorsal skin lumps are common and can be treated by excision and skin grafting.

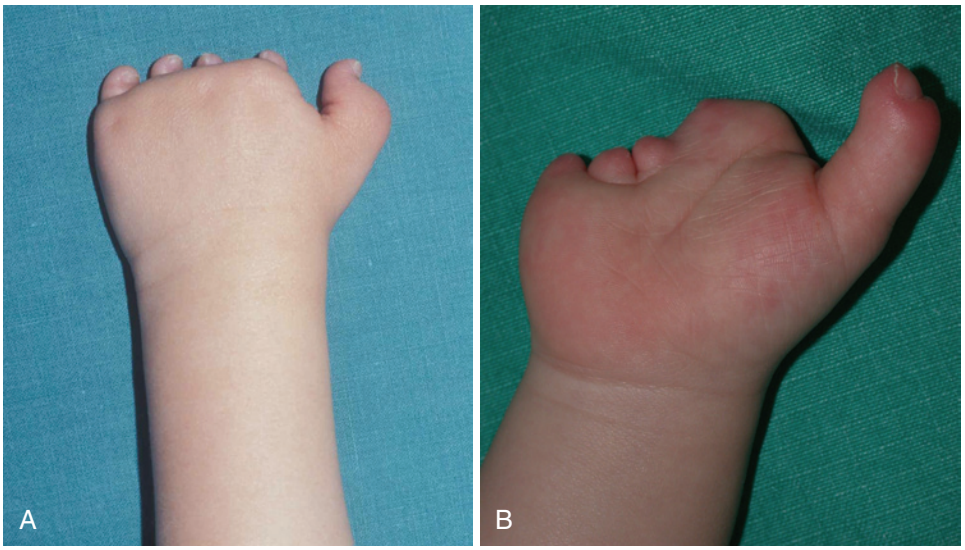

FIGURE 36.75 Types of symbrachydactyly. **A,** Symbrachydactyly with a reasonable thumb but absent fingers represented by nubbins with nail remnants. **B,** Complete absence of the fingers that becomes more pronounced toward the ulnar side of the hand.

Treatment of Digital Absence. Digital absence is common in ring constriction syndrome. The number of absent digits is variable. The digits appear similar to a transverse absence. The proximal enabling structures are present and may be used to control and drive a transferred digit. The means of reconstructing profound absence of digits is addressed later.

CRITICAL POINTS *Amniotic Disruption Sequence (Amniotic Band Syndrome or Constriction Ring Syndrome)*

- Amniotic disruption sequence is characterized by partial or complete circumferential constrictions around limbs or digits.
- The consequences of amniotic disruption sequence include syndactyly of digits, terminal absence, and digital edema distal to the constrictions. Occasionally, a peripheral nerve injury may occur secondary to a constriction.
- Mild constriction rings are treated by excision and lude syndac.
- Release of syndactyly follows the standard techniques of digital separation and resurfacing. Early release of the distal connection, however, with delayed formal separation and reconstruction of the commissure may be considered to relieve the tethering effect between digits of unequal length.

Symbrachydactyly

Symbrachydactyly is a term (fused short fingers) used to describe a spectrum of deformity ranging from digital hypoplasia to aplasia or deficiency of the hand or forearm. The condition has been difficult to place within the IFSSH classification[157] because the anomaly displays features of undergrowth, failure of differentiation, and failure of formation.[38,112] Symbrachydactyly shares features with transverse absence and may represent the end stage of this spectrum.[91,186] Blauth and Gekeler[24] originally classified symbrachydactyly into four types in a progressive spectrum of deficient digits: short finger type, cleft hand type, monodactylous type, and peromelic type. The most severe types, monodactylic and peromelic, are characterized by transverse absence of digits and the presence of rudimentary distal nubbins or stumps, which may include remnants of nail plate, bone, or cartilage (Figure 36.75). An alternative classification has been proposed and focuses on the number of phalanges missing (Table 36.9). This scheme also identifies a teratologic sequence passing from the presence of five digits to complete midforearm amputation.

TABLE 36.9 Classification of Symbrachydactyly

Type	Description
1. Triphalangia type	A hand with no missing bone; all four fingers should have three phalanges, even though some phalanges (often the middle phalanges) are short
2. Diphalangia type	A hand in which one phalanx (usually the middle one) is missing in one or more digits
3. Monophalangia type	A hand that has a finger or fingers with only one phalanx
4. Aphalangia type	A hand in which all three phalanges are missing in a digit or digits
5. Ametacarpia type	A hand with absence of a metacarpal bone as well as three phalanges in a digit or digits
6. Acarpia type	A hand that has absence of all the digits and partial or complete absence of the carpal bones
7. Forearm amputation type	An arm with absence of the distal portion of the forearm; usually, there are rudimentary digits on the stump

Adapted from Yamauchi Y, Tanabu S: Symbrachydactyly. In Buck-Gramcko D, editor: *Congenital malformations of the hand and forearm*, London, 1998, Churchill Livingstone, pp 149–157.

Clinical Features

Symbrachydactyly occurs sporadically. There appears to be a spectrum of deficiency, beginning with short middle phalanges, extending to absence of the central rays, and culminating in

absence of the entire hand. The defect is believed to be mesodermal, which explains the remaining distal finger ectodermal structures (pulp, nail fold, and nail). This results in the characteristic "nubbins" or "buds" that represent vestiges of digits and are the hallmark of symbrachydactyly (see Figure 36.75).[112]

Symbrachydactyly may occur with Poland syndrome, with unilateral hand hypoplasia associated with absence of some shoulder girdle muscles. The sternal head of the pectoralis major muscle is most commonly absent, although considerable chest wall deformity may also be present. The correlation between these conditions and other syndromes with similar findings is unknown. Previously, there existed some confusion between oligodactyly (i.e., few finger form of symbrachydactyly) and cleft hand.[13,111] The central deficiencies form of symbrachydactyly was previously called atypical cleft hand; however, the deformity is now known to be transverse rather than longitudinal, with the implications for reconstruction as discussed below.

ANATOMY

Each form of symbrachydactyly occupies a place on the continuum from the normal hand through the various degrees of deficiency to complete absence of the hand. The severity of deficiency correlates with the degree of aberrant anatomy (see Table 36.9). As stated previously, the presence of proximal enabling structures offers hope for reconstruction of functioning digits (Figure 36.76).

In all degrees of symbrachydactyly, the central rays are the most abnormal. In the mild forms (types 1, 2 and 3), the skeletal elements are the most affected. The middle phalanges are reduced in size and may be absent. Because mild symbrachydactyly rarely requires surgical exploration, little is known about the aberrant soft tissue anatomy apart from the incomplete simple syndactyly that is apparent on clinical examination.

In more severe symbrachydactyly (type 4), the central rays virtually disappear and are replaced by finger nubbins with aponeurotic attachments to extrinsic tendons around the end of the hypoplastic metacarpals. The nubbins may contain small remnants of phalanges that articulate with the metacarpal. These nubbins have vestigial connections via the palmar aponeurotic and retinacular system to the extrinsic tendons. This connection is apparent by the ability of the nubbins to pucker into the palm during hand use. In the absence of phalangeal remnants, the metacarpals are usually small and may only be present at their bases. The fifth finger is least affected; however, it typically lacks a middle phalanx. It usually has a competent MCP joint and a variably stable distal joint, which is commonly radially deviated. This angulation is partly the result of the oblique pull by the extensor tendon, which bridges the "U"-shaped cleft. The thumb is also variable in form. The first web space may be narrowed, and the thumb may lack full circumduction at the basal joint. The extrinsic flexor tendons often share a muscle belly and may be coalesced into a single tendon mass within the carpal canal. Lumbrical muscles are usually absent even when digits are present, and interosseous intrinsics are absent or highly abnormal. The extensor tendons along the dorsum of the hand appear quite normal and often have independent extensor indicis proprius or extensor digiti quinti tendons.

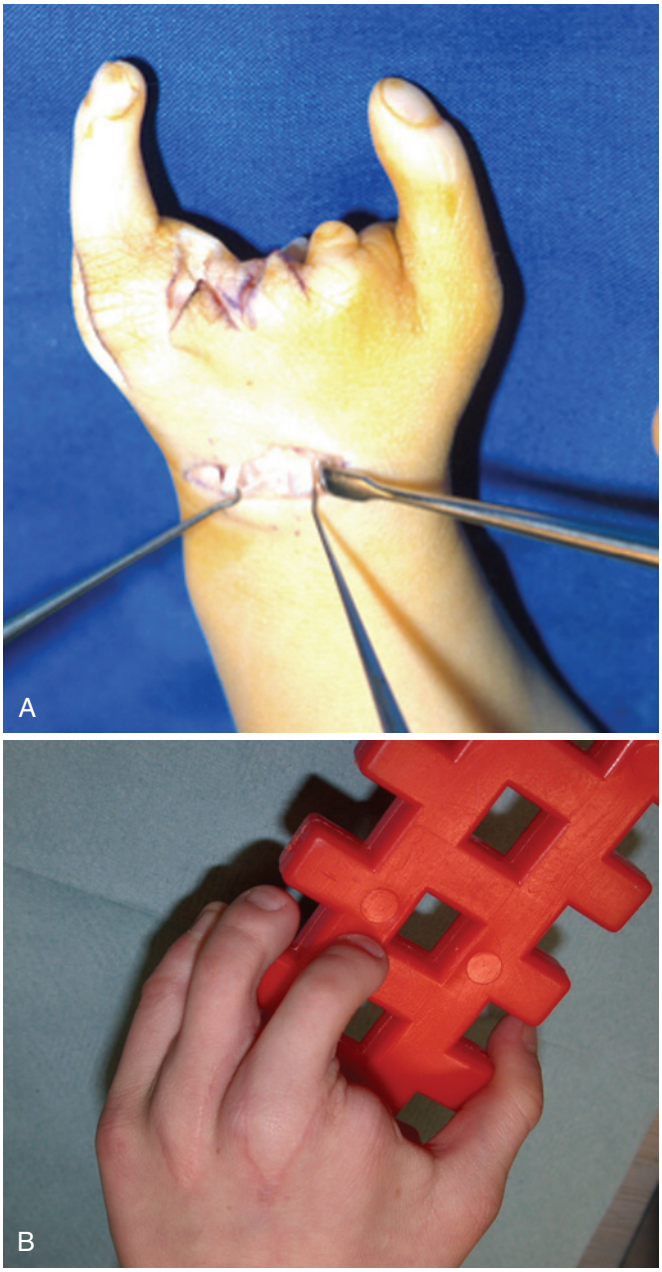

FIGURE 36.76 A, Oligodactylic form of symbrachydactyly. Exploration revealed the presence of extensor and flexor tendons and nerves providing adequate components to allow reconstruction with double second toe transfer. **B,** Good prehensile function achieved with free toe transfers contributing to stability and strength of pinch.

In the advanced monodactylic or single-digit form of symbrachydactyly (type 5), the anatomy is widely abnormal. Surgical attempts at reconstruction have provided considerable information about the aberrant anatomy. The thumb may or may not have a proximal phalanx. The extrinsic tendons end in a conjoined fashion at the level of the metacarpal end. The aberrant rays may lack even vestigial metacarpals, and the fifth ray is usually represented by a short metacarpal. Flexor tendons are conjoined and end at the tips of the skeletal rays. The flexor tendons attach to the extensors and to the aponeurotic system, which yields a variable amount of movement of the finger

nubbins. The extensor tendons are disordered and may be conjoined, although the extensor indicis proprius or extensor digiti quinti are often still distinct. The wrist extensors appear normal. The excursion of the extensor tendons is variable. In general, a wrist and nubbins that are active and mobile correlate with tendons that have some useful excursion. The tendons may be conjoined, and Vilkki[175] has recommended exploration into the forearm to divide the donor tendon from any common muscle belly to prevent a quadriga effect.

In the more severe degrees of symbrachydactyly (types 6 and 7), there are no useful intrinsic muscles to the fingers. Nerve abnormalities are common. In our experience gained from exploration of over 300 cases, the radial nerve is almost always present, regardless of the severity. In contrast, the median and ulnar nerves are small and may be absent. The presence of a thumb or fifth finger implies the presence of the corresponding median or ulnar nerve. Rarely, complete absence of all major nerves in the hand may be found. The peromelic form of symbrachydactyly (type 6) has severe skeletal absence. There may or may not be a carpal row and particular attention should be paid to the status of the thumb ray CMC joint (see the following). The wrist motors may be present. The flexor or extensor tendons of the fingers may be vestigial but have minimal excursion.

FIGURE 36.77 Severe symbrachydactyly that is a candidate for free phalangeal transfer. The thumb has a metacarpal, and tethering of skin to the underlying tendons indicates the presence of active motors.

Management

Treatment of Short Finger Types (Types 1, 2, and 3). This group of symbrachydactyly has short fingers with small or absent middle phalanges. It may be associated with syndactyly, especially of the fifth finger. This fifth finger often deviates in a radial direction. Function is usually excellent (Video 36.2). Release of the incomplete syndactyly of the webs may produce an apparent lengthening of the digits and improved span of the hand. Where the skeletal elements of the digits are hypoplastic and the soft tissues and skin of the digits are relatively preserved, the digit can be stabilized and augmented with a free phalangeal bone graft, although expectations for useful growth in such grafts should be muted, as we indicate in the following.

Treatment of the Oligodactylic (Few Fingers) Type (Type 4). This type of symbrachydactyly is characterized by some degree of absence of the central three rays (Figure 36.77). The nubbins that represent the central digits usually have no considerable function, and the nail remnants can cause local irritation and infection due to the paronychial deformity. Nail remnants and/or nubbins can be removed by simple excision. Prehension can usually be achieved with a pincer grasp between the thumb and fifth finger. Depending on the stability and orientation of these digits, the capacity for prehension can be improved with osteotomy of the metacarpals. The potential for tendon transfers to augment the power of pinch is limited because of the paucity of adequate long tendons in the limb. The first web can be narrow, and the span of grasp can be improved by soft tissue release and lengthening of web with local flaps.

The addition of digits to the deficient central hand with vascularized toe transfers is possible in these hands because skeletal remnants and extrinsic tendons are present in most. The rationale for digital construction is to improve the power of pinch with a greater opposable pulp area to improve pinch. The carrying function of the hand can also be improved. Although the transferred digits retain the appearance of the toe, they are less discordant than may be expected and the appearance of the oligodactylic hand is improved. There is controversy as to whether this surgery is justified in children who are likely to adapt well and develop reasonable prehensile function with the thumb and ulnar elements present; our experience justifies free toe transfer, however. If a fifth ray and thumb are already present, these digits will be used in preference for fine manipulations, but the addition of two central rays by transfer of second toes from each foot offers further options for large or heavy object grasp, with subsequent benefits in function and patient-reported benefits in the appearance and completeness of the hand.

Treatment of Monodactylic (Single-Finger) Type (Type 5). The hand with this type of symbrachydactyly lacks all fingers and has only a thumb, which is of varying size and quality. A markedly deficient thumb may be present with a very short metacarpal and underdeveloped basal articulation. The digits are represented by metacarpal bases and finger nubbins with nail remnants. These nubbins have vestigial connections via the palmar aponeurotic and retinacular system to the extrinsic tendons. This connection is apparent by the ability of the nubbins to pucker into the palm during hand use. The wrist is usually sufficient for function. Free toe transfer is a surgical option to improve function.

Treatment of Peromelic (Short-Limb) Types (Types 6 and 7). The hand with this type of symbrachydactyly has only nubbins with nail remnants. There is a transverse absence at or about the metacarpal row, although more proximal absences may be seen. Finger nubbins may even be noted on a midforearm stump. Reconstruction of prehensile function is difficult because there are limited proximal structures. Vilkki has used a free vascularized toe transfer to the radial side of the distal forearm to achieve lateral pinch, although this should be performed either distal to the radial epiphysis or after growth has ceased[175]; otherwise, the toe will be left behind in the midforearm as the radius grows in length (Figure 36.78).

FIGURE 36.78 Failure to place the vascularized toe transfer distal to the radial epiphysis will result in a toe that will be left behind in the midforearm as the radius grows in length. (Courtesy of Shriners Hospital for Children, Philadelphia.)

CRITICAL POINTS *Symbrachydactyly*

- Symbrachydactyly is a spectrum of deficiencies that begins with short middle phalanges, extends to absence of the central rays, and culminates in absence of the entire hand.
- Treatment of symbrachydactyly is variable and depends on the degree of digital suppression. Mild forms with a competent thumb and digit or digits require no treatment. Severe forms with an absent thumb or absent fingers may benefit from extraperiosteal phalanx transfer or microsurgical toe-to-hand transfer.

Acquired Transverse Absence of Fingers in Children

Acquired cases of transverse absence are also seen in childhood. Traumatic amputation is prevalent in countries that use child labor in the manufacturing industry. These injuries may be bilateral and pose extraordinary challenges in reconstruction.[178] Other traumatic causes include burns, electrocution, thrombosis, and embolism. Lastly, infection may lead to gangrene of the extremities, primarily from meningococcal septicemia.

Construction or Reconstruction of Fingers

There are three main ways to augment the existing digit or ray in a child. The digit may be lengthened by a bone graft (most commonly, a free phalangeal transfer from the foot) or by distraction, or may have composite parts of another digit transferred to it (on-top plasty). Where the digits are absent, the digit(s) can be constructed by free vascularized toe transfer.

Free Phalangeal Transfer. In the adult, many surgeons have found that the placement of bone grafts on the terminal part of the skeleton of a digit results in early and complete resorption of that graft. Resorption, however, is not invariably the case in the child. There are many descriptions of enduring transfers of whole or partial phalanges from within either the hand or foot. Some authors have reported poor results in terms of growth using this technique,[178] whereas others have reported growth and improved function.[33,72,164] Radocha and colleagues[132] have defined three important conditions for success in these transfers if growth is to be observed: (1) transfer must be done before the age of 15 months; (2) periosteum must be included in the transfer; and (3) collateral ligaments and tendon insertions must be repaired.

The authors agree that the earlier the transfer is completed, the better the chance of any subsequent growth. The inclusion of periosteum allows more rapid revascularization of the free transfer, probably through inosculation, which may help to conserve the bone. The role of load across the physis is uncertain, but Radocha and colleagues[132] found unequivocal evidence that attachment of ligaments and tendons to the transferred bone was important. The best growth results in our children have been seen in those cases in which the phalanx was affixed to the proximal skeleton using chondrodesis, presumably increasing the amount of force transduced across the growth plate. Using the phalanx as a hemiarthroplasty at the MP level, however, has produced mobile and stable digits. For stability, there must be some long remnants of the flexor and extensor tendons at the level of the nubbin and the phalanx must be secured by direct soft tissue repair. Once consolidated, the phalanges have been shown to be robust enough to tolerate distraction lengthening.[121]

The phalanges should not be harvested from the second toes unless microvascular toe transfer has been excluded as an option. Free phalangeal transfers are not a simple reconstructive option. While a successful transfer may grow and add function, this result is not inevitable, because wound complications and skin necrosis can result from oversizing the graft and, in the longer term, the surviving phalanx can be unstable and prone to angular deformity. In addition, the donor site in the foot can be troublesome and a source of morbidity unless properly managed. Overall, the results of free phalangeal transfers appear inconsistent, and ample discussion with the familiy is necessary prior to surgery. For the most part, our practice prefers whole vascularized toe transfer compared with free phalangeal transfer because of the greater growth, mobility, and stability. The ideal recipient for free phalangeal transfer is a patient with a digital ray with a small remnant of proximal phalanx with tendon attachments and a suitable skin envelope. Free phalangeal transfer is especially useful in the thumb in cases of monodactylic symbrachydactyly (see Figure 36.77). In these cases, the fingers can be constructed from two toe transfers (see later), and the free phalangeal transfer augments the length of an otherwise competent thumb.

The requisite in the hand is a mobile, flexible adequate skin envelope, which is common in transverse absence or symbrachydactyly. The transfers should be planned in patients who can expect to have some functional improvement and are not indicated in patients who will have no increase in prehensile function. The absence of extrinsic tendon function is a relative contraindication. The parents must be aware of the potential aesthetic side effects for the foot, which are more important in patients undergoing concomitant microvascular toe transfer. Finally, the procedure is relatively contraindicated in the older child; we do not offer this treatment in children older than 15 months of age.

The donor site in the foot is a serious limitation of this technique. Methods for dealing with this have included suturing together the extensor and flexor tendons in the gap left by the phalanx, but our experience has been that the options to prevent

a short floppy toe(s) are limited. In an attempt to minimize the donor deficit, we have inserted a cylindrical apophyseal bone graft from the iliac crest, which has improved the appearance at the foot donor site.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT FOR FREE PHALANGEAL TRANSFER

Preparation of the hand. Under tourniquet, the empty skin nubbins may be approached either by dorsal or volar longitudinal incision. The skin may be closed using a "Z"-plasty when additional length is required. The nubbin is opened, and some fat is removed to accommodate the toe phalanx. Gentle traction on the nubbin with a skin hook reveals the extent of the cavity created for the transfer. The metacarpal head is evaluated and usually has a thin layer of articular cartilage overlying the epiphyses of the metacarpal. The metacarpal head is capped with a coalescence of the flexor and extensor tendons (Figure 36.79). The authors' preference is to incise this in a cruciate manner and to raise the dorsal and volar capsule with the extensor and flexor tendons. The radial and ulnar parts of the capsule are preserved as collateral ligaments. Each of these elements will subsequently be repaired to the phalangeal transfer.

In children with a remnant of proximal phalanx, the procedure is simpler, because the tendons do not require exploration. The end of the residual phalanx is prepared for chondrodesis with the free toe phalanx.

Harvesting the graft. The toe phalanx is approached through a zigzag incision on the dorsum of the toe. The harvested phalanx is usually the proximal phalanx of the third or fourth toe. The second toe may be preferred in cases in which microsurgical toe transfer is not being considered. After the dorsal exposure, the extensor apparatus is split in the midline of the digit and the toe phalanx dissected from its surrounding attachments, leaving the periosteum intact. The fibrous flexor sheath is divided laterally on the volar surface, taking care not to injure the flexor tendon. The distal capsular attachments are incised adjacent to the phalanx. The phalanx is harvested with the volar plate and capsular attachments (Figure 36.80). Frequently, a small cap of the distal portion of the proximal phalanx is retained within the toe.

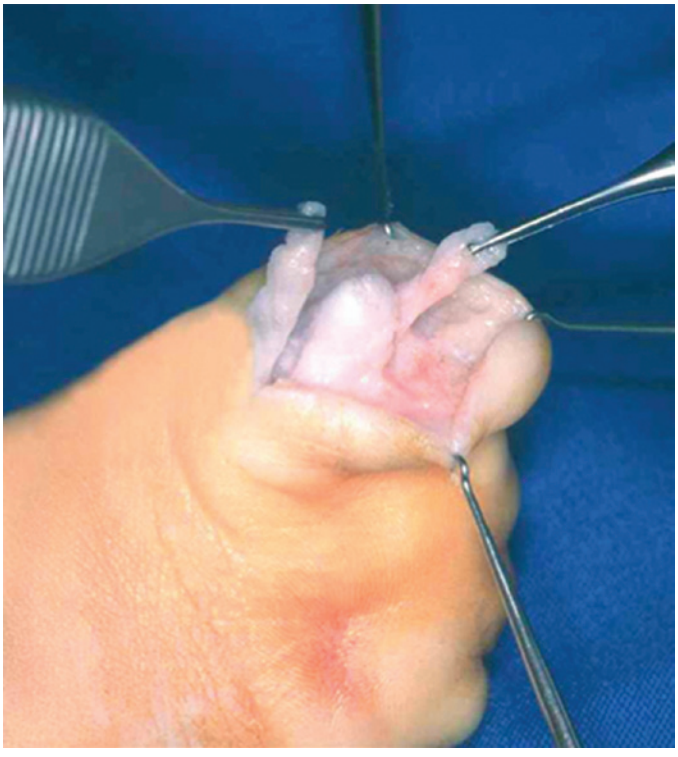

FIGURE 36.79 The flexor and extensor tendons are identified and separated over the metacarpal head.

The donor defect may be closed in a variety of ways. Some have advocated simple longitudinal Kirschner wire fixation, whereas others have recommended suturing the flexor and extensor tendons together to serve as a spacer.[33] We prefer harvesting a cylindrical graft from the iliac crest that is capped with apophyseal cartilage (see Figure 36.80). The graft is placed into the toe with the apophyseal cartilage directed proximally. The tubular cancellous bone abuts the small fragment of distal toe phalanx that was retained within the foot. The graft and toe construct are fixed with a longitudinal Kirschner wire. The extensor tendons and skin are repaired. This pin is removed 4 to 6 weeks later.[26]

Placement of the graft. The graft is transferred to the hand. The volar capsular attachments and flexor tendon within the hand are sutured to the volar plate on the free phalangeal graft. The graft is transfixed with a longitudinal Kirschner wire passed from proximal to distal and exiting through the apex of the skin envelope (Figure 36.81). This wire is withdrawn, the phalangeal graft aligned with the metacarpal head, and the wire advanced to fix the graft in place. The wire should be placed with as little trauma and heat dissipation as possible to avoid physeal plate injury. The collateral ligaments are repaired to the lateral margins of the capsule at the metacarpal head. The dorsal capsule and extensor tendon are repaired to the dorsal capsule of the free phalangeal graft. The skin is closed either with a "Z"-plasty or directly with absorbable sutures, and the hand is immobilized in an above-elbow cast. The Kirschner wires in the foot and the hand are removed 4 to 6 weeks after surgery. The parents may move the phalanx gently.

Complications. Complications include skin necrosis and absent growth of the transferred phalanx. Skin necrosis occurs when the transferred phalanx is too large for the skin envelope. Absent growth is more likely in the older child, when the tendons or ligaments are not repaired or when the periosteum is not included in the transfer. Scarring may occur in the foot, especially when a longitudinal incision is used. Contraction may result in dorsal displacement of the toes that may become unstable.[70] In addition, the donor defect may be worse in cases in which the extensor and flexor tendons have been sutured together as a "spacer." This technique may lead to unstable toes that angulate and override adjacent digits.

Distraction of Digits. Osteotomy of one of the skeletal elements of the short ray and distraction using an external fixator can lengthen the digit.[105] The procedure can only be used where the phalanx or metacarpal is long enough to accommodate a distraction frame. The bone generated in the distraction gap may be adequate for stability or augmented prior to removal of the frame with bone graft. A limited gain in length can be achieved, which may improve prehension, particularly in the thumb that is too short to reach the ulnar digit(s). The procedure is time consuming and requires a cooperative family and patient.

FIGURE 36.80 **A,** The bone graft, including the apophysis, is harvested from the iliac crest with a tubular osteotome. **B,** The proximal phalanx has been harvested from the third toe (with the second toe preserved for possible future microvascular transfer). The tubular bone graft to replace the phalanx has been fixed with a longitudinal wire.

FIGURE 36.81 Toe proximal phalanx in place with Kirschner wire fixation and extensor tendon attachment.

Transposition of Rays. This technique involves transposition of rays to allow prehension. In certain hands, the thumb lacks enough excursion to reach the fingers. Transposition of a finger or fingers into a more radial position can allow pinch or grasp. Transposition may be combined with microvascular toe transfer to enhance hand function (Figure 36.82).

Microvascular Toe Transfer for Hypoplastic Digits. Single-stage microvascular toe-to-hand transfer is not a new concept. The technique has primarily been used for posttraumatic conditions in adults. Before the 1990s, relatively few reports dealt with children. Lister reviewed 12 toe transfers for congenital deficiency of the thumb and reported good return of sensibility but poor return of IP motion.[100] Kay and colleagues extended the indications to include reconstruction of the congenital hand with an absent thumb or finger.[95]

Choice of Technique. For adults, many variations of toe transfers have been developed, including the wraparound free flap,[117] the twisted toe transfer,[65] the double-toe transfer,[95,125] the great toe transfer,[125] and the trimmed toe transfer.[181] The donor defect must be minimized, especially in children. For this reason, we are reluctant to transfer anything other than the second toe. This limits the reconstruction to two digits, although fortunately the commonest indication in children is symbrachydactyly, which is invariably unilateral. In traumatic cases with bilateral injuries, the decisions about sacrifice of more toes for hand function are correspondingly far more difficult. These

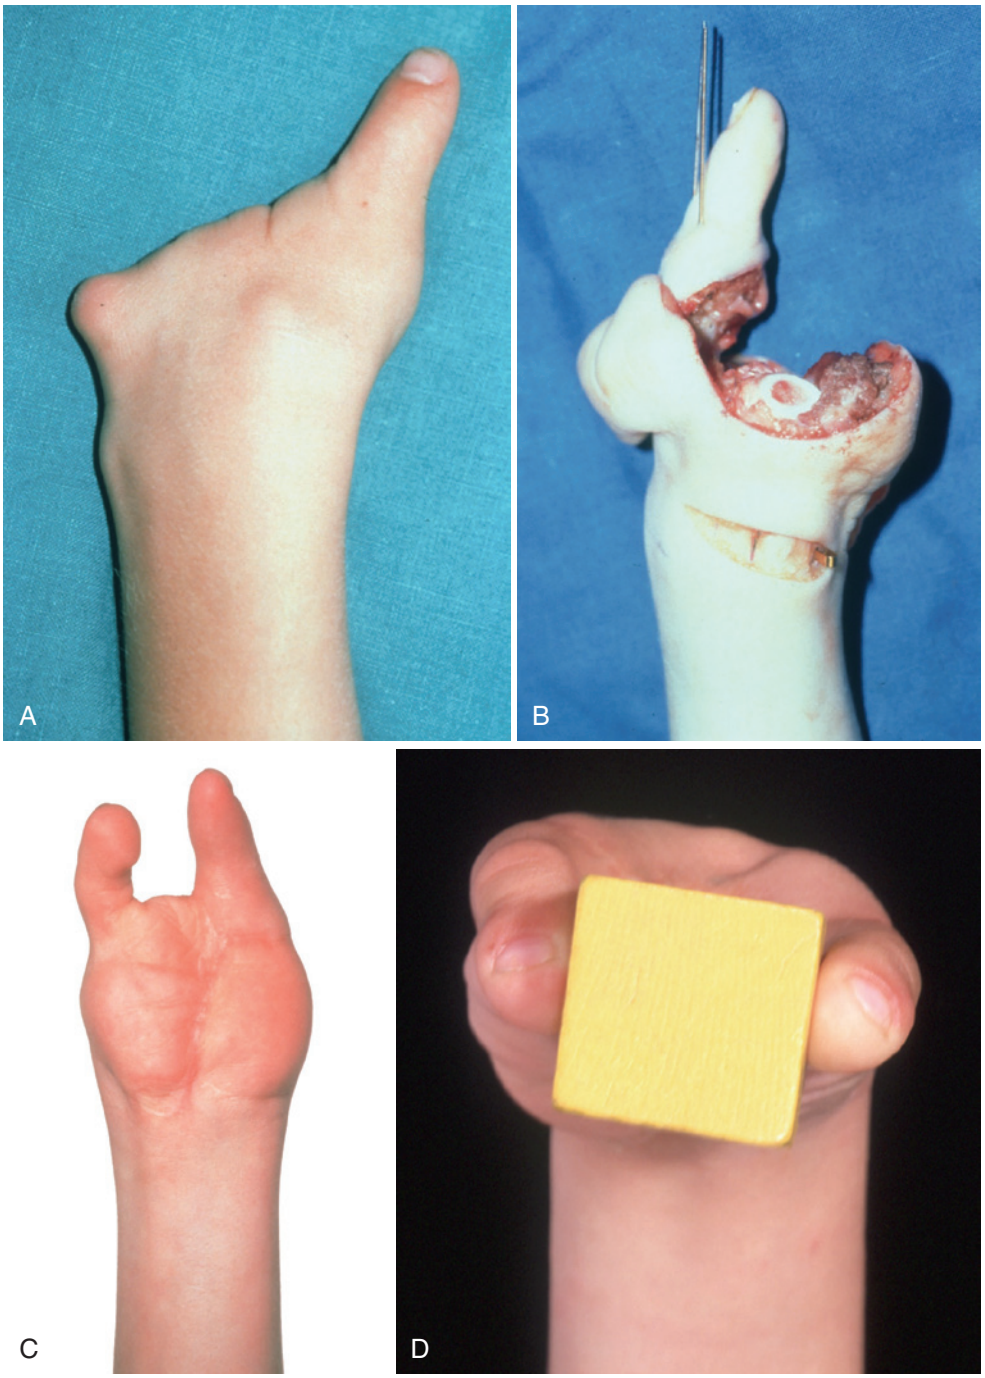

FIGURE 36.82 **A,** The left hand of a child with congenital digital absence. Although a thumb ray is present, there is no active or passive movement at any level in that ray, including the basal joint. The hand has no prehensile function. **B,** Rather than creating a mobile ulnar ray against a static radial ray, it was decided to transfer the existing "thumb" to the ulnar border of the digit as a microvascular pedicle transfer. A single second toe transfer to the radial ray was undertaken at the same procedure to create a thumb. **C,** Postoperative result with the static ulnar ray and the thumb present on the radial ray. **D,** Strong small-object pinch and grasp resulted from this combination of transfers.

second toes can be transferred in separate operations or in the same operation (synchronous bilateral second toe transfer). In very select cases, when either single or bilateral second toe transfer is not appropriate or possible, transfer of the great toe may be considered with caution. The aesthetic defect is greater and there may be functional consequences. Rarely, a wrap-around free flap or partial toe transfer may be used, but only in the older child because growth is not a property of such transfers.

Indications. The indications for digital reconstruction include transverse deficiencies in the thumb and/or fingers (Figure 36.83). Longitudinal deficiency has been a contraindication because of the deficient proximal structures, such as tendons and nerves. Transfer of an adjacent digit usually

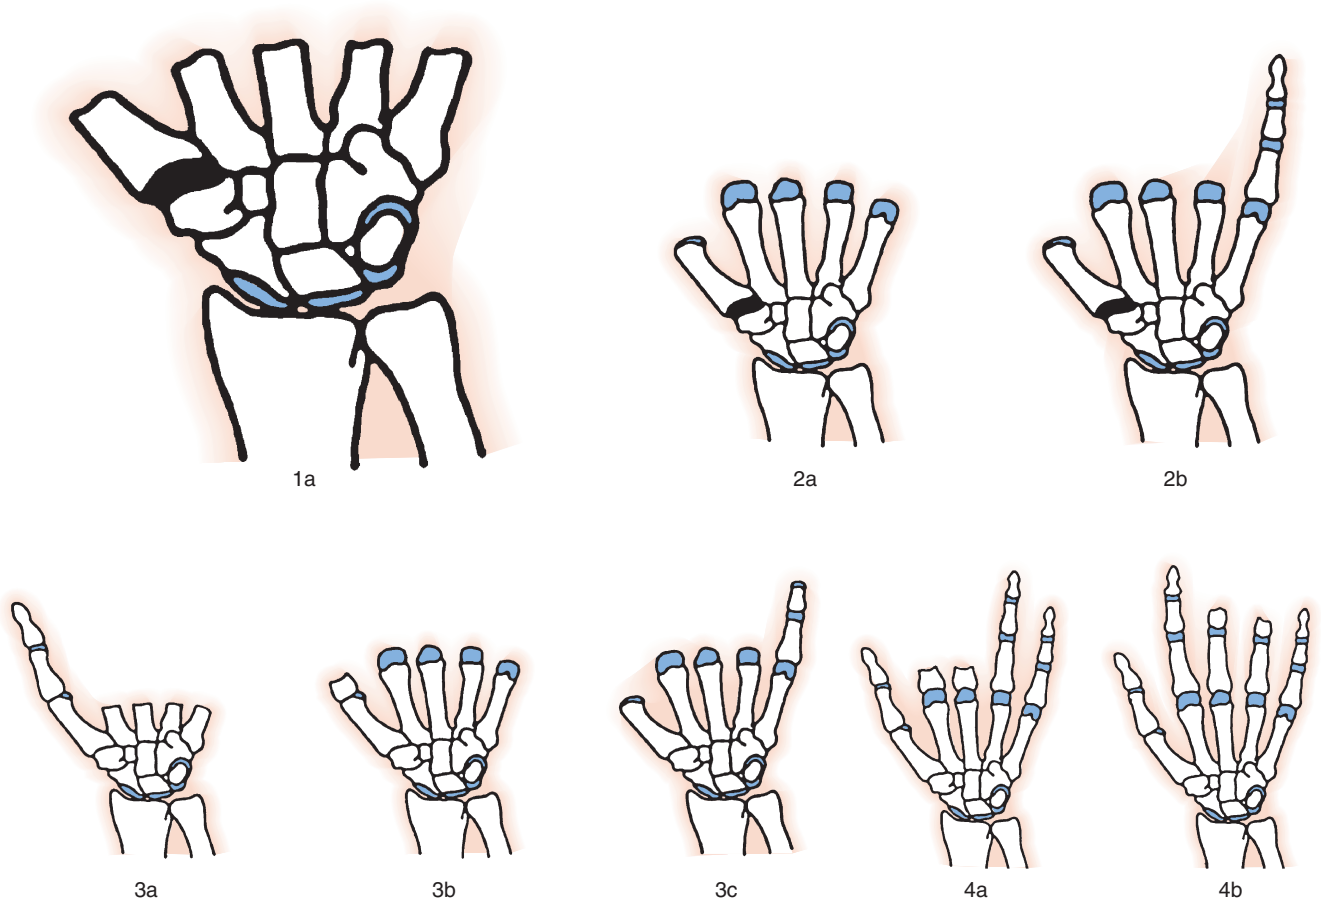

FIGURE 36.83 A simple grouping of common types of congenital transverse deficiencies in the hand based on the authors' experience of the reconstructive options available and the probable functional outcome. Group 1a: The absence is at a proximal level through the base of the metacarpal or at the carpometacarpal level. There is no circumduction in the thumb ray, and here bilateral second toe transfers will allow pincer grip between the toe pulps. It is likely that a choice will have to be made between small- or large-object grasp because the range of motion in the reconstructed toes is unlikely to allow both. Group 2a: The absences are at the distal level of the metacarpals, and the basal joint of the thumb is competent. Reconstruction at this level with one toe on the first ray and one toe on the fourth ray will allow good small- and large-object grasp with competent pulp-to-pulp pinch by virtue of the basal motion in the thumb. Group 2b: Distal metacarpal loss with a poorly competent basal joint but the presence of a relatively normal fifth ray. The mobility present in all the joints of the fifth ray, including the basal joint, means that any reconstruction on the thumb ray will probably allow both small- and large-object grasp. Single toe transfer to the thumb ray is therefore indicated, and the optional transfer of a further toe to the ring finger ray is unlikely to result in great improvement. One further option in this situation is microvascular pollicization of the fifth ray and a double toe transfer to the hand on the third and fourth rays. This has the advantage of producing a fuller hand but retaining and restoring mobility in the first ray. Group 3a: Proximal metacarpal level in the hand with a competent and strong first ray. Here, bilateral second toe transfer on the fourth and fifth rays will produce a strong and competent hand even if relatively little motion is restored in the transferred digits. Group 3b: Distal metacarpal absence with the presence of a metacarpophalangeal joint in the thumb. If the patient is seen early in life, free phalangeal transfer in the thumb will convert the patient's hand to essentially a group 3a hand and allow bilateral second toe reconstruction in the hand rays. Group 3c: This common type has a competent fifth finger but requires one toe to reconstruct a competent thumb, and a further toe may then be used on the ring ray to add power and volume to the hand. Groups 4a and 4b: This type of transverse absence is most commonly seen in ring constriction syndrome where function of the hand is already excellent. Little or no functional improvement will result from microsurgical toe transfers, but there are potentially considerable cosmetic benefits from creating a fuller hand. Although function in the hand itself is already good, good function in the reconstructed digits can be expected as a result of the relatively normal structures present proximally in the hand.

reconstructs longitudinal deficiency. In the monodactylous cleft hand, however, we have found tendons and nerves that are available for transfer. This demonstrates the blurring of the clear-cut distinction between categories of digital absence.

Reconstruction of the Thumb. Traumatic or congenital transverse thumb deficiency is the ideal indication for microsurgical toe transfer. The most important determinant of useful outcome is the presence of a stable and mobile CMC joint.[95,96] The recipient structures vary according to the cause of the absence. The proximal structures are virtually normal in ring constriction syndrome. Useful recipient structures are also found in symbrachydactyly or transverse arrest and are more likely to be present when there is a considerable metacarpal remnant. The lack of IP joint motion after transfer reflects the limited amplitude of the extrinsic tendons.[54,101]

Reconstruction of the Fingers. Reconstruction of the fingers is not as common as reconstruction of the thumb. Reconstruction may be indicated after trauma or congenital absence when there is a reasonable thumb present. In such cases, bilateral second toe transfer creates a competent three-digit hand with

powerful pinch and grasp. The presence of existing MCP joints enhances surgical outcome. However, absent MCP joints may still allow satisfactory function. A patient with symbrachydactyly with a thumb and a small finger that is short, deviated, and unstable may be a candidate for bilateral second toe transfer to create a more complete hand. Such cases occupy the borderline between the functional and aesthetic indications for toe transfer. In the absence of proximal phalangeal remnants, we have usually preferred to chondrodese the base of the toe proximal phalanx to the head of the finger metacarpal, accepting less movement in return for more stability. Some surgeons transfer the metatarsophalangeal joint from the foot,[175] but this joint can be laterally unstable and is bulky. In addition, the metatarsophalangeal joint is capable of hyperextension, which is detrimental to prehension.

The Hand With No Digits. Transverse arrest or severe symbrachydactyly without digits requires reconstruction of the thumb and fingers to create any prehensile function. These cases are challenging, and the outcome depends on the level of absence and the competence of the basal joint of the thumb. A substantial thumb metacarpal remnant may be enhanced by bony augmentation. Even a free phalangeal transfer may be attempted to create an articulated thumb, although this should be approached with caution. Successful transfer may change the reconstruction from a hand that requires thumb and finger reconstruction to one that requires only finger restoration.

If thumb augmentation is unlikely to produce a competent digit, the surgeon may consider one transfer to the thumb and one to the finger rays (Figure 36.84). Poor or absent basal joint function requires placement of the digits facing each other. The majority of the movement will originate from the IP joints of the thumb and finger. Postoperative motion is often poor and limits the functional benefits of such transfer. If surgery is selected, a decision must be made to position the transfers to touch in maximum flexion or to place them more widely apart. The former allows small object grasp, whereas the latter allows larger object acquisition. In our experience, small object grasp is preferred to allow the child to hold fine objects such as paper, buttons, and shoelaces.

In the presence of a reasonable basal joint, a second toe is placed on the thumb and another placed on the third or fourth ray. The transfer may create a composite joint, using one articular surface from the toe and one from the finger. The preferred approach, however, is to perform a chondrodesis or arthrodesis between the base of the proximal phalanx in the toe and the shaft of the metacarpal in the thumb and finger. This technique has the additional benefit of stability and precise orientation of the digit, although in the presence of a basal joint allowing circumduction, the alignment of the toe is less critical and eventual function much greater.

Finally, a decision is required regarding the length of the digit to be created. The initial temptation is to create long digits; however, long digits may look bizarre in a two-digit hand (Figure 36.85). This altered appearance may be disturbing for the child compared with shorter digits that allow the hand to appear more compact and natural. The physis of the transferred digit is retained for growth, which may require some resection of the thumb metacarpal to coordinate the length of the thumb and finger.

Contraindications. Contraindications to toe transfer in children are diminishing over time. There are few contraindications from an anatomic viewpoint. Absence of recipient nerves is a contraindication to surgery. We warn parents that when no recipient nerve is found, surgery will be aborted. This is a rare occurrence; even though the median nerve is commonly absent, there is usually an ulnar nerve and dorsal cutaneous nerves, including substantial radial sensory nerves. An exception to this generalization is found when the digital metacarpal remnants

FIGURE 36.84 **A,** Two simultaneous second toe transfers for symbrachydactyly with absent digits at the metacarpal level. There was a competent thumb basal joint. **B,** Useful large-object grasp with considerable power. **C,** Small-object pinch as a result of limited circumduction at the thumb basal joint.

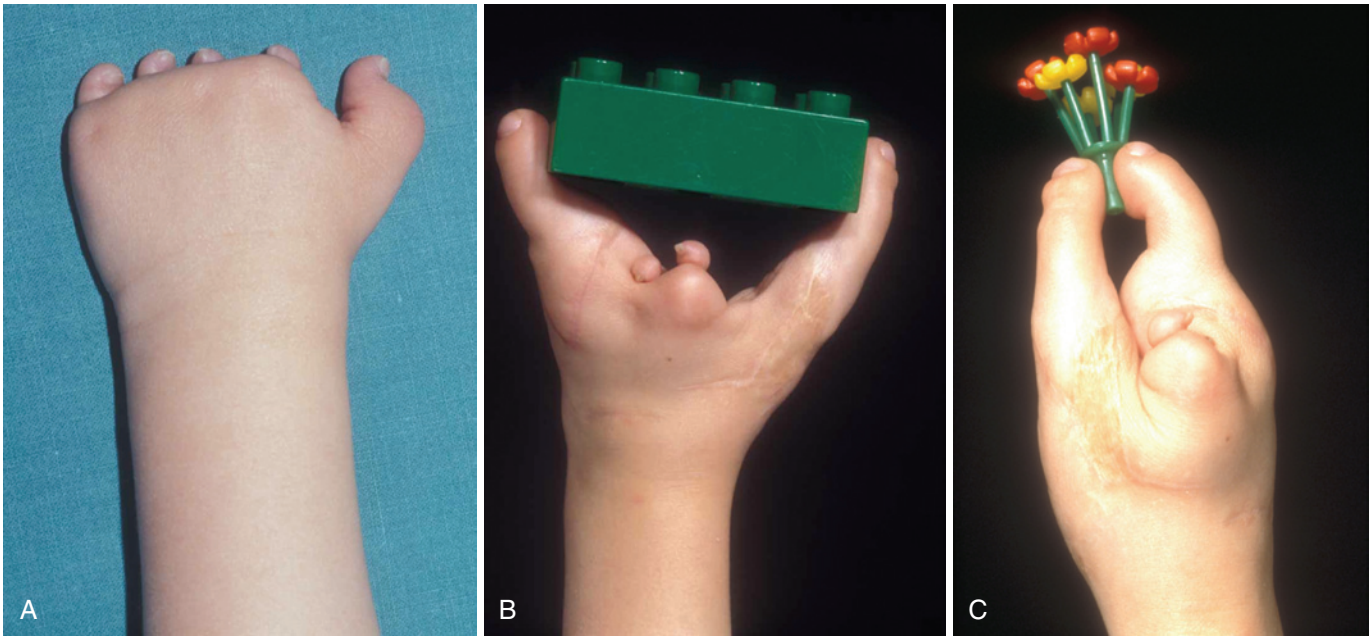

FIGURE 36.85 **A,** Transverse arrest in the hand of a 2-year-old girl. The thumb is absent from the midmetacarpal level distally and is represented by a skin envelope devoid of skeleton. **B,** This child underwent bilateral second toe transfer with one toe to the first and one toe to the fourth ray. An alternative might have been free phalangeal bone graft to the thumb and a double toe transfer to the hand. In this case, the digits have a long, narrow look that gives the hand the appearance of clefting. However, large-object grasp is successfully created. The child refused removal of the skin nubbins within the cleft. **C,** The same hand exhibits good small-object grasp by virtue of the mobility of the basal joint. The length of the digits contributes to their range and power, but they have the disadvantage of poor appearance.

get progressively shorter passing from radial to ulnar: in such situations, we have found the absence of both the median and ulnar nerves to be increasingly frequent. The absence of adequate donor tendons is also a contraindication.

As discussed above, in the transverse absence group, motors are usually present, although the tendons may be conjoined with limited excursion. But, limited IP excursion of a transferred toe may still provide power and an adequate functional result depending on the type of grasp being sought with the surgery. An extremely proximal level of transverse absence (e.g., the distal carpal row or radiocarpal level) will produce a disappointing result, and prosthetic alternatives should be considered. Absence or deformity of the toes precludes surgery.

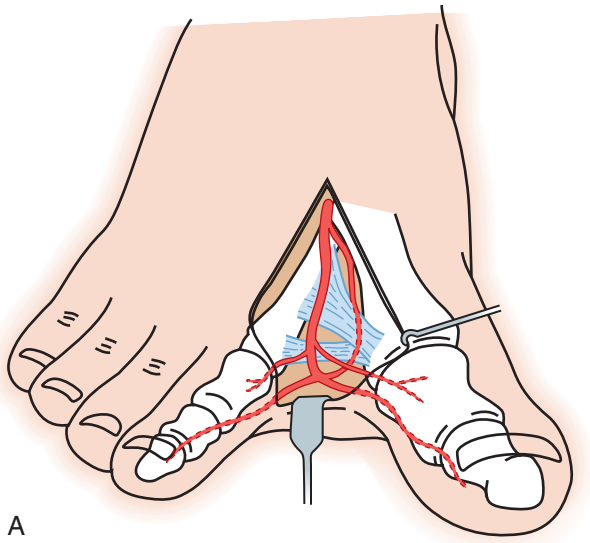
The most considerable contraindications are the psychosocial considerations within the family and competence within the surgical unit. Careful assessment of and counseling for the family and child are essential to ensure an adequate understanding of the aims and consequences of surgery, to accept the donor defect, and to manage the consequences of either a successful or an unsuccessful procedure.[20,28,94]

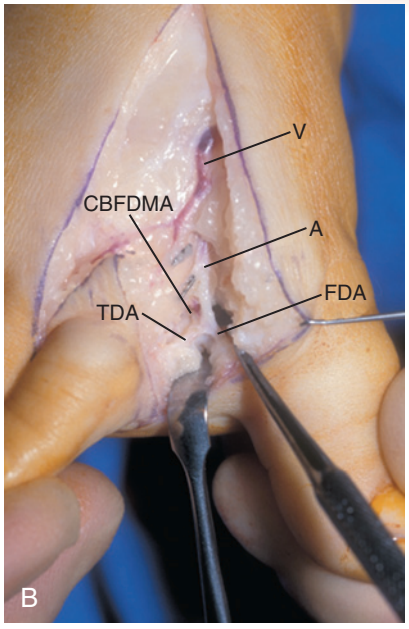
The age of the child is a relative contraindication. Absolute rules about indications and contraindications in respect to age of the child do not exist. We have found no benefit in performing the procedure before 1 year of age, and an analysis of long-term outcomes suggests some disadvantages in terms of ultimate range of motion. There are benefits in completing the surgery before school age, and this reconstruction is rarely accomplished in a single stage. After the age of 6 years, the child becomes involved in the choice of surgery, and this may pose additional problems because the child has enough autonomy to refuse surgery but not enough competence to make reasonable decisions based on future function.

Presurgical Assessment. Angiography is not required unless there is unusual concern about the proximal vasculature. In over 300 transfers for congenital defects in children, we have never failed to find suitable recipient vessels on exploration. In cases of loss secondary to meningococcal septicemia, we have performed angiography only to find normal large vessels reflecting the microvascular nature of this condition. Preoperative assessment by a child's anesthesiologist is required, because the procedure is lengthy and the child must be healthy. Ideally, the same surgeon and anesthetist should collaborate on all cases to maximize the team's experience.

Surgical Technique. The authors prefer to have a single surgical team, believing that any perceived benefit in time saved with two surgical teams is dissipated in divided responsibility, potential confusion, and the lack of space around the operative site in small children. We can perform a bilateral synchronous double-toe transfer in 5 to 8 hours with a single surgical team. Tourniquet times on the feet are less than an hour. Tourniquet times on the hand reach 2 hours as the four anastomoses are completed.

Hand preparation. The hand is explored under tourniquet control. The dorsal exposure is via a transverse incision at the wrist crease. This incision avoids unsightly, often parallel, longitudinal or zigzag incisions on the dorsum of the hand. The extensor tendons, veins, and dorsal branches of the radial or ulnar nerve are identified and marked. Proximal excursion of the extensor tendons is confirmed via traction. The tendon with the greatest excursion is chosen as the donor tendon. When more than one tendon is required, either the extensor indicis proprius or extensor digiti quinti is used in an attempt to achieve some independent function. The venous anastomosis is planned on the dorsum of the hand, and the arterial





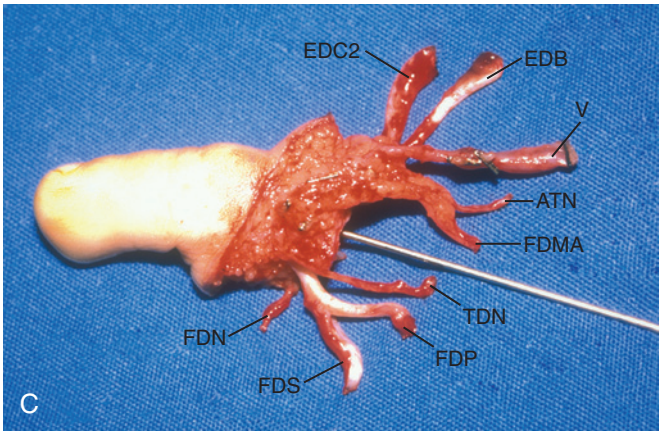


FIGURE 36.86 **A,** The first web space is approached in a distal to proximal direction. The fibular vessel of the great toe is most easily identified and traced proximally to the communication with the first dorsal metatarsal artery, the first plantar metatarsal artery, and the tibial vessel to the second toe. The exact architecture of the junction between these vessels is variable, but all these named vessels are usually present, although either the plantar or the dorsal may be predominant. The dorsal branches to the toes arise from the dorsal metatarsal artery as shown. **B,** The vessels of the first web space. The fibula digital artery (FDA) of the great toe is seen clearly and, when traced proximally, leads to the junction between the first dorsal metatarsal artery (A) and the communicating branch for the first dorsal metatarsal artery to the plantar artery arterial system (CBFDMA). At or about the same level, the tibial digital artery (TDA) of the second toe arises. The dorsal vein (V) and the fibular dorsal artery (FDA) are also clearly seen. **C,** The second toe has been harvested and a Kirschner wire introduced through the base of the proximal phalanx in preparation for osteosynthesis. The individually identified structures are noted: the extensor digitorum communis (EDC2) tendon; the extensor digitorum brevis (EDB) tendon; the dorsal vein (V), a tributary of the long saphenous vein; the dorsal digital nerve, a branch of the anterior tibial nerve (ATN); the first dorsal metatarsal artery (FDMA); the tibial digital nerve (TDN); the flexor digitorum profundus (FDP) tendon; the flexor digitorum superficialis (FDS) tendon; and the fibula digital nerve (FDN).

anastomosis is planned for the palmar surface or in the anatomic snuffbox.

The skin incisions for the recipient site are planned to result in a transverse scar on the palmar surface and a "V"-shaped scar on the dorsum. This shape allows insetting of a tongue of dorsal foot skin. The level of bony union is identified and marked. The proximal palmar exposure is accomplished via a zigzag incision. The median and/or ulnar nerves are identified at the level of the carpal canal along with the flexor tendons. The ulnar artery, the superficial palmar arch, and the radial artery within the anatomic snuffbox are examined and identified for later use.

Retrieving the second toe (points relative to children). The skin pattern on the toe is designed with reference to the defect in the hand, usually incorporating a "V"-shaped flap of dorsal skin. The harvest begins under tourniquet control using the entire skin incision, including a dorsal linear incision running between the first and second metatarsals. A single dorsal vein is isolated. In the child, the major veins lie in a distinctly deeper layer of subcutaneous fat than the smaller superficial veins. We have developed a method for defining the vascular anatomy of the toe in a retrograde distal-to-proximal manner.[94,95,179] An assistant separates the first and second toes, and the fibular digital artery of the great toe is identified (Figure 36.86). The artery is traced to its common origin with the second toe vessel. From this bifurcation, both the plantar and dorsal metatarsal arteries may be traced in a proximal direction. This technique facilitates early selection of the artery for anastomosis. In two thirds of cases, there is a sizeable first dorsal metatarsal artery for anastomosis and the plantar artery and vessel to the great toe can be divided. The proximal dissection of the dorsal artery is then straightforward. In one third of cases, the plantar artery must be used for anastomosis and the dissection is more difficult, but in these young, flexible patients, it is considerably easier than in the corresponding situation in the adult. Plantar dissection is facilitated by use of a spreader retractor to widely

and forcefully separate the first and second metatarsals. The deep peroneal branch of the anterior tibial nerve is harvested and usually lies closely applied to the vein and first dorsal metatarsal artery. Both of the plantar digital nerves of the second toe are dissected in a proximal direction and separated from the adjacent component of the common digital nerve.

The flexor tendons are exposed at the proximal edge of the flexor sheath just proximal to the metatarsophalangeal joint. The tendons are retracted distally with the ankle flexed, allowing division deep within the sole of the foot. The bone transection is performed through the metatarsophalangeal joint. Other authors have preferred to incorporate the metatarsophalangeal joint as a mobile joint (but this has disadvantages as well as benefits; see previously). The tourniquet is deflated, perfusion of the toe is confirmed, and hemostasis is achieved. The vascular pedicle is divided just before transfer to the hand.

Osteosynthesis. After the toe is separated from the foot, the bone is prepared on the back table. When the osteosynthesis is planned at the base of the phalanx, the epiphyseal cartilage is progressively shaved away until the pink blush of subchondral bone is encountered. In some cases, a composite joint can be formed between the articular surface of the base of the proximal phalanx of the toe and the articular surface of the metacarpal. Longitudinal Kirschner wires are preferred. The wires cause little damage to the growing epiphyses, are quick to apply, and are adequate to achieve union in these young hands. Crossed Kirschner wires interfere with the adjacent toes, risk damage to the digital vessels, and do not allow correction of rotation after preliminary placement. Interosseous wire and plates are not used because of the proximal growing epiphyses.

Tendon repairs. The toe is brought to the hand, and after osteosynthesis the extensor tendons are repaired. The tendons are passed deep to dorsal skin and fat and are repaired by weave at the wrist level. Two extensor tendon repairs are preferred. After extensor tendon repair, any extensor tendon that passes to an absent ray is divided to prevent a tethering or quadriga effect because the proximal extensor muscles may share a common belly.

Selection of the flexor tendon is more difficult. In symbrachydactyly or transverse absence, inadequate excursion is common. Unless individual flexor digitorum profundus and flexor digitorum superficialis tendons are present in the hand, only the toe flexor digitorum profundus is repaired. An overlapping repair or a weave is performed. The toe flexor digitorum superficialis tendon is cut short and, again, any tendon anlage passing to an absent ray is divided to prevent the quadriga effect from the conjoined proximal muscle mass.

Nerve repairs. Repair as many nerves as possible using the microscope. The nerve repair should be as proximal as possible to ensure good recipient nerve quality in the hand.

Vessel repairs. A single artery and a single vein are repaired. Other authors have recommended repair of more vessels; this confers neither a theoretical nor a practical advantage in our opinion, however, as the failure rate is exceedingly low. Vein grafts are not needed. A warm pack is applied to the limb and the tourniquet is deflated. The transferred digit is observed for 10 or 15 minutes to ensure vascular patency.

Skin repair. The skin is loosely closed with absorbable sutures at wide intervals to allow blood to ooze from the wounds. No attempt is made to close the wound completely and so tension is avoided. Most children will require scar revision surgery, so the use of split-skin grafts is encouraged rather than tight closure. The exception to this tenet is the dorsum of the hand. Considerable swelling may create shear forces on the vein as it passes beneath the distal edge of the dorsal palmar skin and, therefore, skin closure should be complete. The hand is gently wrapped without compression and a plaster slab applied with the elbow at 90 degrees.

Postoperative care. The child is admitted to the critical care unit in a temperature-controlled room for 24 hours after surgery. Core and peripheral temperature, pulse, central venous pressure, and urine output are all monitored. The child is kept relatively sedated and has indwelling regional local anesthetic infusions. The child is discharged to go home 3 to 5 days after surgery. Dressings are changed 6 weeks after surgery, usually under general anesthesia. The Kirschner wires are removed and the digits gently manipulated. A thermoplastic splint is fabricated for nighttime use and during challenging physical activity. Parents are instructed in passive and active motion and to protect the insensate digit from harm, especially self-inflicted harm. The parents are warned that during reinnervation, the child will experience uncomfortable dysesthesias that are normal and transient.

Additional indications and technical alternatives. Another indication for microvascular toe transfer is traumatic loss of digits. Toe transfers have been reported in children for the reconstruction of traumatic defects, including the metacarpal hand. In some cases, these defects are bilateral, and the use of a single toe from each foot will not produce adequate reconstruction of function. The use of transfers from the great toe (wraparound flap or trimmed toe transfer) and the use of monobloc transfer of the second and third toes have been necessary in some of these cases.[102,180]

Transfers from the great toe. Transfers from the great toe are favored in adults for certain aspects of hand reconstruction.[39,98,106,116,181,187] In the congenital hand, great toe transfer is seldom indicated because reconstruction can usually be accomplished using the second toe. In some traumatic defects, however, great toe transfer may be necessary. Considerable aesthetic morbidity results from harvesting the whole great toe. Parents are reluctant to allow such harvest. The wraparound free flap from the great toe contains no epiphysis and is usually unsuitable in the growing child. The wraparound free flap may be used in the older child or in distal digital injuries with soft tissue avulsion.

The metacarpal hand. Loss of most or all of the digits may be a result of trauma. The metacarpals may be spared, and the thumb may or may not escape injury. Adequate function can be expected when the thumb has been amputated distal to the middle of the proximal phalanx and if a portion of the proximal phalanges of the fingers is present. Any more proximal loss usually results in poor function. Such hands are best reconstructed using some form of free toe transfer.[180]

Results. The results of toe transfer in children have been reported.[90,95,100,134] In general, the procedure has been demonstrated to be reliable, with a low microvascular failure rate and with good sensory recovery and functional improvement noted. Growth continued in the transferred toes in the reported series.

The senior author initially reported on 66 toe transfers in 40 children. All but 3 children achieved motion in their transferred

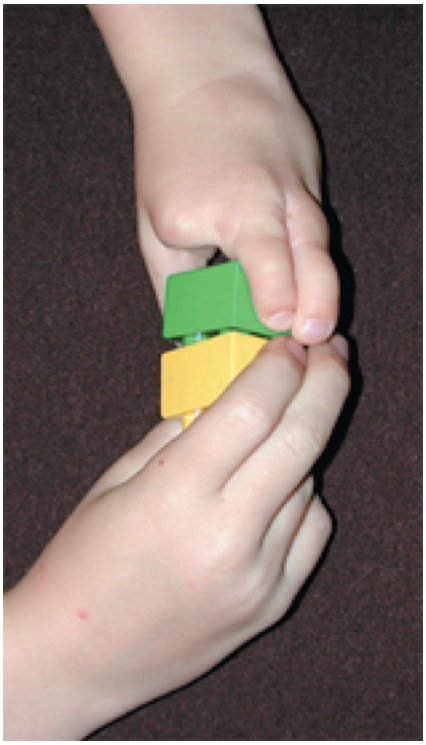

FIGURE 36.87 Results after double synchronous second toe transfer in a child with transverse absence of all fingers but a competent thumb. There was recovery of good sensibility and some prehension.

toes. The mean total range of active motion was 60 degrees and was independent of the number of tendons repaired. The passive range was always greater than the active range. Grasp function was useful and satisfactory for both small and large objects in the majority of cases (Figure 36.87). Sensibility recovery showed two-point discriminations of between 4 and 5 mm. Currently, over 300 transfers have been performed with the loss of a single partial toe transfer. The thumb ray was the most common recipient, and the fourth ray was the second most common beneficiary.

Additional attention has focused on the psychological aspects of surgery. The vast majority of parents (84%) and children (88%) thought the hand was improved after surgery. Only one adult and one child thought the hand looked worse. Scarring was not a dominant complaint of the parents and was virtually ignored by the children. Most parents (80%) believe the hand was incorporated into function most of the time. No adverse effect of toe transfer from the psychosocial viewpoint was found. These results are supported by Richardson and coworkers in their review.[133] The reconstructive surgery appears to have a positive response on the child and family.

Secondary surgery. Microsurgery rarely offers a one-stage reconstruction, and secondary procedures are usually necessary. The need for adjustment of the skin, bone, and tendon transfers is common. Procedures include pulp plasty, scar revision, excision of skin graft, and tenolysis. Opposition transfers and rotation osteotomies may also be needed. Secondary surgery is usually deferred for at least 18 months to allow scar maturation, joint motion, and the incorporation of the transfer into use.

CRITICAL POINTS *Absence of Fingers*

- Digital absence or hypoplasia is due to either longitudinal or transverse absence or hypoplasia. This is an important distinction because of the probable nonexistence, in longitudinal absence, versus the probable presence, in transverse absence, of the supporting neurovascular and motor structures for digital function.
- Transverse digital absence may be a consequence of constriction ring syndrome or be due to the hypoplasia associated with the symbrachydactyly spectrum.
- Symbrachydactyly is a spectrum of deficiency, beginning with short middle phalanges that can extend to absence of the central rays and culminating in absence of the entire hand.
- Treatment of symbrachydactyly depends on the degree of digital suppression. Mild forms with a competent thumb and digit or digits require no treatment. Severe forms with an absent thumb or absent fingers may benefit from extraperiosteal phalanx transfer or microsurgical toe-to-hand transfer.

Expected Outcomes

The outcomes of digital reconstruction depend on the surgery and the extent of hypoplasia in the hand. Augmentation of existing digits with free phalangeal grafts may improve pinch and grasp, but growth is limited and the stability of the graft is variable. The addition of digits to the hand by vascularized toe transfer may add or assist in the development of pinch and grasp in an otherwise limited hand. In general, these procedures should not be undertaken unless the surgery is expected to add at least one new prehension pattern. In rare cases, appearance may be a relative indication, and a satisfactory outcome then depends on the child's and peers' perception.

CLINODACTYLY

Clinodactyly is angulation of the digit in the radioulnar plane distal to the MCP joint (Figure 36.88). Minor angulation, particularly of the small finger, is common to the point of normalcy. It is noteworthy that clinodactyly has been defined as angulation of more than 10 degrees. The anomaly arises because the shape of one (or more) of the phalanges is either triangular or trapezoidal and the alignment of the associated IP joint is deviated away from perpendicular to the normal longitudinal axis of the finger. The abnormal shape develops as a result of asymmetric longitudinal growth.

Epidemiologic Findings

The true incidence of clinodactyly is difficult to ascertain, with figures ranging from 1% to 19.5%. Clinodactyly presents most commonly as an isolated radial inclination of the small finger, owing to the middle phalanx adopting a triangular or trapezoidal shape. This form of clinodactyly is inherited as an autosomal dominant trait and is often bilateral. Expression of the trait is variable, with males more likely to express the phenotype. Clinodactyly is also seen as part of many syndromes and complex hand anomalies.

Severe clinodactyly may present in the neonate or infant, although most cases present later as the angulation becomes more obvious with growth. The reason for presentation is usually appearance, because compensatory abduction of the

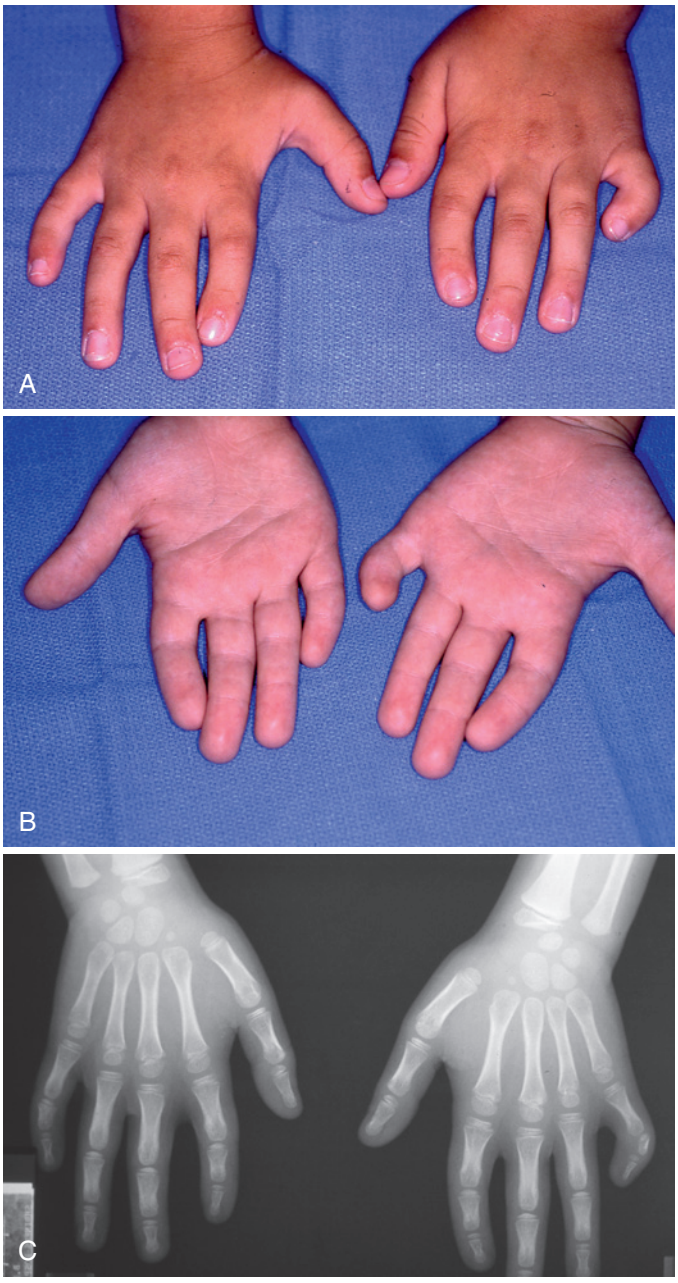

FIGURE 36.88 Five-year-old with bilateral small finger camptodactyly, left more severe than right. **A,** Dorsal view. **B,** Palmar view. **C,** Anteroposterior radiograph. (Courtesy of Shriners Hospital for Children, Philadelphia.)

small finger will prevent substantial interference with flexion. Thumb or central digit clinodactyly may cause functional impairment secondary to altered flexion of the fingers or limit pinch.

The radiographic appearance varies with the age of the patient and degree of bony involvement. In the skeletally mature patient, a triangular or trapezoidal bone will be apparent (see Figure 36.88). In the skeletally immature patient, the secondary center of ossification may be malformed, traverse around the base of the phalanx, and travel along the shortened side of the bone (Figure 36.89). The most severe form of longitudinal epiphyseal bracket forms a "C" shape as the bracket that unites the proximal and distal growth centers. Clinodactyly can be

TABLE 36.10 Classification of Clinodactyly Deformity

Type of Deformity	Area of Deformity	Angulation of Deformity	Associated Deformity
Simple	Middle phalanx	Less than 45 degrees	
Simple complicated	Middle phalanx	More than 45 degrees	
Complex	Bone and soft tissue	Less than 45 degrees	Syndactyly
Complex complicated	Bone and soft tissue	More than 45 degrees	Polydactyly or macrodactyly

Cooney WP: Camptodacytyly and clinodactyly. In Carter P, editor: *Reconstruction of the child's hand*, Philadelphia, 1991, Lea & Feibiger.

classified according to cause or pathologic condition; the most useful classification is that proposed by Cooney (Table 36.10).[43]

ANATOMY

The longitudinal growth of tubular bones such as the phalanges is generated at the epiphyseal growth plate, with axial alignment maintained by factors intrinsic and extrinsic to the growth plate. An abnormal growth plate secondary to a congenital anomaly or postnatal insult will produce progressive deformation with growth. The growth plate anomaly associated with clinodactyly is the "C"-shaped physeal plate extending along one side of the bone, forming a bracket that restricts longitudinal growth on one side of the bone. The pathologic finding was described initially by Jones in his description of triangular or "delta" phalanges in severe clinodactyly. The pathologic condition has been described as a longitudinal epiphyseal bracket, and a spectrum of severity and a classification system have been described. When complete ossification of the bracket occurs early, no longitudinal growth is possible and a short triangular bone, the *delta phalanx*, is produced. If the bracket is incomplete or is cartilaginous, some longitudinal growth occurs and the phalanx is trapezoidal. The epiphyseal bracket affects the middle phalanx most commonly, because this is the last bone to ossify in the digital skeleton. The epiphyseal bracket may also occur in the proximal phalanx or within the extra phalanx in hyperphalangism. More complex variants of the anomaly exist, with the *dual* or *kissing delta phalanx* occurring in specific syndromic anomalies such as *Rubinstein-Taybi syndrome* and *Cenani-Lenz syndactyly*.[56] Acquired causes of clinodactyly include trauma to the growth plate from injury or frostbite or inflammatory arthritis with asymmetric physeal closure. Bone tumors can also produce a secondary angular deformity, though this is usually related to asymmetric deformity of the joint surface produced by expansion of juxtaarticular tumors rather than tethering of the growth plate.

Although the skeletal anomaly generates the angulation of the finger, the underlying soft tissues are affected. Severe angulation leads to soft tissue shortening on the concave side of the digit and possible displacement of the extensor mechanism. This soft tissue deformation requires consideration during surgical correction.

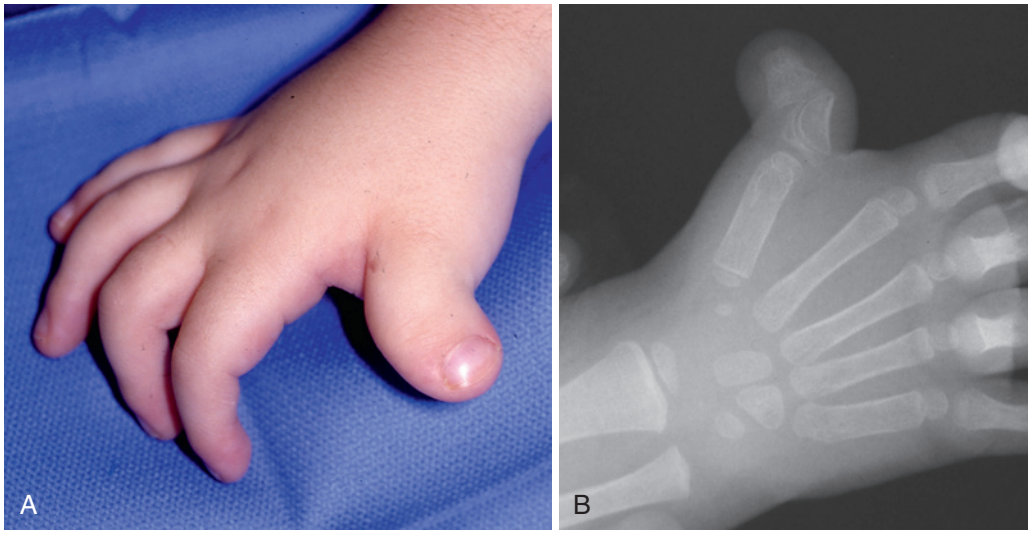

FIGURE 36.89 Three-year-old with Rubinstein-Taybi syndrome. **A,** Thumb clinodactyly. **B,** Anteroposterior x-ray with longitudinal epiphyseal bracket. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Management

The majority of patients with isolated clinodactyly of the small finger present with an aesthetic rather than a functional problem. Surgery should be avoided in these cases, because any improvement in appearance occurs at the risk of scarring and stiffness. Surgical correction is indicated for severe clinodactyly with shortening and angulation, particularly where the radial digits or thumb are involved and angular deformity interferes with pinch.

Splinting for clinodactyly is fruitless. Correction of the skeletal anomaly requires either an osteotomy to realign the digit or resection of the longitudinal epiphyseal bracket to release the longitudinal growth potential of the shortened side of the digit. Realignment of the axis of the digit with an osteotomy may be achieved with a closing wedge or opening wedge, or a combined procedure, the reverse wedge osteotomy. The closing wedge osteotomy (Figure 36.90) is attractive because of its relative simplicity and reliability; however, in the shortened digit a further loss of length may be unacceptable. An increase or maintenance of length is possible with either an opening wedge or a reverse wedge osteotomy. Bone graft is required for an opening wedge osteotomy; this presents its own difficulties in the small child, in whom donor sites are restricted. The reverse wedge osteotomy is technically challenging in the small bones of the child's hand and requires access to both sides of the digit.

Corrective osteotomy is indicated in moderate deviation that interferes with function. If possible, correction is best deferred until skeletal maturity to allow ample time for bone growth. In the skeletally immature patient, osteotomy is technically challenging, with risks of incomplete or excess correction or physeal injury with the additional consequences. In severe clinodactyly or thumb clinodactyly, earlier surgery may be required. Corrective osteotomy tries to achieve a single-stage correction. The soft tissue deficit on the concave side may be addressed with a "Z"-plasty.[151] In severe angulations, "Z"-plasty may be inadequate and a rotational flap or step advancement flap described by Evans and James[58] may be required. For the severe types, realignment of the extensor mechanism may also be necessary to maintain balance of the corrected digit. Clinodactyly in the triphalangeal thumb or hyperphalangism of the fingers may be addressed by excision of the extra malformed phalanx. Ligament reconstruction or arthrodesis of the adjacent joints is obligatory to restore stability.

An alternative to corrective osteotomy is epiphyseal bracket resection and fat grafting (Figure 36.91).[174] This procedure is based on the premise that resection of the bracket will allow the normal portion of the epiphyseal growth plate to generate "catch-up" longitudinal growth on the shortened side and produce angulatory correction over 1 to 2 years. The procedure is performed through a midlateral incision on the short side of the phalanx. The cartilaginous or bony bracket is resected until metaphyseal bone is exposed from dorsal to volar and the growth plate is defined. The defect created is filled with fat, harvested from the forearm, to fill the dead space and prevent fusion across the growth plate. The procedure is limited to patients with open growth plates and is best performed early, although Vickers has performed the procedure with good results on children with only 1 to 2 years of growth remaining.[174] In a review of this procedure,[36] a group of 23 children with 35 operated fingers obtained a mean correction of 11 degrees after a mean follow-up period of 3.2 years. Further analysis revealed that better results were obtained with surgery before the age of 6 years. In addition, fingers with angulation of more than 40 degrees had a greater degree of improvement (20 degrees) compared with those with less than 40 degrees of preoperative angulation (7.5 degrees). Bracket resection does not preclude the use of corrective osteotomy for residual angulation and requires minimal splinting or postoperative immobilization.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

The preferred approach for mild to moderate clinodactyly is to avoid surgery. Surgery is especially rejected in the common mild deformity of the small finger. When the angulation is considerable and the phalanx is a delta phalanx, early epiphyseal bracket resection and fat grafting may be performed. When the patient presents with substantial angulation and is skeletally mature,

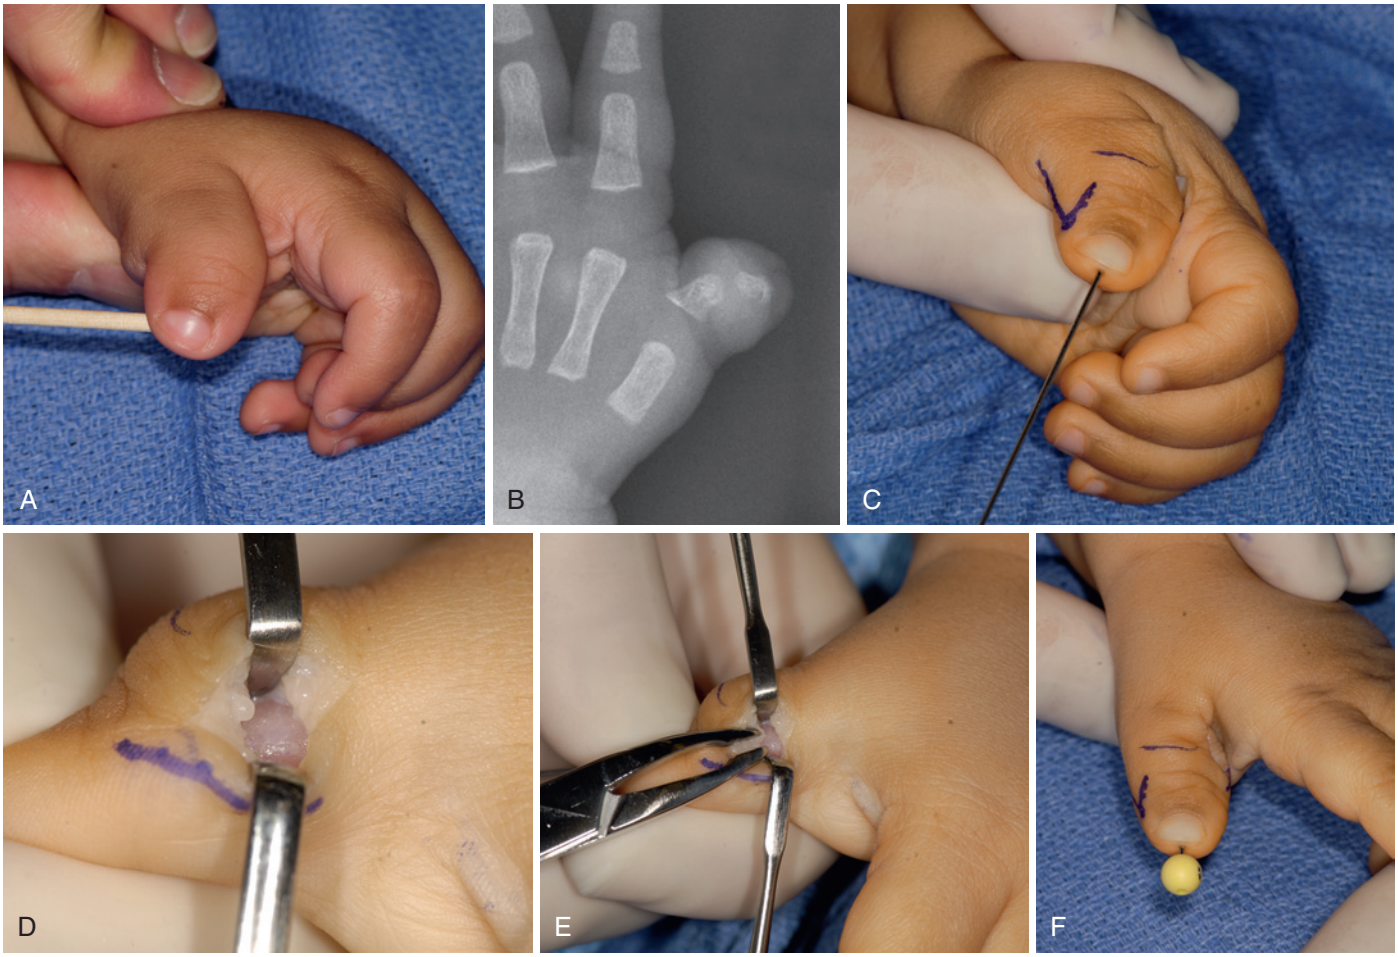

FIGURE 36.90 One-year-old with thumb clinodactyly attributed to abnormal configuration of proximal phalanx. **A,** Preoperative appearance. **B,** Anteroposterior radiograph. **C,** Kirschner wire drilled from tip of thumb into proximal phalanx. **D,** Midlateral approach to the phalanx with elevation of the extensor and flexor tendons. **E,** Rongeur to remove a bony wedge. **F,** Thumb manipulated to crack the remaining concave cortex and longitudinal Kirschner wire is advanced across the osteotomy site. (Courtesy of Shriners Hospital for Children, Philadelphia.)

the decision is based on the configuration of the phalanx. The trapezoidal phalanx tolerates the shortening of a closing wedge osteotomy, whereas a triangular bone will benefit from an opening wedge osteotomy. After corrective osteotomy, fixation is achieved with an axial Kirschner wire. The associated soft tissue deficit with severe clinodactyly can be addressed with the bipedicle step advancement flap described by Evans and James.[58] A reverse wedge osteotomy is technically demanding in small triangular phalanges, and a simple osteotomy is preferred with the addition of bone graft. In patients with thumb clinodactyly, a primary corrective osteotomy is performed to produce a well-aligned thumb column rather than rely on gradual correction with growth after bracket resection.

Expected Outcomes

The expected outcome of surgery in the case of osteotomy is correction of the deformity; however, this may be complicated by stiffness of the digit as a result of scarring and adhesions, so one must balance the extent of the deformity against this risk before deciding on surgery. The outcomes of epiphysiolysis vary according to the extent of growth potential remaining in the digit at the time of surgery.

CRITICAL POINTS *Clinodactyly*

- Clinodactyly is angulation of the digit in the radioulnar plane distal to the MCP joint.
- Minor angulation, particularly of the small finger, is common to the point of normalcy. The cause is usually an abnormal trapezoidal shape of the middle phalanx that leads to radial deviation of the distal IP joint.
- Greater angulation may be secondary to a "longitudinal diaphyseal bracket" or a "longitudinal epiphyseal bracket" along the middle phalanx.
- Mild to moderate clinodactyly requires no treatment.
- Substantial clinodactyly requires realignment of the digit via a closing wedge, an opening wedge, or a reverse wedge osteotomy. The soft tissue deficit on the concave side must also be addressed.

KIRNER DEFORMITY

Kirner deformity is characterized by progressive palmar-radial curvature of the distal phalanx of the digit, usually affecting the small finger. The deviation occurs in two planes, a different situation than the deviation in a single radioulnar plane that occurs in clinodactyly.

In McCarthy JG [editor-in-chief], May JW, Littler JW [volume editors]: *Plastic surgery*, vol 8, the hand, part 2, Philadelphia, 1990, WB Saunders, pp 337–340, with permission. Redrawn by Elizabeth Martin.)

FIGURE 36.92 Clinical appearance of Kirner deformity of the right small finger.

Epidemiologic Findings

The incidence ranges from 0.15% to 0.25% of the population, and females are affected twice as frequently as males. The deformity may be inherited as an autosomal dominant trait with incomplete penetrance. The homozygous state is responsible for expression of the deformity in multiple digits and both hands. The deformity occurs sporadically in at least half of the cases. A distinction between the familial and sporadic cases is the age of onset, and this forms the basis of a classification proposed by Song.[155] Early-onset or congenital Kirner deformity is present at birth and associated with a family history. The deformity does not progress with growth. Late-onset Kirner deformity develops in late childhood or adolescence and is sporadic in incidence. Initially, swelling along the dorsum of the distal phalange(s) of the small fingers develops in one or both hands. There may be some discomfort associated with this stage, but usually the swelling is painless. The deformity ensues with the development of the palmar-radial curvature of the distal fingertip (Figure 36.92), which is marked by the clubbed or beaked appearance of the fingernail. Once established, the deformity is stable. Joint motion at the distal IP joint is preserved.

Kirner deformity has been seen in cases of Cornelia de Lange syndrome, Silver syndrome,[148] Turner syndrome, and Down syndrome. The differential diagnosis in the unilateral deformity is a delayed presentation of distal phalangeal trauma, particularly a physeal fracture with palmar angulation or burn or frostbite injury to the physis. A thorough history together with the physical and x-ray findings usually enables a confident diagnosis.

ANATOMY

Kirner deformity has been attributed to an abnormality of the physis of the distal phalanx. The subsequent distal deformity develops secondary to either asymmetric physeal growth or traction across the damaged physis from the flexor tendon. An alternative and attractive theory suggests that an abnormally distal insertion point of the flexor digitorum profundus tendon leads to excessive traction on the developing skeleton[21,50] or a normal flexor tendon acting on an abnormal osteopenic distal phalanx. A vascular cause for the deformity has also been postulated.

Kirner deformity is characterized by distortion and widening of the physeal plate along with curvature of the diaphysis of the distal phalanx (Figure 36.93). Radiographs show an abnormality of the epiphysis with the palmar lip of the epiphysis relatively lengthened and the metaphyseal margin of the physis sclerotic and ragged. Physeal plate closure is delayed and begins in the dorsal half of the physis. The histologic condition of the phalanx at this stage demonstrates lysis at the junction of the metaphysis and physis. Later, the diaphyseal curvature is well established, and in the mature form of the deformity, the physis has completely fused and normal bone density is restored throughout the deformed phalanx.

Management

Kirner deformity has little effect on function. Musicians and keyboard operators may identify specific problems related to small finger position. The indication for surgery is primarily restoration of the finger appearance. The patient must be counseled carefully about the potential risks of surgery and expected results.

Splinting the small finger into extension has been reported as effective in relieving discomfort in the early swelling stage of the deformity, although no benefit in prevention or correction of deformity was obtained. Other investigators have reported prolonged serial splinting useful in correcting the deformity if

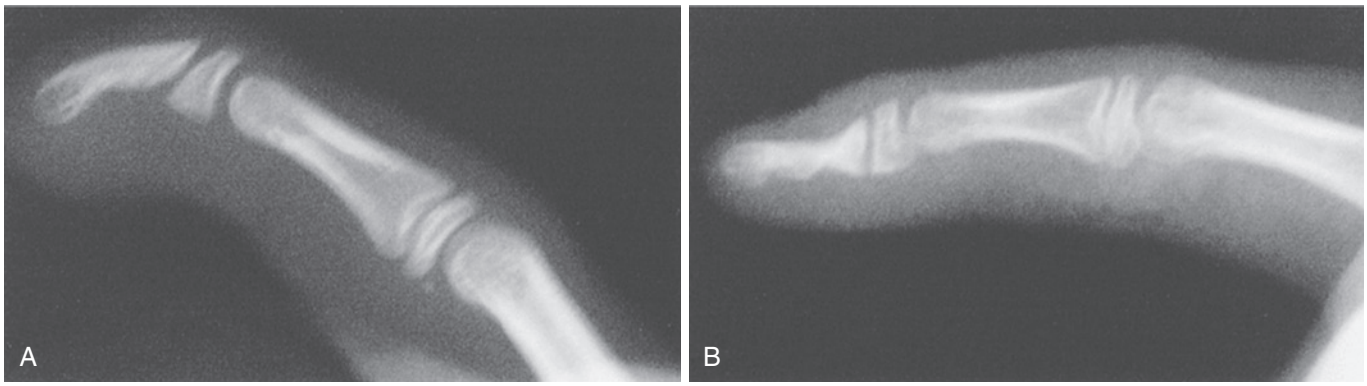

FIGURE 36.93 Preoperative **(A)** and postoperative **(B)** radiographs of Kirner deformity treated with an osteotomy.

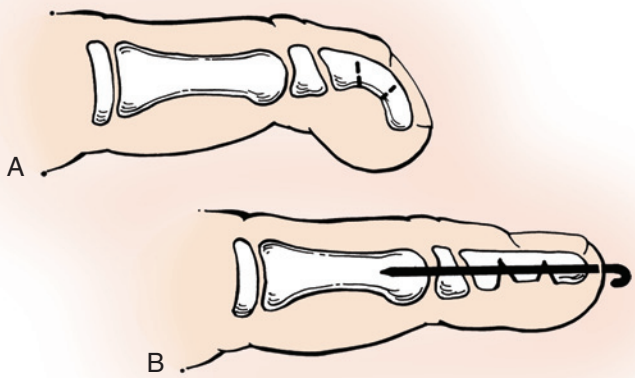

FIGURE 36.94 **A** and **B,** Multiple opening wedge volar osteotomies are used to straighten the distal phalanx over a Kirschner wire. it has been applied in the early stages and before completion of growth. Benatar has reported the correction of the deformity by early release of the abnormal component of the long flexor tendon insertion.[21] If the epiphysis remains open, another option is to perform a dorsal hemiepiphysiodesis or resect a dorsal wedge including the dorsal growth plate to prevent progression of the deformity. For the mature deformity, corrective osteotomies have been used to improve the alignment of the phalanx and corresponding nail growth (Figure 36.94). The deformity has been addressed with a dorsal closing wedge osteotomy or, alternatively, two or three opening wedge osteotomies of the volar cortex to unfold the phalanx. The technique of distraction lengthening has also been used to correct the deformity.[118]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Splinting can be attempted in the early stages of the deformity, although it needs to be rigorously monitored to be effective in preventing or correcting the deformity. Although there may be a role for early surgery as recommended by Benatar,[21] we do not routinely divide the distal part of the flexor tendon insertion to limit the deforming force on the developing bone. Usually, corrective surgery is deferred until the patient is able to participate in the decision-making process, because surgery is primarily performed for appearance rather than function. The authors' preference is to use volar osteotomies to correct the phalangeal curvature. The nail plate is removed and a radial dorsolateral incision preserving the paronychial fold is used to expose the distal phalanx. The osteotomies are planned distal to the flexor tendon insertion. Two or three are used, depending on the size of the phalanx. The volar periosteum is incised, and the dorsal periosteum is preserved so it can act as a hinge for the correction and prevent injury to the overlying nail matrix. The osteotomies are performed with a sharp osteotome. The curvature of the phalanx is corrected, and fixation is accomplished with an axial Kirschner wire. The Kirschner wire is left in place until the osteotomies have healed. The digit is protected with a splint during the healing process.

CRITICAL POINTS *Kirner Deformity*

- Kirner deformity is characterized by progressive palmar-radial curvature of the distal phalanx of the small finger.
- The precise cause is unknown.
- Radiographs reveal distortion and widening of the physeal plate along with curvature of the diaphysis of the distal phalanx.
- Kirner deformity develops in late childhood or adolescence, with initial swelling along the dorsum of the distal phalanx. Subsequently, a palmar-radial curvature of the distal fingertip develops over time.
- Kirner deformity has little functional effect, and the indications for surgery are limited.

MACRODACTYLY

Macrodactyly is a descriptive term used for a disproportionately large digit noted at birth or that develops within the first years of life. Both the soft tissue and skeletal elements are diffusely enlarged in the affected digit(s). Several alternative terms have been used, including *megalodactyly*, *gigantism*, *macrodystrophia lipomatosa*, and *macrodactylia fibrolipomatosis*. *Macrodactyly* is the widely recognized term that is preferred.

Macrodactyly is uncommon. In Flatt's series of upper extremity anomalies, the incidence of macrodactyly was 0.9%.[64]

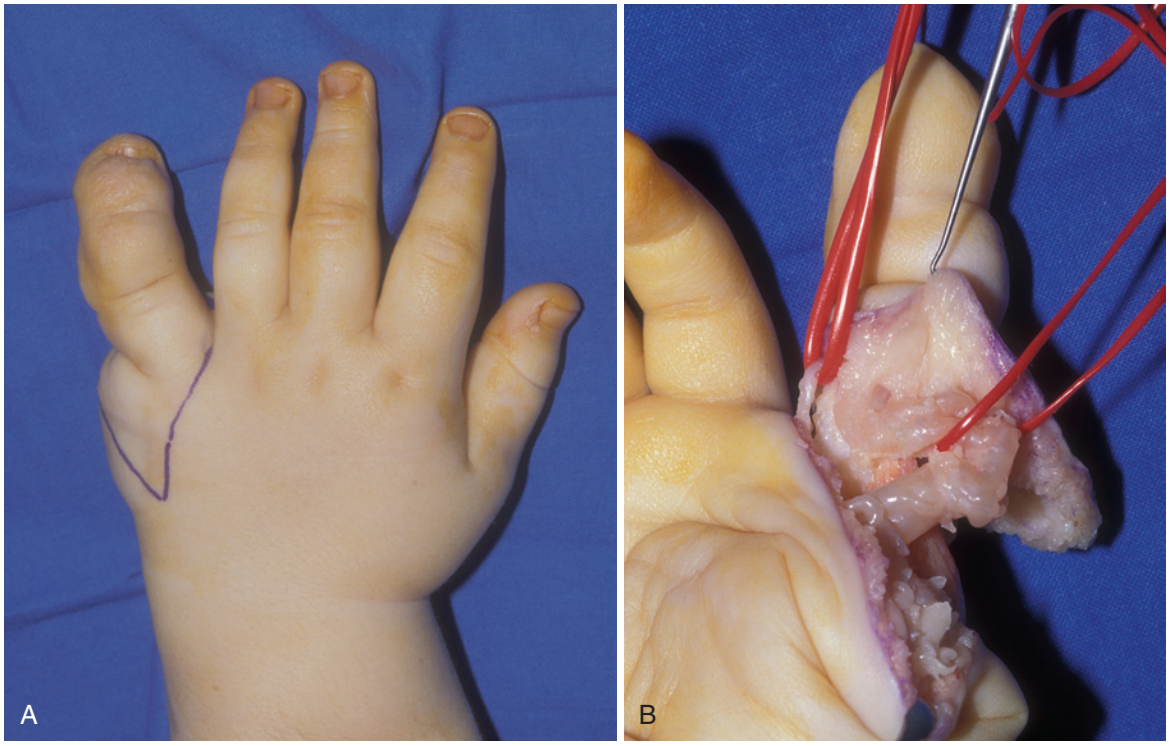

FIGURE 36.95 **A** and **B,** Macrodactyly of the fifth finger associated with lipofibromatous change in the ulnar digital nerve along with a normal radial digital nerve.

Most cases appear sporadically without evidence of inheritance. The most common form of macrodactyly is as an isolated anomaly associated with lipofibromatosis of the proximal nerve (Figure 36.95). Macrodactyly may also be part of a more diffuse hypertrophy or a component of a broader syndrome such as neurofibromatosis. Digital overgrowth can also occur secondary to a specific lesion within the digit, such as a tumor (soft tissue or bone), vascular malformation, or lymphedema. These cases are not considered true macrodactyly, because the overgrowth is secondary to the specific lesion.

Flatt's classification of macrodactyly centers on the pathologic basis of the deformity (Table 36.11). The original classification has been supplemented by the addition of the type IV group.

Macrodactyly associated with lipofibromatosis is often noted at birth or develops within the first 3 years of life. The growth of the enlarged digit may be disproportionate *(progressive macrodactyly)*, or the digits may maintain a consistent proportion to the remainder of the hand (*static macrodactyly*). A recent report noted the development of the progressive growth pattern in two children initially diagnosed with the static form of macrodactyly after a debulking procedure. The anomaly is usually unilateral and may affect more than one digit. Enlargement of multiple digits is two to three times more common than enlargement of a single digit. The index finger is the most frequently affected digit, particularly in combination with the thumb or long finger. Affected radial digits usually deviate in a radial direction. In contrast, affected ulnar digits deviate in an ulnar direction. Where two digits are involved, the deviation is usually divergent (Figure 36.96). Enlarged thumbs are typically

TABLE 36.11 Classification of Macrodactyly

Type	Description
Type I: Gigantism and lipofibromatosis	Macrodactyly associated with enlarged nerves infiltrated with fat within the digit and extending proximally through carpal tunnel; most common form of macrodactyly deformity
Type II: Gigantism and neurofibromatosis	Macrodactyly usually occurs in conjunction with plexiform form of neurofibromatosis and is often bilateral; may be osteochondral masses associated with the enlarged skeleton
Type III: Gigantism and digital hyperostosis (see Figure 36.99)	Hyperostotic form of macrodactyly with osteochondral periarticular masses developing in infancy; no significant nerve enlargement; very rare and not hereditary; the digits are nodular and stiff, and there may be other skeletal anomalies
Type IV: Gigantism and hemihypertrophy	Rare anomaly without known inheritance pattern or etiologic pattern; macrodactyly part of hemihypertrophy; all digits involved, but less severe than type I or II; deformity marked by intrinsic muscle hypertrophy or abnormal intrinsic anatomy; deformities present with flexion contracture, ulnar deviation, and an adducted thumb deformity

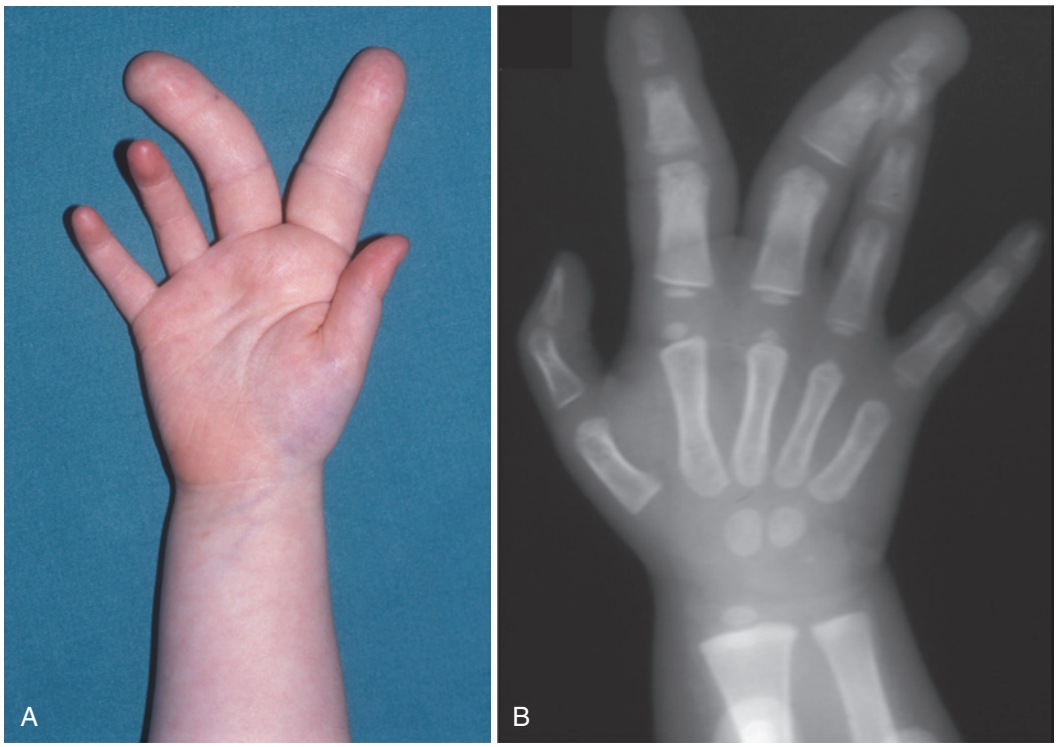

FIGURE 36.96 **A** and **B,** Macrodactyly of two adjacent fingers. The fingers usually deviate away from each other.

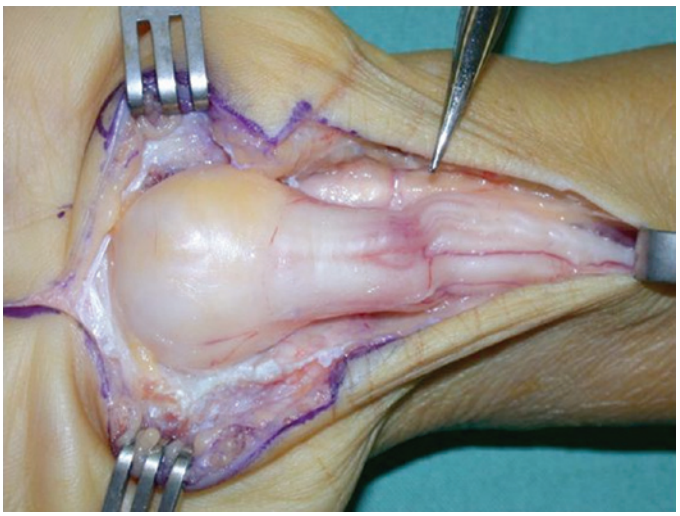

FIGURE 36.97 Median nerve involvement in a patient with macrodactyly of the thumb. This resulted in carpal tunnel syndrome, which required decompression.

abducted and extended. Osseous growth and deviation continues until physeal closure: however, soft tissue enlargement may continue into adulthood. The enlarged digits stiffen during growth, which further limits function.

Radiographs reveal an enlarged skeleton with advanced bone age compared with the normal digits (see Figure 36.96). The phalanges may be trapezoidal with deviation of the digit. Osteoarthritic changes may be noted early with osteophyte development. If angiography is performed, one of the digital arteries is often enlarged. Apart from the obvious digital deformity, soft tissue swelling in the palm may be present associated with fatty infiltration of either the median or ulnar nerves (Figure 36.97). This may be severe enough to result in a compression neuropathy. The thickening of the flexor sheath may produce triggering if digital range of motion is preserved. Syndactyly is seen in 10% of cases (Figure 36.98).

Macrodactyly associated with neurofibromatosis is diagnosed by the characteristic cutaneous stigmata (pigmented skin lesion, café-au-lait spots, multiple neurofibromas, pedunculated skin tumors, and ocular lesions) of type I neurofibromatosis.

Hyperostotic macrodactyly is rare and can be distinguished on clinical examination by nodular enlargement of the digit and profound loss of motion secondary to periarticular osteochondral mass formation (Figure 36.99). Although unusual, concurrent peripheral nerve lipofibromatosis has been reported with hyperostotic macrodactyly. The radiographic appearance of the periarticular osteochondral masses confirms the diagnosis.

Macrodactyly may also be part of a broader gigantism anomaly affecting the entire limb or body part in addition to the enlarged digit. The gigantism may be *segmental gigantism*, affecting only a part of one limb; *hemihypertrophy*, affecting one side of the body (associated with neurofibromatosis or Klippel-Trénaunay syndrome); or *crossed gigantism*, affecting regions on both sides of the body (Figure 36.100). Sometimes the hemihypertrophy can be subtle, but if a patient has macrodactyly of all digits, the remainder of the limb should carefully be examined for enlargement.

Other syndromes that feature digital enlargement include Ollier disease (multiple enchondromas), Maffucci syndrome (multiple hemangiomas and enchondromas), Klippel-Trénaunay-Weber syndrome (cutaneous hemangioma, atypical varicose veins, and hemihypertrophy), and Proteus syndrome[183] (hamartomatous dysplasia with features of macrodactyly, pigmented nevi, and subcutaneous hamartomas). Proteus syndrome is

FIGURE 36.98 **A** and **B,** Macrodactyly with associated syndactyly. This combination occurs in about 10% of patients.

extremely variable with regard to phenotype and associated anomalies.

ANATOMY

The cause of true macrodactyly is unknown. Potential mechanisms have been postulated, including an abnormal nerve supply leading to unimpeded growth, an increase in blood supply, and/or an abnormal humoral mechanism stimulating growth. The most convincing theory is based on the association between peripheral nerve pathologic findings and macrodactyly, because the most common type of macrodactyly is associated with fatty infiltration and enlargement of the nerve associated with the digit (see Figure 36.95). This lipofibromatosis of the nerve has been alternatively reported as a fibrolipoma,[30,138] lipofibroma, or hamartoma.[5,123] Although it is commonly associated with macrodactyly, lipofibromatosis of the nerve can occur in isolation.[149] The macroscopic findings are an increased amount of subcutaneous fat, an enlarged tortuous digital nerve(s), and skeletal overgrowth in all dimensions. Most macrodactyly occurs in a single digit or in a region innervated by a single nerve. Where a common digital nerve is affected, the digits it supplies diverge, leading to speculation that the overgrowth is greater in the territory supplied by that nerve and hence the divergence, and also to speculation that the affected nerve itself causes the overgrowth. This speculation is not confirmed. The term *nerve territory–oriented macrodactyly* describes this relationship.

Typically, the palmar aspect of the finger is more affected than the dorsal aspect, and the distal finger is more enlarged than the proximal finger. The tendons have a normal appearance, although the flexor tendon sheath may be thickened. Histologic findings of the digital tissues show thickening of the skin with decreased sweat gland density, abundant subcutaneous fat with increased fibrous stroma, fatty infiltration of the digital nerves with endoneural and perineural fibrosis, and enlarged digital arteries. The bony structure shows wide medullary canals, irregular trabeculae, and thickening of the periosteum. Macrodactyly associated with neurofibromatosis is similar, although the plexiform nerve has an increased fibrovascular stroma and nodular appearance rather than fibrolipomatosis changes.

Exostoses and other skeletal deformities may be noted in the enlarged digit. Hyperostotic macrodactyly is marked by periarticular exophytic osteocartilaginous masses (see Figure 36.99) and is typically not associated with enlargement of the associated peripheral nerve.

Management

Macrodactyly is a disfiguring anomaly. Patients usually present in childhood, although they may present later with a compression neuropathy secondary to pathologic enlargement of affected nerve(s). Children with macrodactyly are often subject to teasing and have social difficulties. As a consequence, the hand is often concealed and ignored. Indications for surgery include functional and aesthetic improvements. The enlarged digit(s) often obstructs grasp and pinch.

Macrodactyly is extremely difficult to treat. The progressive and diffuse nature prevents complete correction to normal. The expectations of the parents and sometimes the child must be carefully managed prior to surgery. In particular, the inability to establish a normal digit and the probable need for multiple stages of surgery should be established. Available surgical options can be divided into procedures that limit ongoing growth, that reduce the size of the digit, or that correct deviation, or amputation (Table 36.12). The procedures may be combined at the same time or staged according to the patient's needs. In addition, carpal tunnel or Guyon canal decompression may be needed in cases with concurrent compressive neuropathy (see Figure 36.97).

Limiting Digital Growth

Proposed methods to limit growth include ligation of the digital arteries, compression bandaging, stripping the digital nerves, or resection of the digital nerve.[86] The most reliable method,

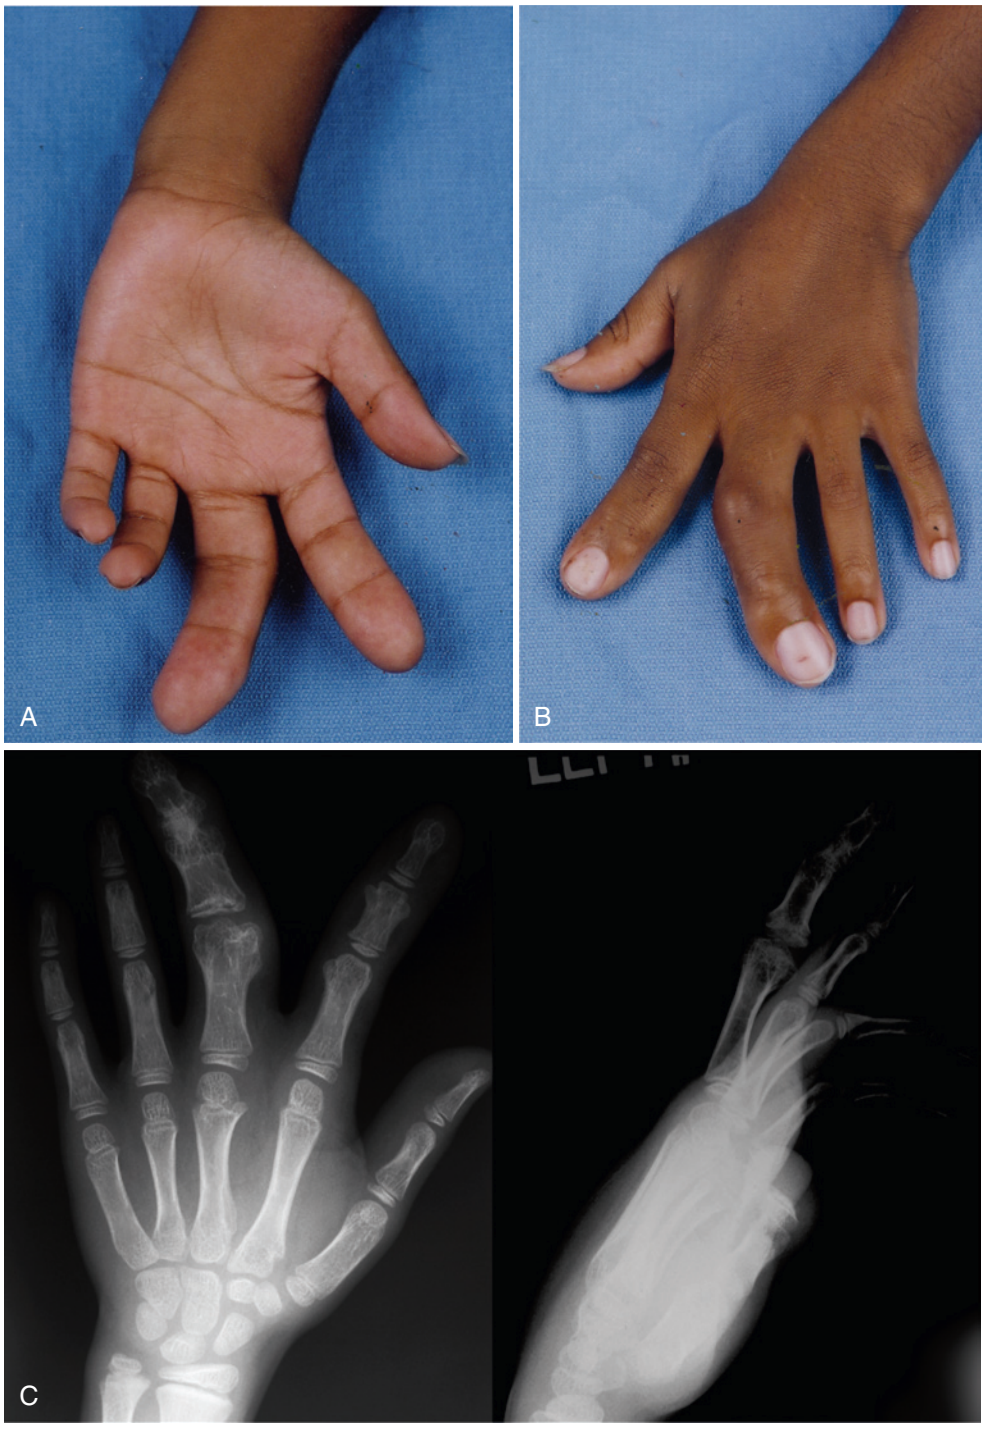

FIGURE 36.99 Hyperostotic macrodactyly. **A,** Palmar view of the hand of a 6-year-old boy with macrodactyly of the left index and middle fingers. **B,** Dorsal view. **C,** Radiographs showing periarticular exophytic osteocartilaginous masses. (Courtesy of Shriners Hospital for Children, Philadelphia.)

however, is epiphysiodesis.[86] This may be accomplished by various methods, including burring or drilling, resection of the epiphyseal plate, or physeal stapling in larger bones. Epiphysiodesis is performed when the digit reaches the length of the corresponding digit in the parent of the same gender as the child. Digital deviation can be corrected simultaneously by a closing wedge resection of the physis (Figure 36.101). Progressive deviation can also be managed by hemiepiphysiodesis on the convex side of the digit, although not as reliably as corrective osteotomy. Percutaneous Kirschner wires are often required to stabilize the phalanx after physeal resection, particularly if combined with a wedge osteotomy. Complications of physeal arrest include joint stiffness, excessive bone formation at the site of the physis, or secondary angulation after incomplete physeal destruction. Physeal arrest does not reduce soft tissue growth or the transverse (appositional) growth of the skeleton. Nerve

TABLE 36.12 Treatment of Macrodactyly

Goal of Treatment	Procedure		
Limiting growth	Digital nerve stripping Epiphysiodesis		
Digit reduction	Soft tissue Skeletal	Debulking Terminalization Reposition nail unit on shortened skeleton Resection of distal portion of nail and pulp	Palmar pedicle (Barsky procedure)[14,63] Dorsal pedicle (Tsuge procedure)[166] Nail island flap[137] Tsuge[167] Hoshi[83] Fujita[67] Bertelli[22]
Correction of deviation	Closing wedge osteotomy (combined with epiphysiodesis as required)		
Correction of thumb macrodactyly	Metacarpophalangeal arthrodesis Millesi procedure[109]		
Amputation	Ray amputation (with transposition of digit for central ray amputation)		

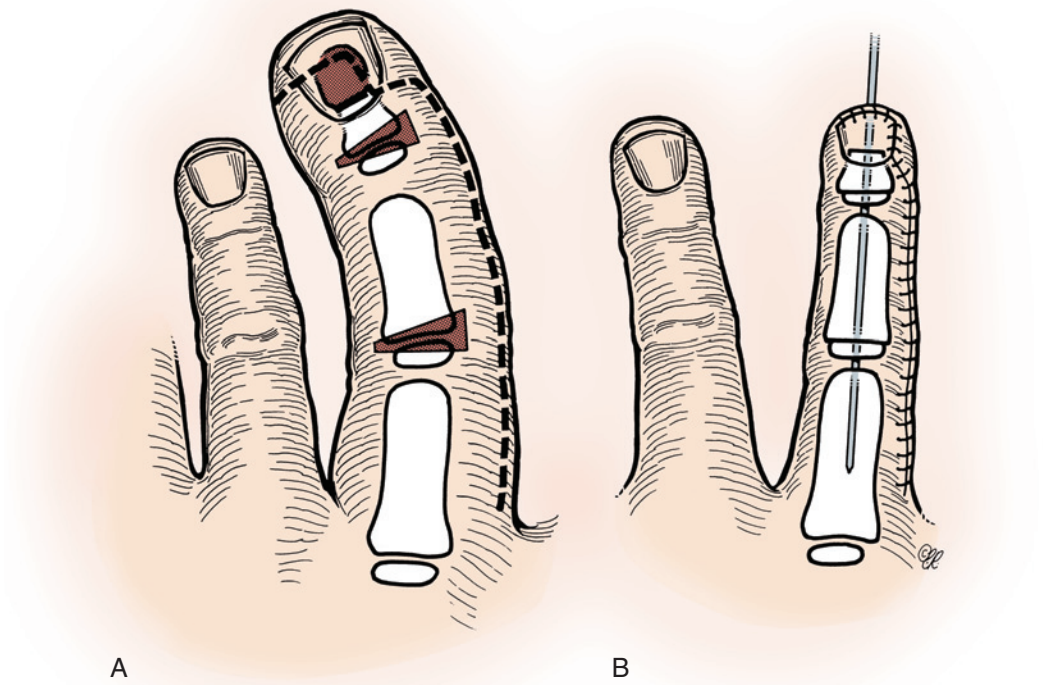

FIGURE 36.101 **A** and **B,** Excision of the epiphyseal plate and partial removal of the bone by osteotomy can stop growth and correct angulation all in one maneuver, as suggested by Tsuge. (Copyright © Elizabeth Martin.)

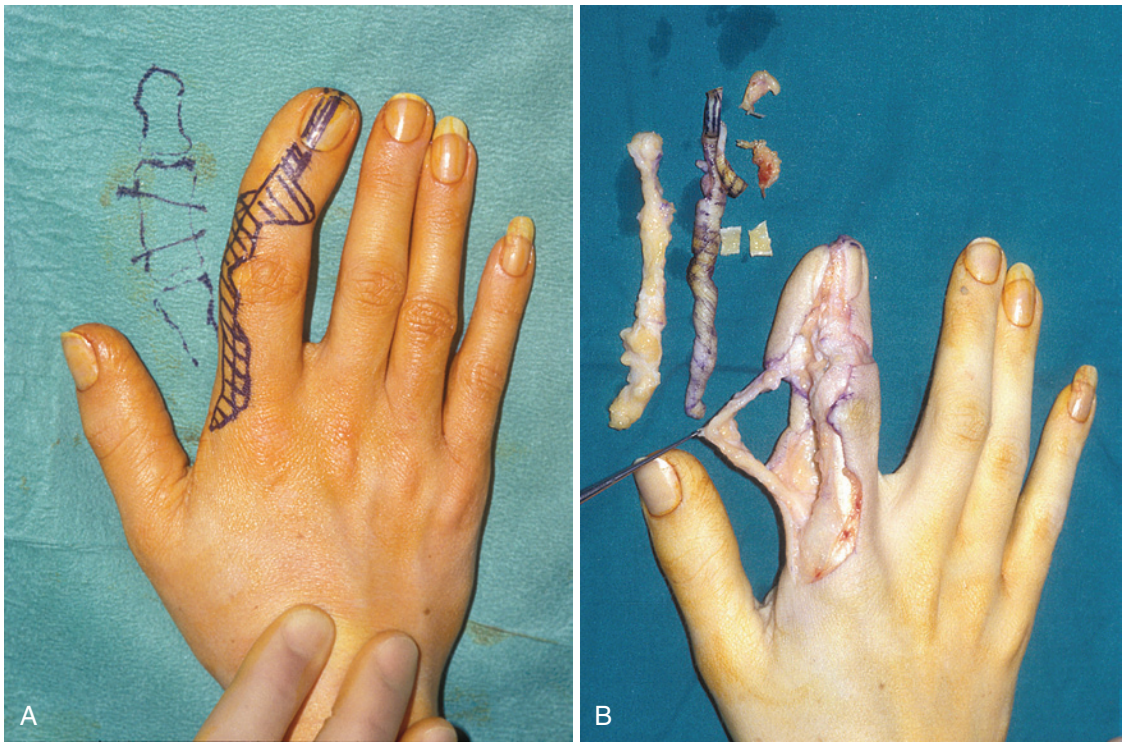

FIGURE 36.102 **A** and **B,** Reduction of the index finger by using a combination of angulation osteotomy, resection of skin and fat, debulking of the enlarged digital nerve, and narrowing of the nail bed.

resection and repair or grafting is rarely recommended, given the risk of adding the insult of a permanent sensory deficit to the already stiff and deformed digit.

Reducing the Digit

Debulking the soft tissues reduces the size of the enlarged digit (Figure 36.102). Usually, one side of the digit is debulked at a time. The digit is approached through a midlateral incision. Skin flaps are elevated to the volar and dorsal midline, and the neurovascular bundle is dissected from the subcutaneous fat. The fat is resected, and the excess skin is excised. Care must be taken to maintain viability of the undermined skin flaps. An alternative approach is to address the palmar aspect of the finger via a Bruner incision.

Skeletal reduction can be achieved by either narrowing or shortening. Narrowing the skeleton can be achieved by burring the sides of the phalanges or performing a longitudinal ostectomy. This ostectomy is limited by the attachment of the flexor sheath and has been complicated by hematoma and/or joint stiffness. Skeletal shortening can be achieved by several techniques. A deviated digit can be shortened and realigned via corrective ostectomy. A trapezoid rather than a wedge resection has been recommended to increase shortening. Excision of the middle phalanx has also been reported,[159] with a stable joint created between the distal and proximal phalanges. The amount of resection, however, is limited by the telescoping of the excessive soft tissue. The simplest procedure is "terminalization" of the enlarged digit, although the loss of the nail may only exacerbate the appearance of deformity.

Several techniques attempt to preserve the nail and shorten the digit. The Barsky procedure involves shortening the digit by filleting the distal phalanx, excising the skin over the dorsum of the middle phalanx, and placing the nail on the end of the middle phalanx.[14] Flatt modified this technique by preserving the distal part of the distal phalanx and fusing this to a shortened middle phalanx to reduce the skeleton.[64] Considerable bony shortening (>3 cm) may require concomitant flexor digitorum profundus shortening. The excess palmar skin produced by the shortening can be excised at a second stage. The use of a palmar pedicle maintains a reliable blood supply and good sensation in the distal finger. In contrast, the Tsuge procedure preserves the nail on a dorsal skin pedicle, including the dorsal cortex of the distal phalanx[166] (Figure 36.103). The digit is shortened, with excision of the pulp and the palmar part of the distal phalanx. The nail is fitted into a recess on the dorsum of the middle phalanx. A fold of skin is produced on the dorsum of the digit, which can be revised with a second procedure.[167] The dorsal pedicle, however, has proven to be unreliable in the fingers but has been used in the toes with success. The Rosenberg technique[137] transposed the nail farther by raising the nail unit as an island flap on the digital neurovascular pedicle. After excision of the distal phalanx and pulp, the nail unit was repositioned on the dorsum of the middle phalanx.

An alternative to transposing the nail unit onto a shortened skeleton is to reduce the nail and shorten the digit further with segmental ostectomies along the length of the digit. Tsuge narrowed the width of the nail and distal phalanx by ostectomies and shortened the digit by excision of the MCP joint. Hoshi and associates combined soft tissue debulking and skeletal shortening with excision of the tip of the distal phalanx and nail, proximal shortening with DIP arthrodesis, and debulking via the convex side of the deviated digit.[83] Using a similar

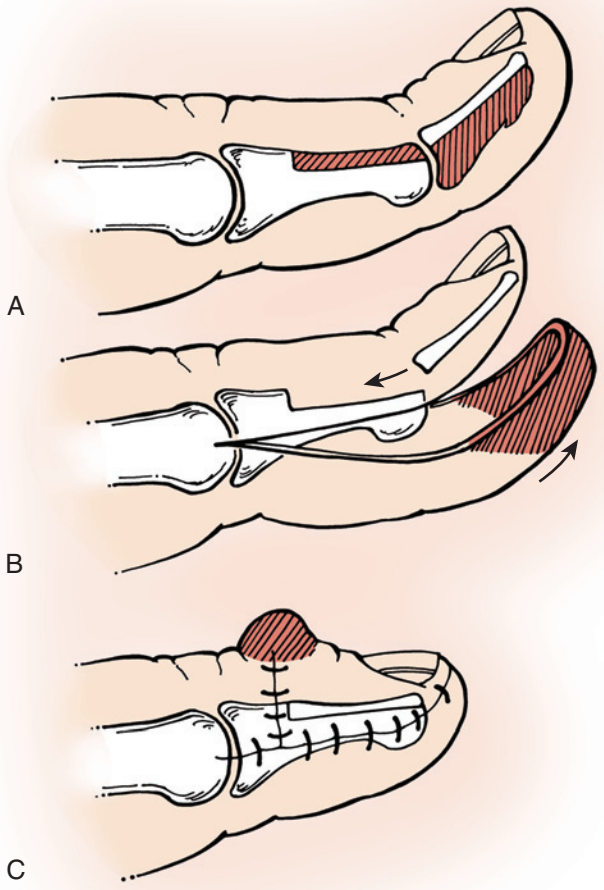

FIGURE 36.103 Tsuge method for reducing the length of a macrodactylous finger. **A,** The incision is midlateral to the end of the finger. The volar part of the distal phalanx and the dorsal part of the middle phalanx are removed. **B,** Excess volar skin and soft tissues are removed from the end of the finger. **C,** The dorsal part of the distal phalanx and nail are recessed to fit the middle phalanx. The remaining excess dorsal soft tissue can be removed later. (Copyright © Elizabeth Martin.)

technique, Akinci reported good results in a series of older children and adults who had undergone combined skeletal and soft tissue debulking based on the concave neurovascular bundle.[2] Fujita and colleagues raised a palmar flap, including the radial neurovascular bundle along the length of the digit, which left the ulnar neurovascular bundle, skeleton, and flexor tendon on the dorsal flap.[67] The ulnar one third and distal end of the palmar flap and the radial one third and tip of the distal phalanx and nail were excised to match each other. The thumb can be addressed using similar techniques. Debulking is similar, and shortening can be performed via MCP arthrodesis. Millesi devised a more complicated pattern of reduction osteotomies that preserves joint motion. The nail width and length are reduced, but the central nail is excised. This technique often results in ridging of the nail.[108]

The number and variety of techniques described are testament to the difficulty in achieving a result acceptable to the surgeon and patient, and hence there is motivation for further refinement of the operations for this condition.

Amputation

The ultimate reduction procedure is amputation. This procedure is an option for macrodactyly isolated to a single digit or showing progressive uncontrollable growth (Figure 36.104). Amputation of the thumb should be avoided unless the overgrowth is so great as to preclude any function. Ray amputation of a border digit and transmetacarpal amputation of a central digit and adjacent digit transposition are the procedures of choice.

In cases where amputation is considered early, it can be possible to sometimes offer digit substitution with transfer from the foot; if the native MCP joints are competent, this is very effective. Alternatively, an adjacent digit can be moved into the thumb position by pollicization (Figure 36.105).

Hyperostotic Macrodactyly

Loss of motion can be addressed with ostectomy of the osteochondral masses, which may include part of the volar plate. Recurrence is the rule, and arthrodesis is often required after the digit attains adult length. Implant arthroplasty of the MCP joints has been used in very select cases.

Hemihypertrophic Macrodactyly

In hemihypertrophic macrodactyly, contracture of the digit(s) is common, which further impairs motion. Contracture release, debulking of the hypertrophic intrinsic musculature, and soft tissue rebalancing has been performed in a limited number of cases. Skeletal correction may also be required.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Macrodactyly is a devastating anomaly for the child and represents a social stigma, focus of anxiety for parents, and a technical challenge for the surgeon. Multiple procedures are required, and the end result may be unsatisfactory. In contrast, the authors believe that ray amputation is a worthwhile procedure and should be considered early, before the patient invests in multiple procedures to salvage a deformed digit with limited function. Most parents with young children find this a difficult decision and prefer digit-preserving surgery. Experienced surgeons, however, will take the time and convey the trials and tribulations with reduction surgery. The cost to the family and child of multiple operations during childhood must be weighed and the ultimate outcome of a stiff, scarred, and still enlarged digit discussed. There is no doubt that the challenge of macrodactyly reduction can appeal to enthusiastic and skillful surgeons, but this enthusiasm must be tempered with realism.

The surgical plan is based on digital involvement, size of the digit(s), estimated adult length, degree of motion, and overall alignment. For digital conservation in young children, improving the appearance before school age is indicated. Debulking of subcutaneous fat with isolation of the neurovascular bundle is performed via a midlateral approach (see Figure 36.102). One side of the digit is debulked at a time, with a 3-month interlude between operations. This debulking can be combined with corrective osteotomy for deviated digits.

FIGURE 36.106 **A** and **B,** Unsightly macrodactylous digits that have gradually lost motion and stiffened over time as a consequence of surgical reduction and progression of the deformity.

When the digit has reached adult length, longitudinal growth can be terminated with epiphysiodesis of all the phalanges. A midlateral approach is performed with physeal plate ablation using a blade, curet, cautery, or drill. Fluoroscopy guidance is helpful. The physeal plate resection can be configured as a closing wedge osteotomy to correct alignment of the digit (see Figure 36.101). The skeleton is stabilized with Kirschner wires at each level. The soft tissues can be debulked at this procedure.

If a digit exceeds adult length, a shortening procedure is recommended. The procedure used depends on the location and extent of excess. Minimal shortening can be accomplished by reduction of the distal fingertip pulp and nail using the method of Hoshi.[83] Excessive length requires distal phalanx excision and repositioning of the nail to the dorsum via a nail island flap. For the thumb, MCP joint resection and arthrodesis are preferred. These techniques address digital length and alignment, but excessive soft tissue and nail contribute to persistent disfigurement. This deformity can be addressed with debulking, nail bed excision, and longitudinal removal of bone. The procedures are difficult and limited by the finger's vascularity, joint stability, and flexor tendon integrity. Recurrence is common, and functional deterioration with continued growth is prevalent (Figure 36.106). At this point, patients often consider amputation, because removal of the digit may actually improve hand function.

Expected Outcomes

Outcomes in macrodactyly are very dependent on the condition of the hand initially, but no procedure results in a normal appearance, and final function depends on the extent of resection and the stiffness of the reduced digits.

CRITICAL POINTS *Macrodactyly*

- The most common form of macrodactyly is an isolated anomaly associated with lipofibromatosis of the proximal nerve.
- The cause is unknown.
- Most cases of macrodactyly occur in a single digit or in a region innervated by a single nerve (also known as *nerve territory–oriented macrodactyly*).
- Macrodactyly is often noted at birth or develops within the first 3 years of life. Growth of the enlarged digit may be disproportionate (*progressive macrodactyly*), or the digits may maintain a consistent proportion to the remainder of the hand (*static macrodactyly*).
- Macrodactyly is extremely difficult to treat. Its progressive and diffuse nature prevents complete correction to normalcy. Despite multiple surgeries to remove the extraneous tissues, the end result may be unsatisfactory.
- Ray amputation for progressive macrodactyly should be considered early before the patient invests in multiple procedures to salvage a deformed digit with limited function.

THUMB HYPOPLASIA

Thumb hypoplasia is considered part of radial deficiency even with normal forearm architecture. Hence, associated anomalies need to be considered during the initial evaluation. The workup must include entities such as VACTERL association, thrombocytopenia–absent radius syndrome, Holt-Oram syndrome, CHARGE (*c*oloboma of the eye, *h*eart defects, *a*tresia of the choanae, *r*etardation of growth and/or development, *g*enital and/or urinary abnormalities, and *e*ar abnormalities and deafness) syndrome, and Fanconi anemia (Table 37.1 and Figure 37.1). An evaluation of all possibly affected organ systems can be life-saving. The workup should include renal ultrasound, echocardiography, spine radiographs, a complete blood count, and a chromosomal challenge test.[76]

Failure to ascertain the diagnosis of an associated syndrome will have lifelong ramifications for the child, family, and physician. This consequence is particularly evident in children with Fanconi anemia that can be diagnosed early with a chromosomal challenge test before the onset of bone marrow failure. Timely diagnosis allows for years of searching for an appropriate bone marrow match that may prevent the child from dying from aplastic anemia. Patients with thumb hypoplasia and other physical findings, specifically café-au-lait spots and short stature, have an increased risk of having Fanconi anemia.[91] Innovative techniques, such as preimplantation genetic determination, allow the parents to have another child with matching blood characteristics and without Fanconi anemia. At birth, the cord blood can be harvested and used as donor blood for the affected Fanconi anemia child. Numerous hand surgeons and pediatricians fail to consider the diagnosis of Fanconi anemia in children with thumb hypoplasia, leaving the child and the family to suffer the consequences of a painful terminal illness that could otherwise have been treated.

General Considerations in Thumb Hypoplasia

Diagnosis

The diagnosis of thumb hypoplasia is dependent on the degree of deficiency and the presence or absence of any associated anomalies. The combination of thumb hypoplasia and profound radial deficiency is typically diagnosed shortly after birth because the infant's forearm is foreshortened and the hand deviated in a radial direction. Substantial thumb hypoplasia is also recognized early in infancy because there is marked asymmetry between the thumbs. In contrast, mild thumb hypoplasia may go unidentified for years, and the patient may not present to the physician until adolescence. This late presentation is often perplexing to the patient and disconcerting to the parents. The parents cannot understand how they failed to recognize the child's hypoplasia before adolescence. They often relate the thumb hypoplasia to some form of recent trauma and question the diagnosis. Our explanation is quite simple: "As one gets older, the activities of daily of life become more complicated, and therefore subtle differences are not recognizable until the child is older." For example, buttoning, keyboarding, and tying shoes are tasks performed as the child becomes older and are not completed during infancy and early childhood. This explanation removes any feeling of fault and allows the family to focus on the treatment to correct the problem.

The diagnosis is based on the physical examination findings and corresponding x-rays. The length, girth, motion, and stability are important parts of the examination. If there is unilateral involvement, the length and girth are usually compared with the thumb on the contralateral side. A thumb of normal length reaches the point just proximal to the proximal interphalangeal (PIP) joint of the adjacent index finger. On x-ray, a normal thumb is approximately 70% as long as the proximal phalanx of the adjacent index finger. The thumb girth and nail width are approximately 133% and 105%, respectively, of the index finger girth and nail width.[30] The overall thumb motion is assessed along with specific movement at the carpometacarpal (CMC), metacarpophalangeal (MCP), and interphalangeal (IP) joints. Similarly, the stability of each of these joints is assessed by clinical examination and stress testing. Instability of the MCP and/or CMC joints is commonly associated with thumb hypoplasia and directly influences the surgical treatment algorithm. An account of present and absent intrinsic and extrinsic muscles is necessary in order to formulate a surgical plan.

TABLE 37.1 Syndromes or Associations With Radial Deficiency

Syndrome or Association	Characteristics
Holt-Oram syndrome	Heart defects, most commonly cardiac septal defects
Thrombocytopenia–absent radius syndrome	Thrombocytopenia present at birth (may require transfusions) but improves over time
VACTERL association	Vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, esophageal atresia, renal defects, radial dysplasia, lower limb abnormalities
Fanconi anemia	Aplastic anemia not present at birth; develops at about 6 years of age
CHARGE syndrome	Coloboma of the eye, heart defects, atresia of the nasal choanae, retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness

FIGURE 37.1 Three year-old child with coloboma of the eyes associated with CHARGE (*c*oloboma of the eye, *h*eart defects, *a*tresia of the choanae, *r*etardation of growth and/or development, *g*enital and/or urinary abnormalities, and *e*ar abnormalities and deafness) syndrome. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Classification

The Blauth classification of thumb hypoplasia truly guides management (Table 37.2).[39,76] Type I hypoplasia is minor generalized hypoplasia usually affecting the thenar muscles. As stated beforehand, this slight degree of hypoplasia may present later in life as hand function becomes more intricate and demanding. Type I thumb hypoplasia may or may not warrant treatment, depending on the functional impact. If the lack of opposition is causing functional difficulties, a tendon transfer is recommended.

Type II hypoplasia has distinct findings that guide treatment (Figure 37.2 and Case Study 37.1). There is absence of the thenar muscles innervated by the recurrent branch of the median nerve (the abductor pollicis brevis, opponens pollicis, and superficial head of the flexor pollicis brevis) (see Figure 37.2, *A*). The deep head of the flexor pollicis brevis, innervated by the ulnar nerve, is usually present, and it provides MCP joint flexion. The MCP is usually unstable, with laxity or incompetency of the ulnar collateral ligament (UCL) (see Figure 37.2, *B*). The MCP joint can also be globally unstable, with incompetency of both the ulnar and radial collateral ligaments. The thumb/index finger or first web space is narrowed and the intervening skin is taut (see Figure 37.2, *C*). The web space can appear to be less narrow because the unstable MCP joint drifts into valgus, masking the narrow web space.

TABLE 37.2 Thumb Deficiency Classification and Treatment Paradigm

Type	Findings	Treatment
I	Minor generalized hypoplasia	No treatment
II	Absence of intrinsic thenar muscles First web space narrowing Ulnar collateral ligament (UCL) insufficiency	Opponensplasty First-web release UCL reconstruction
III	Similar findings as type II plus: Extrinsic muscle and tendon abnormalities Skeletal deficiency A: Stable carpometacarpal joint B: Unstable carpometacarpal joint	A: Reconstruction B: Pollicization
IV	Pouce flottant, or floating thumb	Pollicization
V	Absence	Pollicization

Type III hypoplasia has the same characteristics as type II hypoplasia with the addition of extrinsic muscle and tendon deficiencies. Absence or hypoplasia of the extrinsic extensors (extensor pollicis longus and extensor pollicis brevis) or flexors (flexor pollicis longus) requires an observant examination of the active movement at the MCP and IP joints. Type III hypoplasia is subdivided into types IIIA and IIIB, which is a crucial differentiation in the treatment paradigm. A type IIIA thumb has a stable CMC joint that is worthy of reconstruction and can provide a worthwhile prehensile thumb. A type IIIB thumb has an unstable CMC joint that requires ablation and pollicization. The unstable CMC joint precludes successful reconstruction because the surgery cannot overcome the basal joint instability. A simple explanation to parents is that this effort would be similar to "trying to build a house without a stable foundation." Multiple valiant surgical attempts to reconstruct the CMC joint have yielded inferior results (outcome and function) compared with a successful index finger pollicization.[40,42]

Differentiating between a type IIIA (stable) and a type IIIB (unstable) thumb can be difficult in some cases, but it is fundamental to formulation of a treatment plan. The first metacarpal base and the trapezium do not ossify until about 6 years of age. Therefore, plain radiographs are often unreliable for evaluation of the CMC joint architecture. In a grossly hypoplastic CMC joint, the metacarpal base tapers to a point and the proximal metacarpal is absent (Figure 37.3). However, this plain x-ray finding is not present in milder type III hypoplasia. Advanced imaging studies, such as ultrasound or magnetic resonance imaging (MRI), can be helpful to visualize and evaluate the integrity of the cartilaginous metacarpal base and the trapezium.[76] Repeat examinations, however, may be equally as reliable to detect a thumb unworthy of reconstruction. A child with an unstable CMC joint usually completely ignores the thumb and uses the index finger and long finger for scissor pinch. In addition, the index finger pronates and the long

CASE STUDY 37.1

Andres was a 9-year-old with type II thumb hypoplasia (eFigure 37.1). Thumb reconstruction was planned, using the present CMC and thumb of adequate girth.

The surgical technique is displayed in eFigure 37.2 and Video 37.1. The long-term outcome is shown in eFigure 37.3 and Videos 37.2 and 37.3.

FIGURE 37.4 One year-old with severe type IV thumb hypoplasia (pouce flottant or floating thumb). (Courtesy of Shriners Hospital for Children, Philadelphia.)

finger/index finger web space widens. In these circumstances, thumb reconstruction is contraindicated and index pollicization is preferred.

Type IV hypoplasia represents a profound deficiency known as a *pouce flottant*, or *floating thumb* (Figure 37.4). The thumb remnant is attached to the hand solely by a narrow bridge of skin containing a single neurovascular element. The thumb is floppy and is entirely ignored.

Type V hypoplasia is complete absence of the thumb. On occasion, there will be a small skin nubbin present.

Thumb hypoplasia can also be found in children with ulnar deficiency (Figure 37.5). The treatment for thumb hypoplasia

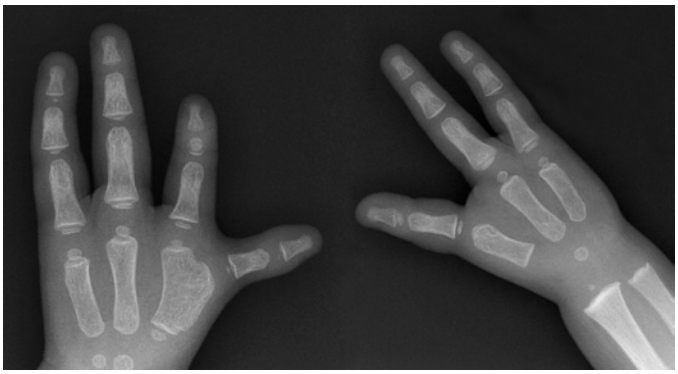

FIGURE 37.5 Radiograph of 4-year-old with bilateral ulnar deficiency and marked left thumb hypoplasia. (Courtesy of Shriners Hospital for Children, Philadelphia.)

in ulnar deficiency and radial deficiency is the same. Pollicization is indicated for marked thumb hypoplasia. The surgical technique for pollicization is similar, with minor modifications, such as skin design.

The standard indications for pollicization can be expanded to include a thumb smaller than a small finger.[40] This decision to ablate the thumb and pollicize the index finger requires a prolonged conversation with the parents about the rationale for this recommendation. Parents generally come to understand that "function trumps form" and that thumb ablation and index finger pollicization will result in a thumb that is more functional than the small, scrawny thumb that may be formed by reconstruction.[22] When in doubt, parents are given a list of other parents who have made a similar difficult decision regarding thumb ablation. This parent-to-parent communication is invaluable.

Treatment for Thumb Hypoplasia

An experienced hand therapist is invaluable in the evaluation of the child with a hypoplastic thumb. Although there is little need for nonoperative management, the hand therapist's input is essential and can provide support for the family and facilitate the decision-making process. Following surgery, the therapist becomes a primary care provider who directly affects the success of the procedure.

The classification schema guides treatment. Type I hypoplasia usually does not warrant surgical intervention, because the functional impairment is negligible. Type II or IIIA hypoplasia diminishes function and often requires surgery to provide stability, improve motion, and enhance function. Type IV or V hypoplasia requires index finger pollicization if the index finger is "suitable" for becoming a thumb. A stiff index finger will be a stiff thumb and may not enhance hand function. Therefore, determining the risk/benefit ratio of pollicization requires ample thought and consideration. The operation should follow the Peter Carter 2-4 rule: For some children, surgery can indeed be done "to" them, but it may not necessarily be "for" them. We have slightly modified the 2-4 rule to state that the operation should be done "to" the patient and "for" the patient.

Thumb Reconstruction

Thumb reconstruction for type II and IIA hypoplasia requires addressing all the deficient elements. The narrowed thumb/index finger web space, MCP instability, and thenar muscle absence all require treatment. Thumb/index finger web space narrowing is treated with skin rearrangement and soft tissue release. A four-flap "Z"-plasty lengthens the tight skin and provides a rounded contour to the web space. The theoretical increase in length is 150%.[9] The deeper soft tissue release includes the investing fascia around the adductor pollicis. The princeps pollicis artery and its branches must be identified and protected before division of the fascia. An extremely tight web space may also require partial release of the adductor muscle and/or first dorsal interosseous muscle to obtain adequate breadth.

MCP instability necessitates stabilization. Unidirectional instability with an incompetent UCL is the most common finding. Ligament reconstruction can be performed with local tissue or preferably the residual length of donor tendon from the opposition transfer. Bidirectional or global instability is more challenging to manage. Reconstruction of both the radial and ulnar collateral ligaments with a tendon graft is an option. MCP joint chondrodesis is preferred, however, to achieve firm stability and provide a stable platform for the opposition transfer to function. The details of MCP joint chondrodesis are discussed in Chapter 39. UCL insufficiency can be secondary to an anomalous connection between the flexor pollicis longus and extensor pollicis longus muscles (i.e., *pollex abductus*).[19,48,83] The pollex abductus attenuates the UCL over time and prevents active thumb IP joint motion. The key to determining its presence is the physical examination prior to surgery. During attempted thumb IP flexion, the MCP joint deviates into valgus rather than bending the IP joint. Surgery must release the pollex abductus when UCL reconstruction is performed.

Thenar absence requires a tendon transfer to provide thumb opposition. There are a variety of donor muscle-tendon units to choose from, including the flexor digitorum superficialis (FDS) (long or ring finger), abductor digiti minimi, extensor carpi ulnaris, and extensor indicis proprius.[69] Each donor muscle-tendon unit has its advocates and its advantages and disadvantages. The long or ring finger FDS is preferred because of its length, power, expendability, and synergism and the technical ease with which it can be used. If the FDS is unavailable, the other donor options are considered.

Flexor Digitorum Superficialis Opponensplasty With Ulnar Collateral Ligament Reconstruction. The patient is placed supine on the operating room table (Box 37.1 and see Videos 37.2 and 37.3). The procedure is usually performed under general anesthesia. A single dose of intravenous preoperative antibiotics is administered. The limb is prepped and draped in sterile fashion. Chlorhexidine gluconate and alcohol prep (ChloraPrep, CareFusion, Leawood, KS) is preferred and may be more effective than Betadine prep in eliminating bacteria.[71] In addition, when chlorhexidine is used, iodine, which can migrate beneath the tourniquet and cause burns, need not be used.

The limb is exsanguinated and the tourniquet is inflated. The incisions are carefully drawn (Figure 37.6). The narrowed thumb/index finger web space is widened via a four-flap "Z"-plasty. Each limb of the "Z"-plasty should be equal in length. The radial limb can be extended in a proximal direction to expose the UCL and the MCP joint. The ring finger FDS tendon is isolated at the base of the finger and in the distal forearm. A short oblique incision is made at the base of the ring finger, and

FIGURE 37.6 Four-flap "Z"-plasty to widen the narrowed thumb/index finger web space. (Courtesy of Shriners Hospital for Children, Philadelphia.)

BOX 37.1 Surgical Steps in Thumb Reconstruction

Limb is exsanguinated and the tourniquet is inflated
Four-flap "Z"-plasty of thumb/index finger web space with release of tight fascia
Ring finger FDS tendon is isolated at base of finger and in distal forearm
Thoracodorsal neurovascular pedicle is isolated
Ring finger FDS tendon pulled through carpal tunnel and into forearm
Radial one half of the distal 2 to 3 cm of FCU tendon made into a loop for the FDS tendon
Ring finger FDS tendon passed through the FCU loop
Skin incision along the radial side of thumb MCP joint
Subcutaneous tunnel is made between the radial side of thumb and the volar forearm FCU loop
FDS tendon is passed under the skin to the radial side of the thumb
Metacarpal head is isolated and a 0.045-inch Kirschner wire drilled across the metacarpal head parallel to the joint surface
Hole is enlarged with a drill bit to allow passage of the FDS tendon
MCP joint is reduced and stabilized with a longitudinal 0.045-inch Kirschner wire drilled antegrade from the tip of the thumb across the MCP joint
FDS tendon is passed through the drill hole to ulnar side of thumb for ligament reconstruction
FDS tendon is sutured to the surrounding bone and periosteum along the radial side of the thumb while setting the appropriate tension in the tendon transfer
FDS tendon is directed to the base of the proximal phalanx and sutured directly into the bone to reconstruct the UCL
Skin is closed with absorbable suture and the limb is immobilized in a long-arm thumb spica cast for 3 weeks

FCU, Flexor carpi ulnaris; *FDS*, flexor digitorum superficialis; *MCP*, metacarpophalangeal; *UCL*, ulnar collateral ligament.

a zigzag or oblique incision is made along the volar ulnar forearm. The flexor carpi ulnaris (FCU) tendon is also isolated. An additional skin incision is made along the radial side of thumb MCP joint to expose the ultimate site for FDS tendon attachment. The FDS tendon is identified at the base of the ring finger and separated from the flexor digitorum profundus (FDP) tendon. The FDS tendon is also isolated in the forearm (Figure 37.7). The FDS tendon is tagged with a suture and cut at the base of the ring finger while the underlying FDP tendon is guarded. An Allis tissue forceps (Jarit, Hawthorne, NY) is placed around the ring finger FDS tendon in the forearm and used to roll the tendon through the carpal tunnel (Figure 37.8). If the FDS tendon fails to roll into the forearm, it must be retrieved into the hand using tag suture. An assessment for FDP and FDS attachments and/or entrapment within the Camper chiasm is performed.

FIGURE 37.7 Ring finger flexor digitorum superficialis tendon is identified at the base of the finger and within the forearm. (Courtesy of Shriners Hospital for Children, Philadelphia.)

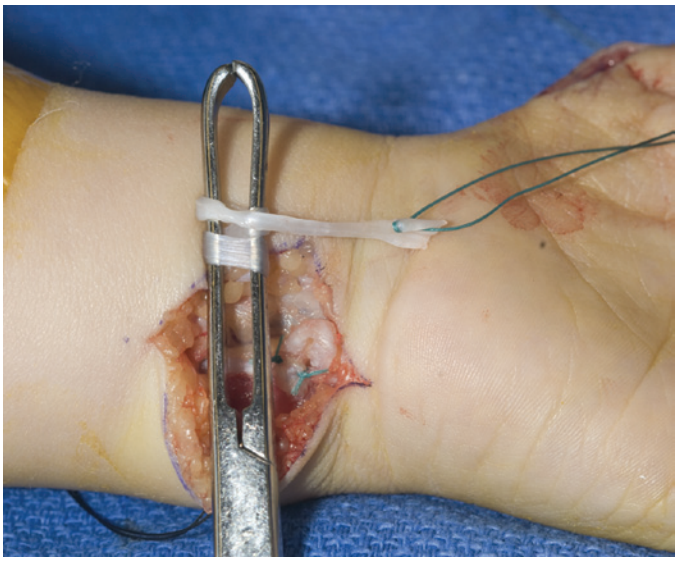

FIGURE 37.8 Ring finger flexor digitorum superficialis tendon rolled into volar forearm incision. (Courtesy of Shriners Hospital for Children, Philadelphia.)

An FCU tendon loop is constructed as a pulley for the FDS tendon. The distal 2 to 3 cm of FCU tendon is isolated. The radial half of the FCU tendon is harvested, preserving its distal attachment into the pisiform (Figure 37.9). The radial half of the tendon is passed through the retained FCU at the pisiform and sutured to form a loop. The ring finger FDS tendon is

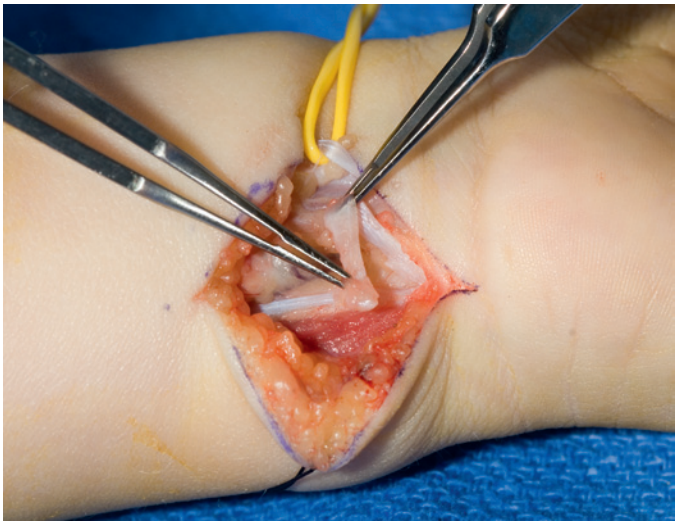

FIGURE 37.9 One half of the distal 2 to 3 cm of the flexor carpi ulnaris tendon is used to construct a pulley for the flexor digitorum superficialis tendon. (Courtesy of Shriners Hospital for Children, Philadelphia.)

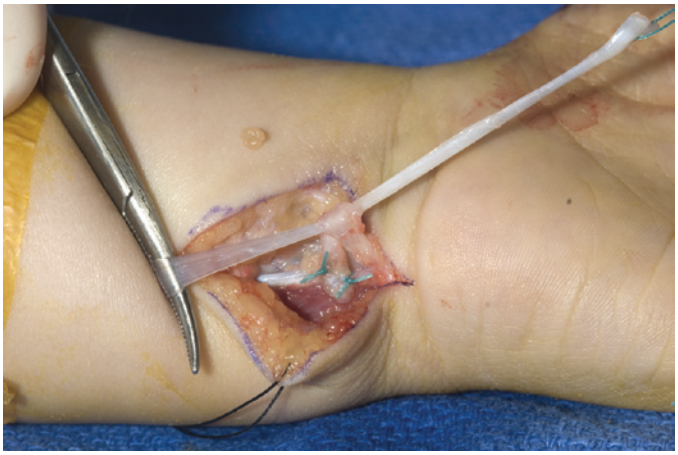

FIGURE 37.10 Ring finger flexor digitorum superficialis tendon is passed through the flexor carpi ulnaris loop. (Courtesy of Shriners Hospital for Children, Philadelphia.)

passed through the FCU loop prior to transfer across the palm (Figure 37.10).

A subcutaneous tunnel is made between the radial side of thumb and the volar forearm incision for channeling the ring finger FDS tendon. The FDS tendon is passed under the skin to the radial side of the thumb (Figure 37.11). The metacarpal head is isolated and a 0.045-inch Kirschner wire drilled across the metacarpal head parallel to the joint surface (Figure 37.12). Minifluoroscopy ensures appropriate Kirschner wire positioning. The hole is enlarged with a drill bit to allow passage of the FDS tendon. The MCP joint is reduced and stabilized with a longitudinal 0.045-inch Kirschner wire drilled antegrade from the tip of the thumb across the MCP joint. The wire is cut short and a Jurgan pin ball (Jurgan Development and Manufacturing, Madison, WI) applied. The FDS tendon is passed through the drill hole to the ulnar side of the thumb for ligament reconstruction (Figure 37.13). If the diameter of the tendon is too large, one slip of the FDS can be removed.

FIGURE 37.11 The flexor digitorum superficialis tendon is passed through the subcutaneous tunnel to the radial side of the thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 37.14 Flexor digitorum superficialis tendon is used to reconstruct the ulnar collateral ligament. Note longitudinal Kirschner wire exiting tip of the thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

At this point, the wrist is placed into slight extension and the FDS tendon tensioned until the thumb is positioned in opposition. Tenodesis is used to assess tension, and after correct tension is achieved, the FDS tendon is sutured to the surrounding bone and periosteum along the radial side of the thumb. This maneuver sets the tension in the opposition tendon transfer. Typically, the tendon can be seen tenting the skin when the wrist is placed into extension. The remaining FDS tendon that had been passed through the metacarpal head is used to reconstruct the UCL. The FDS tendon is directed to the base of the proximal phalanx and sutured directly into the bone. Usually, the FDS tendon is long enough that it can be passed back onto itself to complete a double-stranded repair (Figure 37.14).

The skin is closed with absorbable suture and the limb is immobilized in a long-arm thumb spica cast for 3 weeks. The Kirschner wire is removed and a short-arm thumb spica splint is fabricated. Active motion and therapy are initiated. Protective splinting of the thumb is continued until 3 months after surgery.

Pollicization

Pollicization is indicated for types IIIB, IV, or V hypoplasia. The technique is similar for each type, with subtle variations depending upon whether a hypoplastic thumb is present or absent. In type IIIB hypoplasia, vascularized fat from the ablated thumb can be used to augment the first web space or thenar eminence.[76,84] In type IV or V hypoplasia, this option is unavailable.

Pollicization Procedure. The current technique of pollicization represents a consolidation of contributions from surgeons over the past 100 years (Box 37.2, Case Study 37.2, and see Video 37.4).[40,49] Following general anesthesia, the child is placed in the supine position. Preoperative antibiotics are routinely administered. The extremity is prepped and draped in sterile fashion. A sterile pediatric tourniquet (Delfi Medical Innovations, Vancouver, Canada) is placed on the upper arm. Exsanguination should be gentle so that some filling of the digital vessels can be maintained in order to facilitate visualization.

BOX 37.2 Surgical Steps in Pollicization

Limb is gently exsanguinated and the tourniquet is inflated
- Skin incision proposed by Ezaki and Carter
- Palmar skin is incised and the radial neurovascular bundle is isolated
- Dissection proceeds in an ulnar direction to identify the common digital vessels to the index finger/long finger web space
- Proper digital nerves to the ulnar side of the index finger and the radial side of the long finger are isolated
- Proper digital artery to the long finger is ligated with a ligature clip
- First annular pulley of the index finger is incised
- Divide intermetacarpal ligament between index finger and long finger
- Dorsal skin incision is sharply elevated with preservation of dorsal veins
- The first dorsal and palmar interossei muscles are released with a portion of the hood
- Metacarpal index finger is shortened by a saw cut at the metaphyseal flare and a knife cut through the physis leading to an epiphysiodesis
- Index metacarpophalangeal joint is fixed into hyperextension using nonabsorbable suture material passed through the epiphysis and dorsal capsule
- Kirschner wire drilled antegrade through the metacarpal epiphysis, into the proximal phalanx, and out the proximal interphalangeal joint
- Kirschner wire used as a joystick to align the index metacarpal into 45 degrees of abduction and 100 to 120 degrees of pronation
- Kirschner wire is drilled retrograde across the metacarpal base into the carpus
- Transfer the first dorsal interosseous to the radial lateral band and the first palmar interosseous to the ulnar lateral band about the PIP joint
- Skin is closed with absorbable suture with resection of any redundant skin and Kirschner wire is cut short

The skin incision must allow index finger transposition and reconstruction of an abundant thumb/index finger web space. The skin incision proposed by Marybeth Ezaki and Peter Carter is used because it allows more glabrous skin to be placed along the palmar aspect of the index finger (Figure 37.15).[39] The palmar skin is incised first, and the radial neurovascular bundle is isolated, although the artery can be extremely small. In children with type IIIB or IV hypoplasia, the single vessel to the hypoplastic thumb can be traced to the radial neurovascular bundle of the index finger to ease identification (Figure 37.16). The dissection next proceeds in an ulnar direction to identify the common digital vessels to the index finger/long finger web space (Figure 37.17). The proper digital nerves to the ulnar side of the index finger and the radial side of the long finger are isolated. Proximal nerve microdissection is required to further separate the proper digital nerves prior to pollicization. On occasion, as the dissection of the digital nerve proceeds in a proximal direction, one will encounter a neural loop that encircles the artery. This loop must be addressed to prevent constriction of the artery during index finger transposition. The loop can be widened to avoid arterial compression or the smaller of the two nooses can be cut. The proper digital artery to the long finger is ligated with a ligature clip (Figure 37.18). This allows tension-free index finger pollicization vascularized by the radial digital artery and the common digital artery to the index finger/long finger web space. The ligature clip acts as a visual reminder of the location of the proper digital artery.

The first annular pulley of the index finger is incised to prevent buckling of the flexor tendons after index finger

CASE STUDY 37.2 Pollicization

Emma is a 4-year-old with ulnar deficiency and marked left thumb hypoplasia (eFigure 37.4). Treatment included bone and joint reorganization and muscle reorganization:

Bone and joint reorganization:

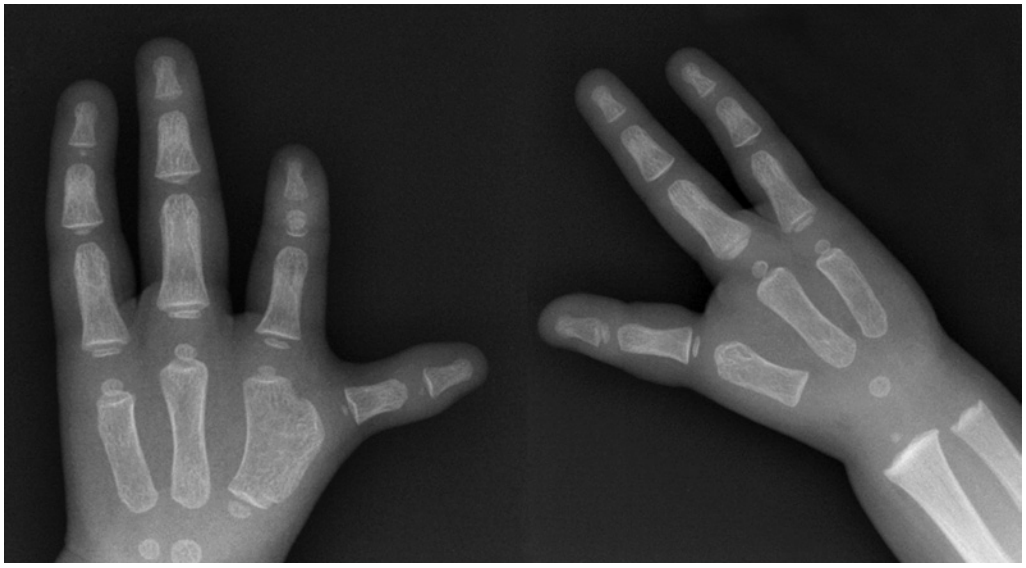
- DIP joint → IP joint
- PIP joint → MCP joint
- MCP joint → CMC joint
- Metacarpal → Trapezium

Muscle reorganization:

- First PI → adductor pollicis
- First DI → abductor pollicis brevis
- Extensor indicis proprius → extensor pollicis longus
- Extensor digitorum communis → abductor pollicis longus

The surgical procedure is demonstrated in Video 37.4 and eFigure 37.5.

The challenging rehabilitation required communication and experience (eFigure 37.6), but a successful outcome was achieved (eFigure 37.7 and Video 37.5).



eFIGURE 37.4 Left thumb hypoplasia. (Courtesy of Shriners Hospital for Children, Philadelphia.)

shortening (Figure 37.19). The intermetacarpal ligament is also divided (Figure 37.20). The dorsal skin incision is sharply elevated with preservation of as many dorsal veins as possible. The extensor or flexor tendons are not shortened, because these musculotendinous structures adapt over time.

The first dorsal and palmar interosseous muscles are dissected to their attachments into the extensor hood (Figures 37.21 and 37.22). The interosseous muscles and tendons are released with a portion of the hood in expectation of transfer. The tendons must be carefully dissected from the MCP joint collateral ligaments to avoid entering the joint. The neurovascular bundles must also be shielded during elevation of the interossei. Prior to cutting the metacarpal, the eventual insertion sites for the tendon transfers are identified and tagged within the extensor mechanism over the PIP joint. This facilitates later transfer of the first dorsal and first palmar tendons into the radial and ulnar lateral bands, respectively.

The index finger must be shortened. The distal cut is made directly through the physis using a knife (Figure 37.23). This

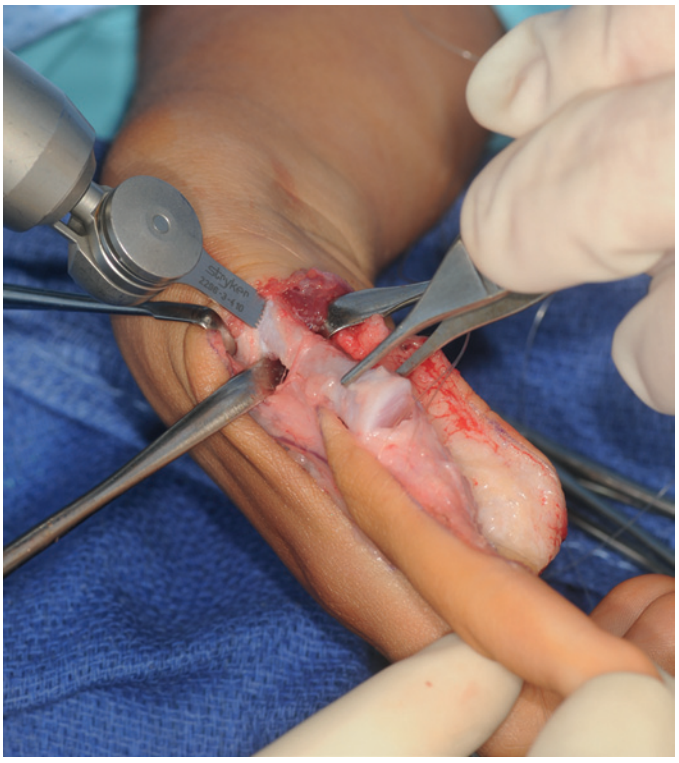

FIGURE 37.24 Fine-bladed saw is used to cut the metacarpal base through the metaphyseal flare in the plane of the intended thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

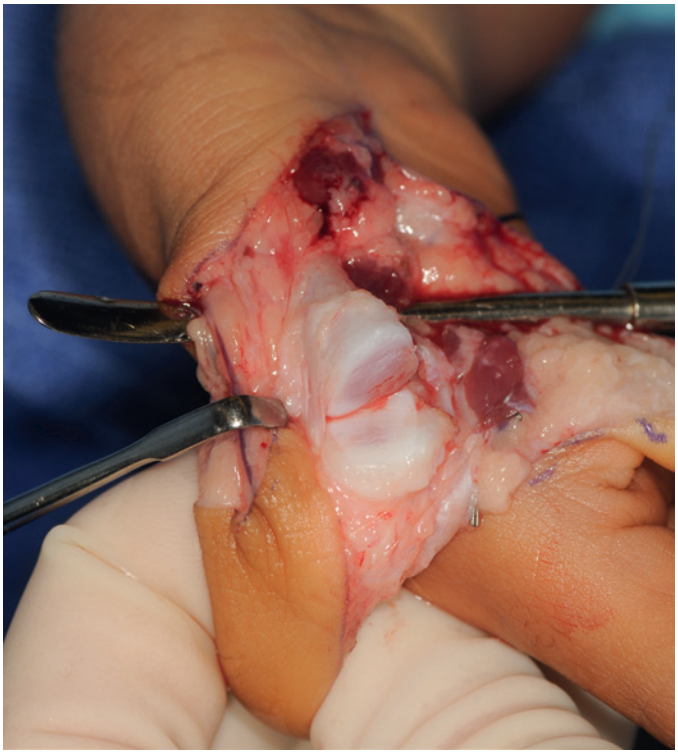

FIGURE 37.23 Distal metacarpal cut directly through the physis. (Courtesy of Shriners Hospital for Children, Philadelphia.)

physeal cut leads to growth plate ablation (epiphysiodesis) to prevent unwanted growth of the index metacarpal. A fine-bladed saw is used to cut the metacarpal base through the metaphyseal flare in the plane of the intended thumb (Figure 37.24). The index metacarpal bone is removed from its base to the epiphysis (Figure 37.25). A rongeur is used to widen the base by opening or pedaling the surrounding cortex to promote healing (Figure 37.26).

The normal index MCP joint hyperextends and the normal thumb CMC joint does not hyperextend. To correct this discrepancy, the index MCP joint is fixed into hyperextension, placing the remaining metacarpal head into flexion (Figure 37.27). This is achieved by suturing the MCP joint into hyperextension using a suture material passed through the epiphysis and dorsal capsule. Subsequently, a Kirschner wire is placed through the metacarpal epiphysis or the base of the proximal phalanx (Figure 37.28). The Kirschner wire is drilled through the proximal phalanx and out the PIP joint (Figure 37.29). This Kirschner wire is used as a joystick to facilitate index finger positioning (Figure 37.30). Interosseous sutures are rarely used to augment fixation. The index finger metacarpal epiphysis is aligned anterior to its metaphyseal base with meticulous positioning into 45 degrees of abduction and 100 to 120 degrees of pronation (Figure 37.31). Once the position is deemed satisfactory, the Kirschner wire is drilled retrograde across the metacarpal base into the carpus. The Kirschner wire is cut short and a Jurgan pin ball is applied. Further stability is achieved via tendon transfer of the first dorsal interosseous to the radial lateral band and the first palmar interosseous to the ulnar lateral band about the PIP joint (Figure 37.32). The skin is judiciously

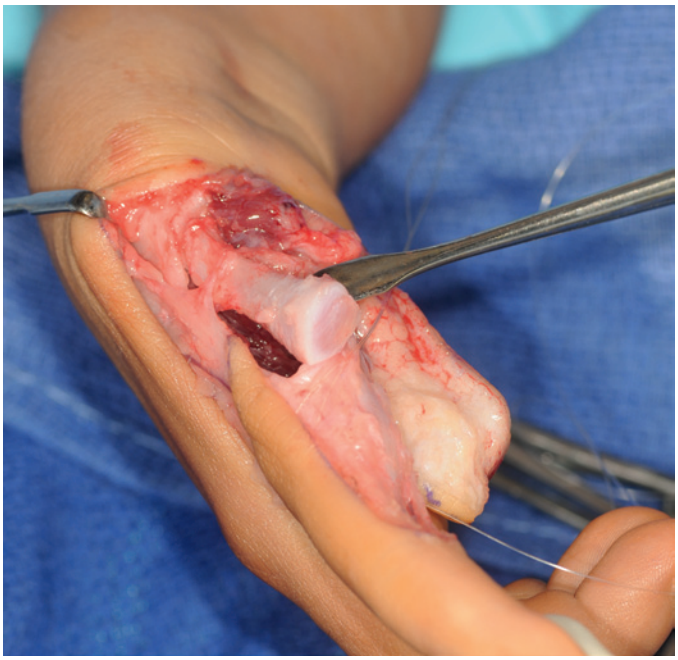

FIGURE 37.25 The index metacarpal bone is removed from its base to the epiphysis. (Courtesy of Shriners Hospital for Children, Philadelphia.)

inset with absorbable suture. Any redundant skin is excised (Figure 37.33). Whenever possible, the first web space suture line is advanced dorsally to minimize any suture line within the commissure (Figure 37.34). The tourniquet is deflated and the "thumb" observed for 5 minutes. The arterial circulation typically returns rapidly, although vasospasm can result. Time,

FIGURE 37.27 The index metacarpophalangeal joint is fixed into hyperextension, placing the remaining metacarpal head into flexion. (Courtesy of Shriners Hospital for Children, Philadelphia.)

warm soaks, and patience routinely lead to resolution. Persistent lack of blood inflow requires exploration for arterial spasm that can resolve with lidocaine, arterial kinking, or iatrogenic injury. Venous congestion is a more common problem that requires reapplication of a looser dressing and/or release of any taut sutures.

Once adequate arterial ingress and venous egress has been established, the postoperative dressings are applied. Adequate fluffy dressings are necessary to equalize the anterior-posterior and medial-lateral dimensions of the hand. This allows uniform compression without constriction. A long-arm soft cast (Scotchcast Soft Cast Casting Tape, 3M, St. Paul, MN) is applied with the elbow flexed to more than 100 degrees and a substantial supracondylar mold to decrease the chance of unintended removal. This fiberglass casting tape can be unwrapped in the clinic, avoiding the frightening cast saw. The child is admitted overnight with the arm elevated to promote venous drainage. The thumb can be covered the next day if vascularity has been maintained throughout.

The Kirschner wire is removed 4 weeks after surgery and a short-arm thumb spica splint is fabricated. Occupational therapy is started with an emphasis on thumb usage. The initial goal is large object acquisition followed by acquisition of smaller objects and eventually fine pinch. Standard wound care is also performed consisting of scar massage and softening techniques. Active motion and therapy are initiated. Protective splinting of the thumb is continued until 3 months after surgery.

Outcome

Thumb Reconstruction. The results for thumb reconstruction for type II or IIIA hypoplasia are difficult to decipher because

comparison among studies is confounded by the heterogeneity of the patient populations, severity of the hypoplasia, and reconstructive techniques used. If the surgical plan for reconstruction has addressed each deficient component of the thumb, the function following reconstruction is usually good compared with the function present before surgery, regardless of the outcome measure employed (Figure 37.35).[41] Some degree of MCP joint stiffness is inevitable after ligament reconstruction, however; this stiffness has little impact on functional outcome as long as the IP and CMC joints are supple.

The results of tendon transfers, bone lengthening, and joint stabilizations for higher-grade hypoplastic thumbs are poor compared with the results of pollicization.[2] Children who require a five-digit hand for cultural reasons may gain some benefit from these procedures as long as the family has realistic expectations.

Pollicization. The results after pollicization depend mainly on the preoperative status of the index finger and surrounding musculature. Index finger pollicization provides better functional and aesthetic results in isolated thumb hypoplasia than it does in patients with an associated hypoplastic or absent radius. A mobile index finger moved to the thumb provides stability for grasp and agility for fine pinch (Figure 37.36).[42] Parents are extremely grateful and amazed at the results, often providing moving testimonials (see Video 37.5). In contrast, a stiff index finger in the thumb position provides a stable thumb

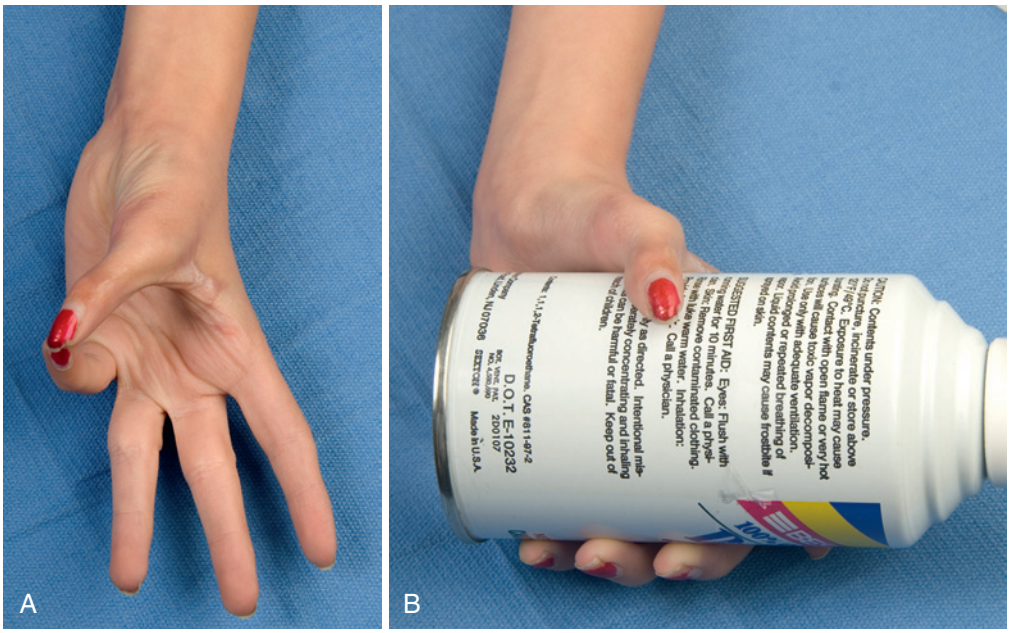

FIGURE 37.35 Ten-year-old child following left flexor digitorum superficialis tendon opposition transfer. **A,** Excellent opposition to the small finger. **B,** Improved ability to acquire large objects. (Courtesy of Shriners Hospital for Children, Philadelphia.)

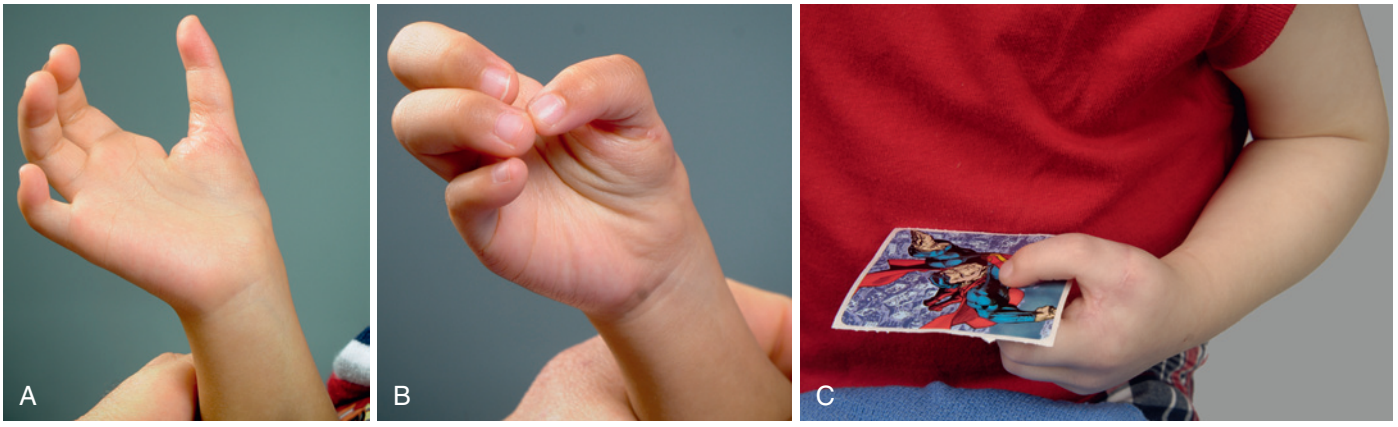

FIGURE 37.36 Three-year-old following index finger pollicization. **A,** Overall appearance. **B,** Movement pattern. **C,** Pinching a sticker. (Courtesy of Shriners Hospital for Children, Philadelphia.)

post for gross grasp but is unlikely to participate in fine pinch. Scissoring of adjacent digits is usually preferred for fine pinch in these cases. A pollicization that is stiff, weak, poorly positioned, and/or unstable will be bypassed in favor of the scissor pinch between adjacent long and ring fingers.

A recent study correlated the primary caretaker's subjective impressions of outcome to objective measures and found that children who had difficulty peeling a sticker from its backing tended to scissor pinch between the long and ring fingers and ignored the thumb for small object manipulation. In these children, the new thumb IP and MCP motion was poor.[98]

Children with a preoperative ulnar-sided grasp pattern secondary to perfect ulnar digit(s) finger mobility and stiff radial digits (often seen in patients with radial longitudinal deficiencies) will maintain their ulnar-sided grasp after pollicization and ignore the new thumb. Patients with mirror hands or five-fingered hands tend to have suboptimal results as well, although the reasons are unclear. One reason may be that the pollicized digit in these patients is more akin to a long finger than an index finger and may therefore lack the same independence of function or cortical representation.

The results of pollicization continue into adulthood, with long-term studies showing sustained functional use of the thumb.[10] In the majority of cases where the child used the index finger as a thumb prior to surgery, pollicization results in good to near-normal hand function in the long term. With no associated conditions that could lessen the outcome, the child can expect about one third of the strength of an unaffected thumb. Large object manipulation is typically better than small object manipulation, but overall, approximately 95% of patients integrate the thumb into daily tasks.[39] The objective and aesthetic outcomes following pollicization have been compared with those of normal thumbs.[29] Generally, the thumb created by pollicization was slightly longer than normal and

smaller in girth. The most frequently cited negative perceptions of the thumb were decreased girth, excessive length, and angulation.

Timing of the surgery has not been demonstrated to affect functional outcomes, although most clinicians feel that operations done in younger patients better take advantage of cortical plasticity. Others have argued that social factors should be the impetus for surgery because the index finger already has cortical representation as a thumb and timing is less important. Pollicization simply makes the index finger appear and work more like a true thumb.[39]

Cortical plasticity and motor relearning are hypothesized to play a critical role in functional development following pollicization. There is a large region of the sensorimotor cortex homunculus dedicated to the hand, and much of it is devoted to the thumb. Researchers are deciphering and understanding the changes in the sensorimotor cortex following injury, repair, and reconstruction.[3] Techniques include transcranial magnetic stimulation, electroencephalography, magnetoencephalography, functional MRI, structural MRI, and positron emission tomography.[23,26,28] Human cortical plasticity is a complex process that involves the unveiling of formerly quiescent connections and sprouting of active afferents from nearby cortical and/or subcortical regions.

Following hand transplantation, the original sensorimotor cortex map for hand activation is reestablished.[50] The transplantation reverses the sensorimotor cortex loss that followed the hand amputation. Similarly, successful toe transfer to the hand produces temporal activation within the sensorimotor cortex consistent with cortical plasticity.[50] Functional MRI has confirmed that when a patient learns to use the toe transfer there is an enlargement in the motor cortical representation. Practice amplifies the changes within the sensorimotor cortex. As the new motor skill is mastered, there is an ensuing decrease in the amount of cortical representation.[3,50] The precise effects of pollicization have yet to be studied, however; similar sensorimotor cortex changes are likely. Undoubtedly, essential alterations must occur in the sensorimotor cortex as the index finger becomes a thumb.

Another factor to consider when deciding on the timing of surgery is the size of the hand. Although the precise best age at which to perform surgery is unknown, the advantages of early surgery are lessened by the anatomic size of the neurovascular and musculocutaneous structures. Pollicization at about 1 to 2 years of age allows some hand growth and still takes advantage of infant and toddler brain plasticity. Late presentation is not a contraindication for pollicization, however; the adolescent likely has less brain plasticity and is often astounded about the change in his or her hand. Preoperative discussion and review of pictures is mandatory to lessen the astonishment following the initial dressing removal.

Complications

Pollicization is a complex procedure with a host of big and small complications. Acute complications are related to vascular compromise. Arterial insufficiency results in failure of the thumb to "pink up" despite time, patience, and warm soaks. Immediate exploration is necessary for arterial kinking or injury. The principal problem needs to be rectified to preserve the arterial inflow into the thumb. The second vascular problem involves venous egress as the thumb turns blue. Rectification requires a series of steps, including loosening of the dressings or release of taut sutures. Subsequently, strict elevation is necessary to promote venous drainage. Loss of the index finger due to vascular compromise after pollicization is rare, with an estimated incidence of 0.2% when a skilled surgeon has performed the operation.[40]

Long-term complications are related to scarring, stiffness, bony problems, and limited motion (Table 37.3). First web space scarring and cicatrix require therapeutic modalities, such as silicone elastomer and massage. Dense recalcitrant scarring requires additional surgery to resurface the web space. Stiffness may be inherent in the index finger prior to pollicization and may not be amenable to treatment. Iatrogenic stiffness related to the surgery requires therapy to mobilize the thumb. Persistent stiffness may have a surgical solution, such as tendinous adhesions. Careful examination is necessary to determine the underlying cause. Bony problems can be related to joint instability, poor thumb positioning, or excessive thumb length. CMC joint instability is uncommon even with a fibrous union. Symptomatic instability, however, warrants revision surgery. A thumb positioned in excessive supination or pronation requires osteotomy and repositioning (Figure 37.37). A long thumb attributed to ongoing growth at the metacarpal physis requires epiphysiodesis and possible metacarpal shortening (Figure 37.38). Limited active motion in the presence of satisfactory passive motion is amenable to tendon transfer, such as an opposition transfer.

TABLE 37.3 Pollicization Pitfalls and Complications

Complication	Causes	Management
First web space contracture	Insufficient web space reconstruction, loss of skin flap, scar formation	Therapeutic modalities Revision web space deepening via "Z"-plasty or dorsal rotational flap
Stiffness	May be attributed to preoperative condition of index finger or secondary to scarring related to surgery	Therapy; inherent stiffness not correctable; surgical adhesions can be treated by tenolysis
Excessive length	Failure to ablate index metacarpal growth plate	Epiphysiodesis and/or ostectomy of metacarpal
Malrotation	Technical error (underrotation or overrotation) or loss of fixation during postoperative care	Rotational osteotomy
Lack of opposition	Primary deficiency in intrinsic muscles or inability to reconstruct interossei	Opposition tendon transfer

FIGURE 37.37 Overrotation of the index finger can result in a thumb that is poorly aligned for pinch. (Courtesy of Shriners Hospital for Children, Philadelphia.)

CRITICAL POINTS *Thumb Hypoplasia*

- Thumb hypoplasia occurs in varying grades and is part of radial deficiency. Therefore, appropriate workup for associated anomalies is necessary.
- The underdeveloped thumb has been classified into five types that guide treatment. The presence or absence of a stable CMC joint is the pivotal factor of retention and reconstruction versus ablation and pollicization.
- Pollicization is the procedure of choice for types IIIB, IV, and V hypoplasias. Attempts at microsurgical joint transfer to restore the CMC joint in types IIIB and IV hypoplasias have been reported; however, the results appear mediocre compared with those of index finger pollicization.
- Pollicization requires a carefully designed skin incision and meticulous surgical technique following the steps outlined in the text. The neurovascular anatomy must be dissected with ligation of the radial digital artery to the thumb. The index finger metacarpal is removed from the physis to its base. The thumb is carefully positioned and the intrinsic muscles (abductor pollicis brevis and adductor pollicis) are reconstructed with the first dorsal interosseous and first palmar interosseous, respectively.
- Results after pollicization are related to numerous factors, including the status of the index digit, the surgical technique, and the ability to restore intrinsic muscle function. Early good results in childhood persist into adulthood.

THUMB DUPLICATION

General Considerations in Thumb Duplication

Epidemiologic Findings

Polydactyly can occur on the preaxial (radial) and postaxial (ulnar) sides of the limb. Preaxial polydactyly is more common in Caucasians, and postaxial polydactyly is more frequent in African-Americans.[18,90] Preaxial polydactyly is also documented in high proportions in Native Americans and many Asian populations.[32,45] Even though preaxial thumb duplication demonstrates a racial predilection toward Caucasian children, most cases are unilateral, sporadic, and without systemic problems.[18]

TABLE 37.4 Classification of Duplicated Thumbs

Type	Duplicated Elements
I	Bifid distal phalanx
II	Duplicated distal phalanx
III	Bifid proximal phalanx
IV	Duplicated proximal phalanx*
V	Bifid metacarpal phalanx
VI	Duplicated metacarpal phalanx
VII	Triphalangeal component

*Most common type.

Classification

Thumb duplication has been classified in various ways based on the degree of skeletal replication (Table 37.4).[88] In the Wassel classification, the extent of duplication is defined and indexed according to whether the components are attached proximally (bifid) or completely separated (duplicated). The most common type is duplicated proximal and distal phalanges that share a common articulation with a bifid metacarpal head (≈50% of cases).[1,18,88] Various adaptations and modifications have been added to this scheme, but the basic premise remains unchanged.[35,67,95] There are some types of thumb duplications that defy classification.

Clinical Features

The diagnosis of thumb duplication is usually straightforward, especially in type IV duplication (Figure 37.39, *A* and *B*). A subtle type I or II duplication, however, may not be readily apparent on physical examination and is only diagnosed by widening of the nail plate (Figure 37.40). The parents are questioned regarding family members with extra digits, as a positive family history may be present. X-rays are routinely obtained and assist in defining the extent of duplication. However, surgical exploration may reveal a cartilaginous connection that is not visualized by x-ray. This operative finding reclassifies a type II thumb to a type I and a type IV thumb to a type III. The surgeon needs to be aware of this possible surgical finding, which may alter the operative plan.

The initial examination includes observation of thumb usage, palpation of the bony elements, and assessment of joint stability. Passive motion, varus/valgus stress testing of the joints, palpation of tendons (especially flexor tendons), and observation of the skin crease may be helpful. Little or absent passive motion at the bifurcation site of the minor thumb (most radial one) suggests an odd-numbered Wassel type I, III, or V. One of the duplicated elements is usually dominant and preferred for prehension. Serial examinations can be performed because the need for treatment is not urgent. Surgery is usually performed

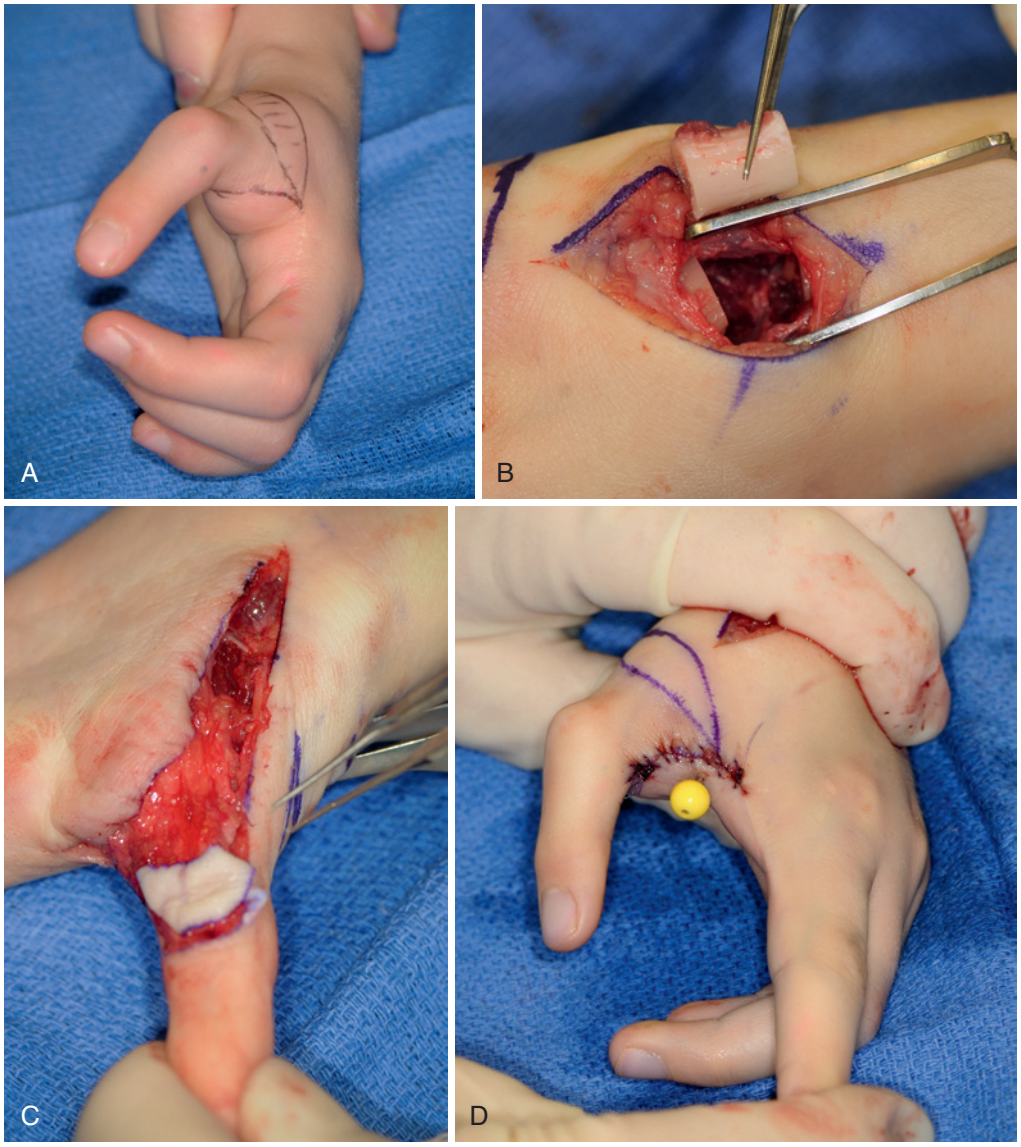

FIGURE 37.38 Six-year-old with a long thumb attributed to ongoing growth at the metacarpal physis. **A,** Clinical appearance of elongated thumb. **B,** Bony resection and epiphysiodesis. **C,** Skin reduction. **D,** Final appearance. (Courtesy of Shriners Hospital for Children, Philadelphia.)

at about 1 year of age, prior to the development of thumb/index finger pinch.

Several investigators have noted that the thumb is not truly duplicated.[18,20,46] Neither component is as robust as a normal thumb. Each thumb is thinner than normal and has diminished mobility. The term *split thumb* seems more appropriate.[18,20] This terminology also makes parents aware that the reconstructed thumb may be smaller in girth after surgery. However, the length of the reconstructed thumb will be similar to that of the other side. The split parts may share bony elements, tendons, ligaments, joints, neurovascular structures, and nails. The surgical goal is to create the best thumb possible using portions of each component to construct a properly aligned and functional thumb, so-called spare parts surgery.[14,18] The ideal reconstruction aligns the thumb along a longitudinal axis, stabilizes the joints, balances the motor functions, provides an adequate nail plate without deformity, and restores sufficient thumb size.[14,18,46,54,64] Reconstruction or preservation of the collateral ligaments is critical for duplications that arise from the joint surface (Wassel II, IV, and VI).

Treatment of Thumb Duplication

Type I or II Split Thumbs

Treatment of type I or II split thumbs depends on the extent and size of each duplicated part. A subtle type I or II duplication that has a common nail and is well aligned does not require treatment (see Figure 37.40). Asymmetric type I or II duplication with distinct components is treated by ablation of the smaller thumb, with transfer of the collateral ligament and centralization of the extensor tendon (Figure 37.41). The skin incision is designed to ensure adequate soft tissue coverage of the retained component. Inadequate soft tissue along the side of the retained thumb (e.g., pulp tissue) can be supplanted with a flap from the deleted component. This will augment the girth and width of the retained thumb and make it comparable to that of the uninvolved side. Proximal exposure is obtained by a zigzag

approach. The extensor tendon to the lesser component is removed with the digit. The remaining tendon is centralized along the retained component. The tendon can be detached and reattached in the midline, or the eccentric portion can be folded over to the midline.[14,18] The flexor tendon(s) are treated in a similar fashion; however, exposure of the retained flexor system is more limited. The collateral ligament from the deleted component is elevated with an osteoperiosteal sleeve and attached via periosteal suture to the reconstructed thumb (Figure 37.42).[51] The IP joint is inspected any for articular anomalies, such as a separate facet for the deleted component. This facet is removed with an osteotome, rongeur, or bone-biter to narrow the articular surface and properly align the joint with the retained component. The neurovascular bundles are preserved to ensure circulation and sensation to the thumb. Additional extraarticular malalignment may require corrective osteotomy

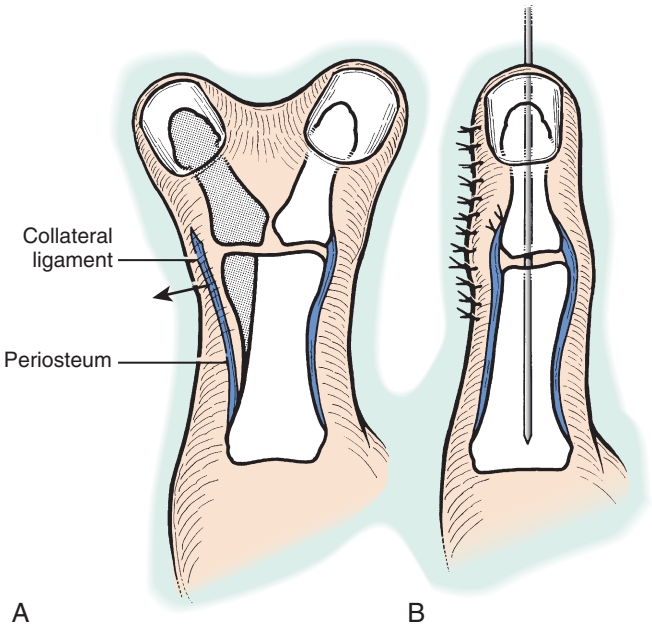

FIGURE 37.42 **A** and **B,** Angular deformity of the residual digit may be corrected by shifting the digit on a smooth common articular surface and creating a snug collateral ligament repair.

to ensure longitudinal alignment of the thumb (see Wassel VII case for details). This realignment is done using a closing wedge osteotomy with a scalpel blade or bone cutter to align the IP joint perpendicular to the thumb axis. A percutaneous Kirschner wire is placed antegrade from the thumb tip across the IP joint. If an osteotomy is performed, this wire also crosses the osteotomy site. The incision is closed with absorbable sutures, and a long-arm thumb spica cast is applied. The cast and Kirschner wire are removed 4 to 5 weeks after surgery. A short-arm thumb spica splint is fabricated; it is removed for therapy and gentle activities. The splint is discontinued 8 to 12 weeks after surgery, depending on the specific procedure performed and aggressiveness of the child.

Symmetric thumb duplication is difficult to treat. Wedge resection of the central portions of the bone and nail from each component and approximation of the retained borders can be performed (Bilhaut-Cloquet procedure) (Figure 37.43). The epiphyses are usually not included in the wedge for fear of growth plate injury. The retained bone is coapted and secured with suture or transverse Kirschner wire fixation. This operation is difficult, and subsequent nail deformity and IP joint stiffness are common problems.[17,82] Baek and colleagues[4] have utilized a modified Bilhaut-Cloquet technique for Wassel type II and III thumbs, for bifid thumbs are symmetric and the nail size is less than two thirds of the contralateral thumb. This technique is extraarticular and preserves a single physis while combining the nail and underlying bone into a single structure (Figure 37.44). In a type III thumb, the distal components are combined in a similar fashion with removal of the redundant proximal phalanx.

Type III or IV Split Thumbs

Type III or IV duplication is treated with selection of a dominant thumb and ablation of the lesser counterpart (Figure 37.45). This decision is not always straightforward and requires careful examination. If the components are equal, the ulnar thumb is preserved to retain the UCL for pinch. The soft tissue(s) from the ablated thumb are used to augment the retained thumb. The skin incision is designed to ensure adequate soft tissue coverage of the retained component. Inadequate soft tissue along the side of the retained thumb (e.g., pulp tissue) and eponychial fold can be addressed with a flap from the deleted component (Figure 37.46, *A* and *B*). This will augment the girth and width of the retained thumb and make it comparable to that of the uninvolved side (Figure 37.47).

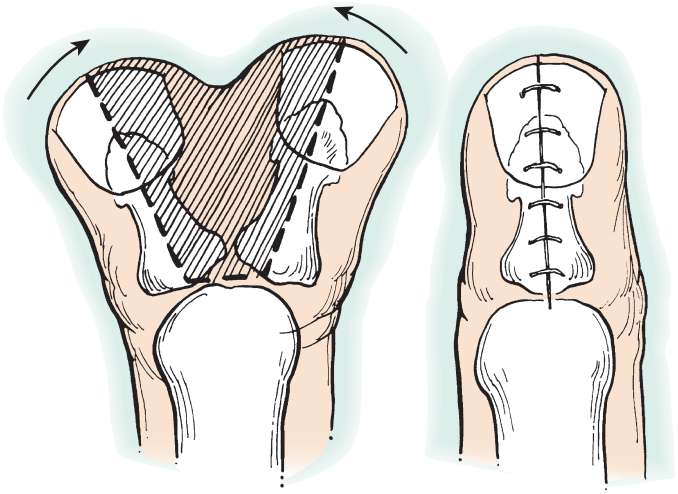

FIGURE 37.43 The classic Bilhaut-Cloquet procedure, in which the lateral portions of two distal phalanges are joined in the midline after excision of the excess central soft and osseous tissues.

FIGURE 37.48 An osteoperiosteal sleeve is raised from the deleted thumb with the collateral ligament and eventually transferred to the reconstructed thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 37.49 Removal of the radial thumb after complete dissection. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Proximal exposure is obtained by a zigzag approach. The collateral ligament is retained with an osteoperiosteal sleeve from the deleted thumb and transferred to the preserved thumb (Figure 37.48).[18,51] After separation from the ulnar or dominant thumb, the radial or lesser thumb is removed (Figure 37.49). In a type IV thumb, the joint surface of the metacarpal is routinely inspected for a separate facet that articulates with the deleted component. Removal of this facet with preservation of the collateral ligament via a proximal osteoperiosteal sleeve is necessary (Figure 37.50). This articular modification correctly aligns the thumb and prevents progressive angulatory deformity. Additional extraarticular malalignment may require corrective osteotomy to ensure longitudinal alignment of the thumb. This realignment can been done using a closing wedge osteotomy to align the joint surfaces in a parallel manner. Tendon realignment is also necessary to centralize the tendons along the retained thumb. Any thenar intrinsic muscles that are attached to the deleted thumb are transferred to the retained thumb. Typically, the abductor pollicis brevis inserts into the radial thumb and must be detached with an osteoperiosteal sleeve along with the radial collateral ligament (Figure 37.51). This composite is reattached to the retained ulnar thumb via periosteal suture to restore joint stability and abductor function (Figure 37.52, *A* and *B*).

In some type IV thumbs, the nail fold does not require reconstruction (Figure 37.53). However, the exact same steps are required during thumb reconstruction. Adhering to the surgical principles will result in a well-aligned thumb.

In a type III thumb, the entire physis and collateral ligament maybe preserved to maintain motion, prevent any chances of MCP joint instability, and avoid damage to the physis (Figure 37.54, *A* and *B*). The osteotomy is designed to preserve the entire proximal phalanx base, and an osteoperiosteal sleeve is not raised (Figures 37.55 and 37.56).

FIGURE 37.50 Removal of the radial facet with scalpel from the metacarpal head. (Courtesy of Shriners Hospital for Children, Philadelphia.)

In cases of ligament reconstruction, the percutaneous Kirschner wire may be placed antegrade from the thumb tip or obliquely across the MCP joint to maintain alignment during the healing process. The incision is closed with absorbable sutures and a long-arm thumb spica cast applied. The cast and

Kirschner wire are removed 4 to 5 weeks after surgery. A short-arm thumb spica splint is fabricated, which is removed for therapy and gentle activities. The splint is discontinued 8 to 12 weeks after surgery.

Type V or VI Split Thumbs

Treatment of type V or VI duplication uses similar principles, with the added complexity of additional intrinsic reconstruction. In addition, the thumb/index finger web space may be narrowed. A concomitant "Z"-plasty or dorsal advancement transposition flap may be required.

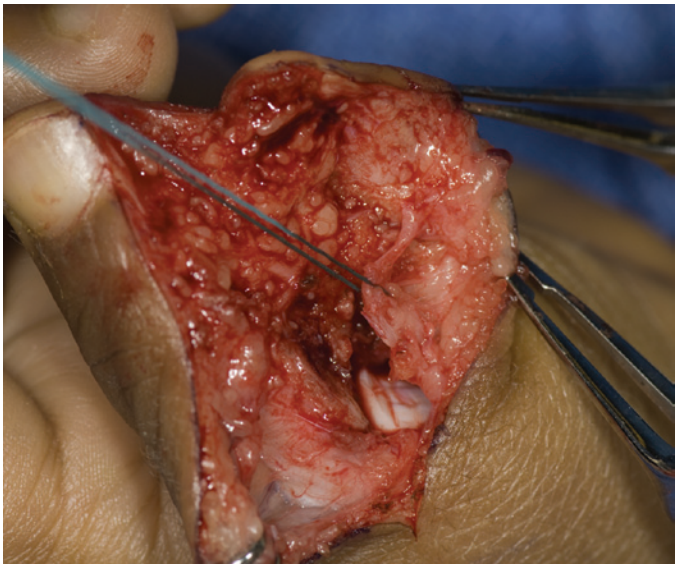

FIGURE 37.51 Osteoperiosteal sleeve radial collateral ligament and abductor pollicis brevis for reconstruction of thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Type VII Split Thumb

A type VII triphalangeal thumb utilizes the principles outlined above for reconstruction (Figure 37.57, *A* and *B*). The x-rays require scrutiny for surgical planning (Figure 37.58). The lesser thumb is excised using an osteoperiosteal sleeve for ligament reconstruction (Figures 37.59 and 37.60). Any persistent bony malalignment requires osteotomy (Figure 37.61). The tendons must be centralized over the reconstructed thumb (Figure 37.62). The skin is closed with absorbable suture (Figure 37.63). The Kirschner wire is removed 1 month after surgery (Figure 37.64). If the retained component is triphalangeal, the extra joint is an added problem. A joint reduction procedure with chondrodesis across the joint with the least motion will reduce the number of joints. This procedure can be done at the time of thumb reconstruction or as a second-stage procedure.

In some cases, the preferred elements for reconstruction come from both thumbs and truly represent "spare parts surgery." An on-top-plasty utilizes the better distal aspect of the deleted thumb and the superior proximal aspect of the retained thumb (Figure 37.65, *A* and *B*). The neurovascular bundles must be carefully dissected and mobilized to allow transposition. Proper rotation and Kirschner wire fixation are critical (Figure 37.66).

Outcomes

The results vary with the degree and complexity of the thumb duplication. Satisfactory results are readily obtainable in type I, II, and IV duplications.[24,43] Less satisfactory results are prevalent in types III, V, and VI and in triphalangeal thumbs.[35,68] The acceptable girth of the reconstructed thumb is unclear, although estimations range from 25% to 33% less than the normal thumb depending on the reconstruction technique.[14,78,82]

The Bilhaut-Cloquet procedure is difficult to perform and its outcome poorly documented.[14,24,35,54,82] Subsequent nail

deformity and IP joint stiffness are common (Figure 37.67).[24,31] Most authors have either abandoned this procedure or reserve its use for symmetric distal type I or II duplication.[18,35,78,79,82] However, Baek and colleagues[4] have reported promising results using an extraarticular technique in a small cohort of children. Nail deformity was avoided and IP motion was maintained.

Complications

The reconstructed thumb is frequently smaller than the normal thumb unless adequate pulp tissue can be transferred form the deleted component. In addition, angulation, joint instability, limited motion, and scar contracture are common problems.[35,68] Reoperation rates of between 20% and 25% have been reported.[58,60] More complicated thumb duplications create more postoperative problems. Any offset in bone axis, persistent joint instability, or tendon malalignment will lead to problems. Joint instability and/or imbalanced tendon action will cause thumb deviation and a "Z"-deformity over time. The approach to the malaligned thumb is to consider the potential underlying cause(s).[58,60] Treatment requires restoration of parallel joint surfaces, restitution of joint stability, and realignment of tendon(s).

Poor motion and persistent instability are even more difficult to treat. Joint contracture often results after articular modification followed by subsequent scarring and arthrofibrosis.

FIGURE 37.62 Extensor mechanism centralized over reconstructed thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 37.63 Final appearance after thumb reconstruction. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Few treatment options are available to restore motion. The thumb with preservation of passive motion without active motion, however, may benefit from tenolysis. Persistent instability combined with limited motion requires ligament reconstruction or arthrodesis. In general, arthrodesis or chondrodesis is preferred to reliably restore stability and alignment.

Enlargement about the MCP joint is also a later problem after surgery (Figure 37.68). This protuberance is usually secondary to inadequate removal of an intraarticular facet in a type IV duplication (Figure 37.69). Arthrotomy and removal of the extra facet will rectify this problem (Figure 37.70). The collateral ligament must be preserved and reattached (Figure 37.71).

CRITICAL POINTS *Thumb Duplication*

- A supranumerary thumb is not a true duplication, because neither component is as robust as a normal thumb. The term *split thumb* is more appropriate.
- Thumb duplication has been classified in various ways based on the degree of skeletal replication. The most common type involves duplicated proximal and distal phalanges that share a common articulation with a bifid metacarpal head (≈50% of cases).
- The ideal reconstruction aligns the thumb along a longitudinal axis, stabilizes the joints, balances the motor functions, provides adequate nail plate without deformity, and restores sufficient thumb size. This often requires using portions of each component, so-called spare parts surgery.
- Surgery requires careful planning and meticulous technique to address the nail, skin coverage, joint congruity, and tendon alignment.
- Any residual offset in bone axis, persistent joint instability, or tendon malalignment will lead to thumb deviation and a "Z"-deformity over time.

TRIPHALANGEAL THUMB

Triphalangeal thumb can occur as an isolated anomaly, can be associated with a systemic abnormality (e.g., Holt-Oram syndrome or FA), or can be concurrent with thumb duplication (Wassel type VII) (Figure 37.72).[18,21] Triphalangeal thumb can also occur with other congenital differences, such as polysyndactyly, thumb hypoplasia, or central deficiency (Figure 37.73).[16,87]

Triphalangeal thumbs can be divided into two distinct forms. The first type has an extra phalanx of variable size within a

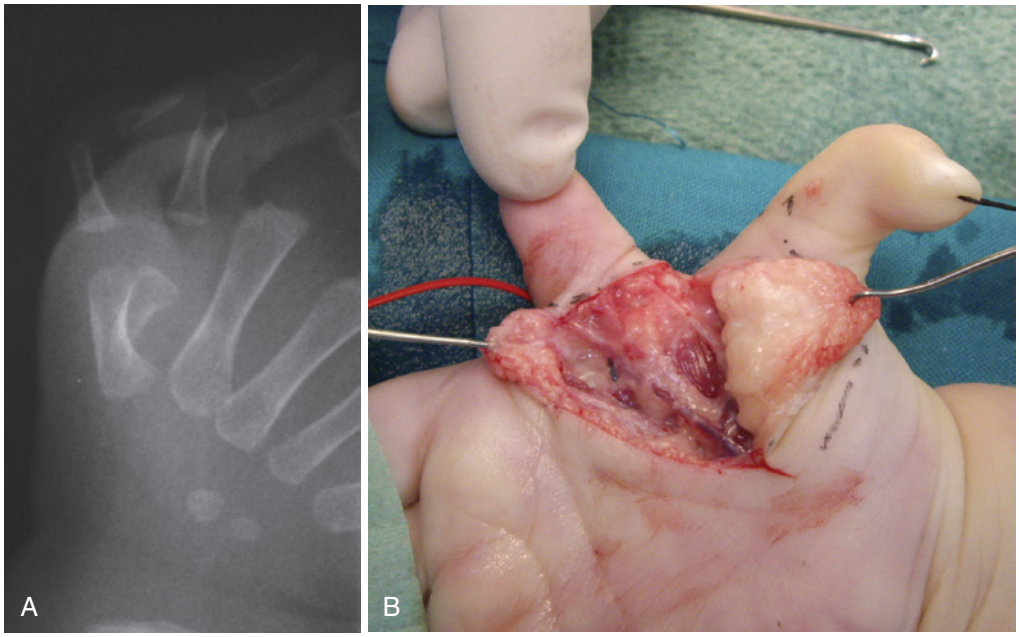

FIGURE 37.65 Two-year-old with complex duplicated thumb. Ulnar thumb has better distal components but no metacarpal base. FIGURE 37.74 Mother and son (see Figure 37.75) with bilateral triphalangeal thumbs of similar appearance. **A,** The mother has slightly longer thumbs with moderate angulation. **B,** Radiographs reveal a trapezoid middle phalanx.

relatively normal appearing thumb (Figures 37.74 and 37.75). The extra phalanx may be triangular, trapezoidal, or rectangular in shape.[56,94] The second variety has a fully developed phalanx that lies in the plane of the fingers. This form is considered a five-fingered hand and probably represents an absent thumb with index polydactyly (Figure 37.76).[73] As with most divisions, there are triphalangeal thumbs that appear to be a pedigree of the two types with characteristics of each form. In addition, the type of triphalangeal thumb can vary across generations.

Both forms of triphalangeal thumbs are inherited as an autosomal dominant trait with variable expressivity and high penetrance.[13,33,56,94] Parents need appropriate genetic counseling regarding the different expressions and phenotypes across the spectrum of a particular mutation. Triphalangeal thumb can also be sporadic in occurrence.

Management Considerations

The management of the triphalangeal thumb can be divided into individual components.[66] The definitive treatment depends on the type of triphalangeal thumb and the presence or absence of any concomitant anomalies, such as thumb duplication. There are multiple elements of the triphalangeal thumb that may require management, including the length and angulation of the digit, the extra IP joint, the status of the thumb/index finger web space, and the presence or absence of thumb opposition.

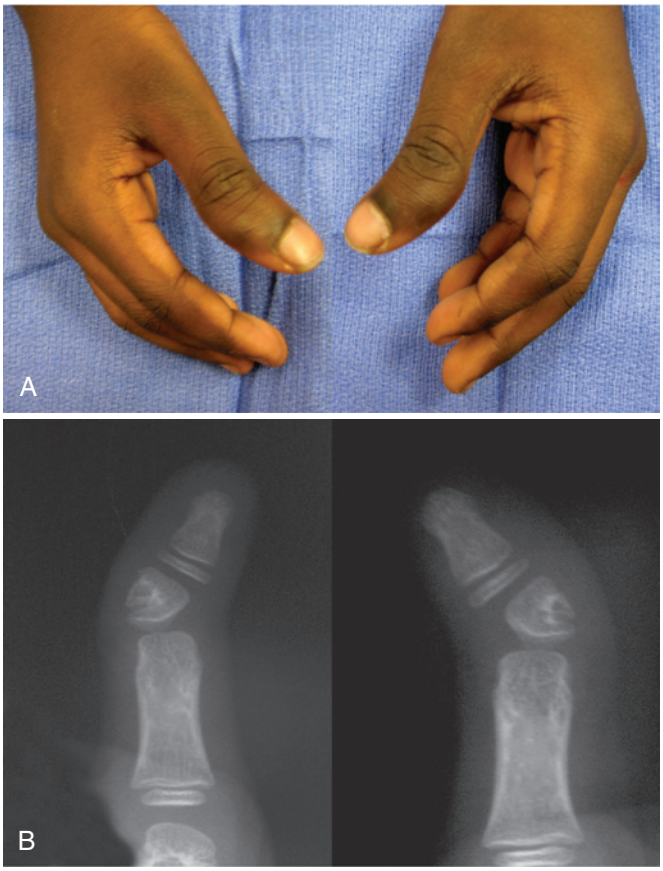

FIGURE 37.75 Child has similar appearance and angulation. **A,** Slightly longer thumbs with apex ulnar angulation. **B,** Radiographs show a more triangular middle phalanx.

FIGURE 37.76 A fully developed phalanx that lies in the plane of the finger is considered a five-fingered hand. (Courtesy of Shriners Hospital for Children, Philadelphia.)

The timing of treatment also depends on any concomitant anomalies. The goal is to reconstruct a thumb with adequate function prior to the development of oppositional pinch, which occurs between 12 and 18 months of age. The treatment of minor length discrepancy or angulation can be delayed until later in life. The proposed plan should be completed prior to school age.

Treatment of Triphalangeal Thumb

Length and Angulation

The extra phalanx has a variable shape and natural history. The length and shape of the extra phalanx will determine the length and alignment. The growth rate of the extra phalanx is variable. Initial treatment consists of observation to assess growth potential. Surveillance also allows an assessment of motion at each IP joint, which is an important factor during reconstruction. The extra bone may ultimately be rudimentary, demonstrate little growth, and require no treatment. In contrast, continual or asymmetric growth will lead to excessive length or progressive angulation, respectively. The angulation is usually in an apex ulnar direction.

A small, wedge-shaped middle phalanx that causes progressive deviation requires excision with ligament reconstruction.[34,66] Surgery is best performed at about 1 year of age. A dorsal approach is preferred, with a longitudinal incision through the extensor mechanism. The extra phalanx is isolated and its size delineated. Osteoperiosteal sleeves are elevated from each side that includes the collateral ligaments. The extra phalanx is removed and the collaterals reattached. The distal and proximal phalanges are coapted and secured with a longitudinal Kirschner wire. This wire skewers the phalanges and provides immobilization until ligamentous healing occurs. The incision is closed with absorbable sutures and a long-arm thumb spica cast applied. The cast and Kirschner wire are removed 6 weeks after surgery. A short-arm thumb spica splint is fabricated, which is removed for therapy and gentle activities. The splint is discontinued 6 weeks after surgery. Lateral pinch should be minimized for the first 3 months to prevent radial deviation at the IP joint. This benign-appearing operation can result in multiple problems, including instability, joint stiffness, and insufficient motion.[34] In fact, I try to avoid simple excision and prefer leaving a small middle phalanx that has negligible effect on thumb function alone. If the phalanx affects alignment and function, a joint reduction procedure is performed as outlined below.

Extra Interphalangeal Joint

The extra IP joint has a variable amount of motion. The extra joint is of little consequence with regard to function. A large, wedge-shaped extra phalanx can produce excessive length with or without deviation. Excision of the phalanx should not be performed, because subsequent instability is common. Fusion of the abnormal phalanx with the distal or proximal phalanx combined with bone shortening removes the extra joint, realigns the thumb, and provides the correct length. The joint with the greatest motion is preserved and the joint with the least movement fused.

A dorsal approach is preferred with a longitudinal incision through the extensor mechanism. The extra phalanx and adjacent joints are isolated. An arthrotomy is performed at the joint with the least motion and is avoided at the joint with maximum motion. The bone is resected from both sides of the joint to shorten and realign the thumb. Asymmetric bony resection corrects any angulatory deformity. The bones are coapted after bony resection. A Kirschner wire is passed retrograde from the tip of the thumb across the osteotomy site for internal fixation. The extensor tendon is approximated and the skin is closed with

absorbable sutures. A long-arm thumb spica cast is applied. The cast and Kirschner wire are removed 5 weeks after surgery. A short-arm thumb spica splint is fabricated; it is removed for therapy and gentle activities.

Thumb/Index Finger Web Space

A narrow web space hampers thumb function. Mild thumb/index finger syndactyly can be managed by web deepening. A four-flap "Z"-plasty deepens the web and provides a more rounded contour than a two-flap configuration.[36,96] Moderate involvement requires a local dorsal rotation advancement flap for adequate deepening. The web space treatment strategy is similar to that for the narrow thumb/index finger web space for thumb hypoplasia.

A five-fingered hand has no web space. Pollicization provides an opposable digit and a thumb/index finger web space.[7,36] The technique is the same as that for an absent or grade V hypoplastic thumb. A two-stage technique to create an opposable digit has also been described.[15] The first stage involves joint reduction, and the second stage combines rotational osteotomy with opposition transfer. A hypoplastic triphalangeal thumb requires removal, and the index finger undergoes pollicization (Figure 37.77).

Absence of Thumb Opposition

The five-fingered hand is often hampered by the lack of an opposable digit. Lack of opposition prohibits thumb function. Tendon transfer to restore opposition is required, using either the FDS or abductor digiti minimi as a donor (see section on thumb hypoplasia). If the thumb/index finger web space is narrow, concomitant web space widening is required. Joint reduction can be performed at the time of tendon transfer or as a secondary procedure.

Concomitant Anomalies

A triphalangeal thumb combined with thumb duplication is treated according to the principles of thumb reconstruction for duplication.[95] Usually, the dominant component is preserved and the nondominant part deleted with use of any important elements (e.g., collateral ligaments). If the triphalangeal component is preserved, treatment of the extra phalanx is based on the above guidelines. The treatment of the triphalangeal portion of the anomaly can be performed at the same time as duplication reconstruction or delayed until later.

A triphalangeal thumb shared with a central deficiency is treated by combining the principles of cleft and triphalangeal thumb reconstruction. The degree of cleft formation and the status of the thumb/index finger web space are critical components. A complete thumb/index finger web syndactyly warrants early thumb separation. The skin from the cleft can be transposed into the thumb/index finger commissure to resurface this web space (Snow-Littler flap).[38,75]

FIGURE 37.77 Index finger pollicization and removal of hypoplastic triphalangeal thumb. (Courtesy of Shriners Hospital for Children, Philadelphia.)

CRITICAL POINTS *Triphalangeal Thumb*

- Triphalangeal thumbs can be divided into two distinct forms. The first type has an extra phalanx of variable size within a relatively normal-appearing thumb. The second variety has a fully developed phalanx that lies in the plane of the fingers; the hand is considered a five-fingered hand.
- The inheritance pattern is usually an autosomal dominant trait with variable expressivity and high penetrance. Genetic consultation is warranted.
- The extra phalanx in a triphalangeal thumb may be triangular, trapezoidal, or rectangular in shape. The growth rate of the extra phalanx is variable, and initial treatment consists of observation to assess growth potential.
- A large, wedge-shaped extra phalanx requires fusion of the abnormal phalanx with an adjacent phalanx combined with bone removal. The joint with the greatest motion is preserved and the joint with the least movement fused.
- A five-fingered hand is treated with pollicization of the nonopposable radial digit.

TRIGGER THUMB

General Considerations in Trigger Thumb

Incidence and Etiologic Findings

Trigger thumb is about ten times more common than trigger finger.[8,63] The exact incidence has become more clearly defined. Ger and colleagues[25] initially reported an incidence of 1 patient per 2000 live births, based on a small sample size. Recently, Kikuchi and Ogino[37] performed neonatal medical checks and subsequent follow-up. They noted an incidence of trigger thumb at 1 year of age of 3.3 cases per 1000 live births. Bilateral involvement is present in approximately 25 to 30% of children.[8,70]

The term *congenital* is probably a misnomer because widespread evaluations of newborns have failed to discover a trigger thumb.[70,74] Slakey and Hennrikus[74] screened 4719 newborn infants for the presence of a trigger thumb and noted no cases of triggering, locking, nodule formation, or fixed flexion contracture. Moon[62] examined 7700 neonates within the first few days of life, and Kikuchi and Ogino[37] examined 1116 babies within 14 days after birth and noted no trigger thumbs. These results suggest that trigger thumb most likely is not present at birth but rather develops with postnatal growth. Furthermore, the term *trigger* is inaccurate because the vast majority of children presents with a fixed flexion deformity of the thumb IP joint (Figure 37.78). A confounding diagnostic factor is the fact that infants posture with their thumb in flexion, which may delay detection.[74]

FIGURE 37.78 Trigger thumb with fixed flexion deformity of the interphalangeal joint. (Courtesy of Shriners Hospital for Children, Philadelphia.)

FIGURE 37.79 Notta nodule is palpated just proximal to the A1 pulley. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Sugimoto[77] has classified trigger thumb into four stages:

Stage I (tumor type): There is a Notta nodule, but no snapping is observed during IP flexion and extension.

Stage II (active triggering): Triggering is observed when the IP joint is actively extended.

Stage III (passive triggering): The IP joint cannot be extended actively, and triggering is observed when the IP joint is extended passively.

Stage IV (rigid type): The IP joint cannot be passively extended (i.e., a fixed flexion deformity exists).

The exact etiologic findings have become better defined with ultrasound studies.[85] Ultrasound imaging of all pediatric trigger thumbs demonstrated normal echotexture of the flexor pollicis longus without evidence of inflammation or trauma. Triggering occurred when the cross-sectional area of the flexor pollicis longus exceeded the cross-sectional area at the A1 pulley (i.e., size mismatch). Triggering resolved when this size disparity was eliminated. Palpation of the nodular thickening of the flexor tendon, or Notta nodule, is readily apparent just proximal to the A1 pulley (Figure 37.79). This nodule is present in all stages and is the sine qua non of a trigger thumb.[70] Passive manipulation into extension may produce a noticeable click or pop in stages III and IV. No further diagnostic testing is necessary, as the history and physical examination are pathognomonic for trigger thumb.

Treatment

The natural history, rate of spontaneous resolution, effectiveness of splint therapy, and timing of surgery remain controversial.

Natural History

The reported spontaneous recovery rate is highly variable. Dinham and Meggitt[12] reported that approximately 30% of trigger thumbs diagnosed prior to 1 year of age resolved, and about 10% diagnosed at between 6 months and 1 year of age resolved spontaneously. Higher rates of resolution have been reported from Japan with longer follow-up periods. Michifuri and associates[57] reported a spontaneous resolution rate of slightly greater than one half of trigger thumbs during a follow-up period of 5.2 years. Sugimoto[77] also found that during an observation period of between 7 months and 12 years, spontaneous resolution occurred in over one third of patients. Baek and colleagues[5] prospectively followed 71 thumbs in 53 children. No treatment such as passive stretching or splinting was rendered. Forty-five thumbs (63%) resolved spontaneously. The median time from the initial visit to resolution was 48 months. These results suggest that trigger thumbs in children retain the potential to spontaneously resolve if followed for a prolonged period.

Nonoperative Treatment

Watanabe and coworkers[89] reported their results following nonoperative treatment consisting of only passive flexion and extension of the affected thumb performed by the mother. Fifty-six thumbs out of 58 demonstrated improvement, especially those that were flexible (stage I). The role of splinting is controversial because the reported success rate varies greatly.[65,74] Success has been reported in 24 out of 33 digits (73%) with nighttime splinting for an average of 10 months' duration.[65] Nemoto and colleagues[65] described a series of 40 trigger digits that were treated by the application of a thumb splint keeping the IP joint in hyperextension during naptime and at night. Twenty-nine thumbs recovered completely, and only three patients required operative treatment. Lee and associates[44] compared the results of splint therapy and observation in a group of 62 reducible trigger thumbs in 50 children. Splinting resulted in complete or partial resolution in 22 of 31 thumbs (71%), whereas observation alone resulted in complete or partial resolution in 7 of 31 thumbs (23%).

Surgical Treatment

The precise timing of surgery is dependent on multiple factors, including the age of the child, degree of deformity, patience of the family, and surgeon preference. We know that a delay in surgery up to 3 years of age is not detrimental with regard to contracture or motion.[74] Therefore, some period of observation seems reasonable, especially in children less than 1 year of age. Children with painful triggering and a rigid deformity (stage IV) older than 1 year of age should undergo surgery. Children older than 1 year with earlier stages of active triggering (stage II) or

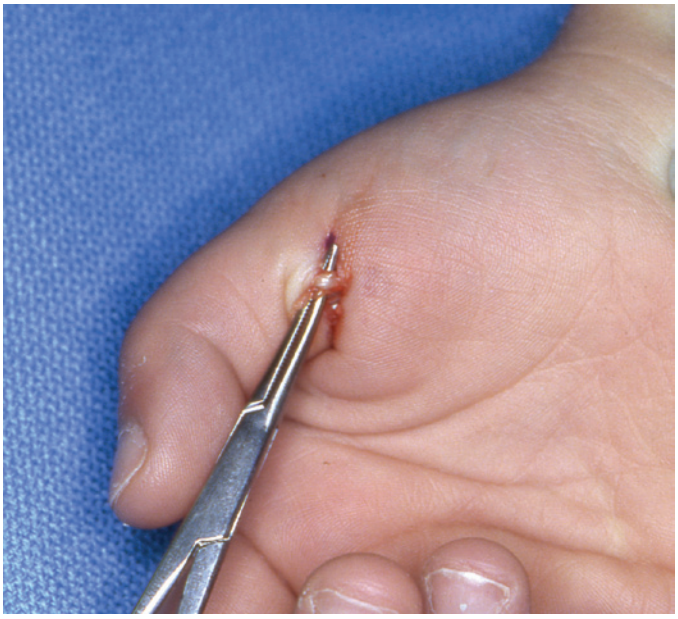

FIGURE 37.80 Radial digital nerve is identified and protected before pulley release. (Courtesy of Shriners Hospital for Children, Philadelphia.)

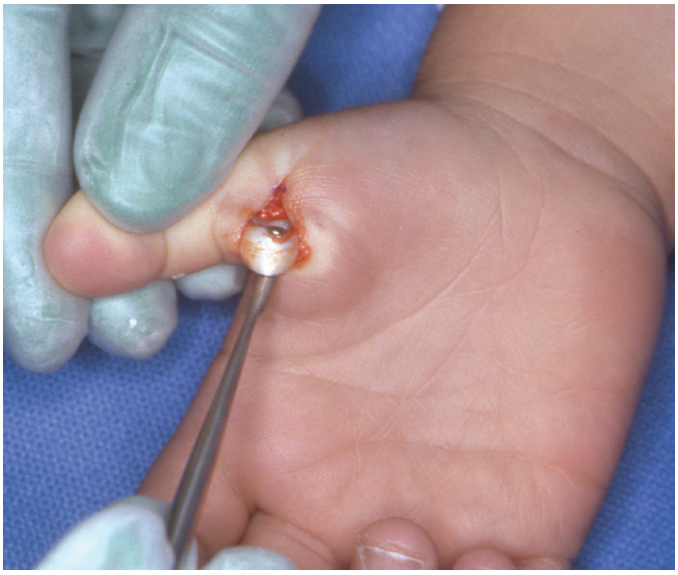

FIGURE 37.81 The flexor pollicis longus is isolated after release of the first annular pulley. (Courtesy of Shriners Hospital for Children, Philadelphia.)

passive triggering (stage III) can continue with nonoperative measures or proceed with surgery. The ultimate choice rests on the surgeon and family; an explanation of the risks and benefits is needed. At our institution, we still recommend surgery for most children older than 1 year of age with persistent triggering.

Surgical Technique. Surgery is performed under general anesthesia, tourniquet control, and loupe magnification. Make a transverse incision over the first annular pulley. Incise only the skin. Spread in a longitudinal fashion through the subcutaneous tissue. Identify and protect the radial digital nerve (Figure 37.80). Isolate the first annular pulley. Release the pulley to expose the flexor pollicis longus (Figure 37.81). Do not address the nodular thickening of the flexor pollicis longus. Inspect the proximal and distal sides to ensure that no further tendon contraction occurs with full flexion and extension of the thumb. Irrigate and close with absorbable suture. Place the child in a forearm-based thumb spica soft cast (Scotchcast Soft Cast Casting Tape, 3M, St. Paul, MN) or just a soft dressing with the IP joint extended. Deflate the tourniquet and awaken the child. Remove the dressings 1 week later and allow the child to return to normal function. Therapy is usually not necessary.

Percutaneous release has been suggested and performed for trigger thumbs in children.[86] However, the same risk of radial digital nerve injury is present in children that is present in adults. In addition, this technique does not negate the use of anesthesia. Currently, I do not offer this technique as a surgical option.

Outcome

Trigger thumb release is uniformly successful, and recurrences are rare.[8,12,63,74] The literature reports that the short-term and long-term results of surgical treatment of pediatric trigger thumb have been excellent.[52,53] Complications are uncommon and are related to surgical technique. Persistent triggering is usually secondary to inadequate release of the flexor tendon sheath. Other complications include wound issues, scarring, tendon bowstringing after release of the oblique pulley, and numbness secondary to digital nerve injury.

Trigger Fingers

Trigger fingers in children are uncommon and less straightforward.[8] In children, trigger fingers are different from trigger thumbs, and the role of nonoperative treatment is even less clear.[8,65,81] In addition, simple release of the first annular pulley may not resolve the triggering. An abnormal relationship between the FDP and FDS tendons, proximal decussation of the superficialis tendon, nodular formation within the flexor tendons, and tightness of the second and/or third annular pulleys have all been implicated as potential reasons. The surgeon must be prepared to perform a more diligent search for alternative causes when release of the first annular pulley does not resolve the triggering. Routine release of the A3 pulley and resection of a slip of the FDS are performed to resolve triggering[8,72] (Figure 37.82). The surgeon should also remember that multiple digit involvement can be associated with inflammatory arthritis, juvenile diabetes, and mucopolysaccharide disorders.

CRITICAL POINTS *Trigger Thumb*

- Trigger thumbs are not "congenital" but rather acquired problems related to a discrepancy between a tight flexor tendon sheath and an enlarged flexor pollicis longus.
- The classic finding is a fixed flexion contracture of the IP joint and a palpable nodule over the flexor pollicis longus tendon.
- Observation and/or splinting can be attempted, especially in children less than 1 year of age; the success rate is variable.
- Surgery involves release of the A1 pulley; the radial digital nerve must be protected.
- Trigger fingers in children are uncommon and less straightforward.
- Trigger finger surgery involves release of the first annular pulley that usually does not resolve the triggering release of the A3 pulley. FDS is usually required.
- Multiple trigger fingers can be associated with inflammatory arthritis, juvenile diabetes, and mucopolysaccharide disorders.

CLASPED THUMB

Congenital clasped thumb refers to a spectrum of thumb anomalies. The range of anomalies commences with mild deficiencies of the thumb extensor mechanism and progresses to severe abnormalities of the thenar muscles, web space, and soft tissues. The initial classifications attempted to subdivide the disorders into individual types and remain inclusive.[80,92] This scheme has not been useful in the clinical setting. A more practical approach has been proposed by McCarroll[55] and expanded by Mih.[59] A type I clasped thumb is usually supple, and the extensor mechanism is either absent or hypoplastic (Figure 37.83). A type II clasped thumb is complex with additional finding(s) of joint contracture, collateral ligament abnormality, first web space contracture, and thenar muscle abnormality (Figure 37.84). A type III clasped thumb is associated with arthrogryposis or its associated syndromes, such as MASA (mental retardation, aphasia, shuffling gait, and adducted thumbs) (Figure 37.85). In this case, the extensor mechanism may have minimal or no abnormality.

This section will discuss the treatment of the relatively mild type I and II clasped thumbs. The more severe type III form is discussed under the congenital contracture section and arthrogryposis.

Clinical Features

The diagnosis of clasped thumb is often delayed because an infant frequently holds the thumb within the palm for the first 3 to 4 months. At presentation, the thumb rests in flexion with an extension lag. Most commonly, the extension lag is present only at the MCP joint, which implies hypoplasia of the extensor pollicis brevis muscle tendon unit.[6,93] Additional extensor pollicis longus and/or abductor pollicis longus anomalies have also been reported (see Figure 37.84).[59,97] Diagnosis of these deficiencies is based on thumb and joint position. Simultaneous extension lag at the IP joint indicates a concomitant deficiency of the extensor pollicis longus. Concurrent metacarpal adduction implies insufficiency of the abductor pollicis longus.

Treatment of Clasped Thumb

Initial treatment of the type I clasped thumb is splinting of the affected joint(s) in extension. The goal is to prevent additional attenuation of the hypoplastic extensor mechanism and to allow hypertrophy over time. Full-time splinting for 2 to 6 months has been shown to be effective. Miura[61] reported on 96 hands in 66 patients that underwent splint application. Good results were obtained in 70% of children that were splinted within 12 months of birth. In contrast, splinting was effective in only 21% of children more than 1 year after birth and none older than 2 years of age. Lin and colleagues[47] reported on 11 infants (17 thumbs) with congenital clasped thumb treated with splinting. The functional results were excellent in 15 and good in 2 patients.

Surgery is warranted for children who have failed splinting or present after 2 years of age. The degree of impairment, however, must be considered during formulation of a treatment

FIGURE 37.83 A type I clasped thumb with absence of the extensor pollicis brevis. (Courtesy of Shriners Hospital for Children, Philadelphia.)

plan. Mild MCP joint extension lag does not hinder hand function and does not always require treatment (Figure 37.86). Frequently, adolescents are seen with a mild clasped thumb that has never been treated and report no problems.

Considerable lack of thumb extension that interferes with grasp warrants treatment. Any associated thumb MCP joint or thumb/index finger web space contracture requires treatment (Figure 37.87). Initially, serial casting or splinting may be tried to stretch the taut skin and correct the contracture. Residual contracture correction must be incorporated into the surgical plan. In a type I clasped thumb, skin and subcutaneous tissue release is usually enough to correct the contracture. Thumb/index finger space deficiency is treated with standard techniques of four-flap "Z"-plasty or dorsal rotation advancement flap (see section on hypoplastic thumb). Palmar skin deficiency requires a rotational flap into the palmar aspect of the thumb MCP joint. A modified dorsal rotation advancement flap, which broadens the apex and increases its length, has been described.[27] This flap design places the suture line far beyond the web, which may lessen web space contracture.

A second incision is performed over the dorsum of the thumb metacarpal and proximal phalanx. The extensor apparatus is explored. The extensor pollicis brevis tendon is usually present but is small and attenuated. A tendon transfer is performed to augment thumb extensor function. The donor tendons depend upon availability and expendability. The extensor indicis proprius tendon is the first choice, but it may or may not be present.[59,93] Absence of the extensor indicis proprius requires selection of an alternative donor tendon. Options are the FDS or abductor digiti minimi muscle.[11,59] The tendon transfer is secured into the attenuated tendon and/or the base of the proximal phalanx. The limb is placed in a long-arm thumb spica cast with the MCP joint in extension for 4 weeks. The cast is removed and a short-arm thumb spica splint fabricated. Gradual active flexion of the thumb is encouraged. The splint is worn only at night beginning at 6 weeks and is discontinued at 12 weeks following surgery.

CRITICAL POINTS *Clasped Thumb*

- Congenital clasped thumb refers to a spectrum of extensor mechanism deficiencies that range from mild to severe.
- A mild clasped thumb is usually supple and possesses an extensor lag at the MCP joint indicative of a deficiency of the extensor pollicis brevis.
- Initial treatment is splinting is objectively effective in children younger than 1 year of age.
- Surgery is indicated for children who have failed splinting or who present at an older age and have a functional impairment.
- Surgical goals are to correct any soft tissue contracture that has developed over time and to augment extensor function via tendon transfer.

Malformations and Deformities of the Wrist and Forearm

Michelle A. James and Andrea S. Bauer

Acknowledgments: The authors would like to acknowledge Mike Bednar, MD, who authored the previous edition of this chapter. We would also like to acknowledge Scott Oishi, MD, Brian O'Doherty, MD, and Scott Kozin, MD, for providing additional text, radiographs, and photos that have enhanced our chapter.

RADIAL LONGITUDINAL DEFICIENCY (CASE STUDY 38.1)

Preoperative Evaluation

Radial longitudinal deficiency (RLD) is a spectrum of malformations affecting the structures of the radial side of the forearm (radius, radial carpus, and thumb), including hypoplasia of the bones and joints, muscles and tendons, ligaments, nerves, and blood vessels.[57] In the Oberg, Manske, Tonkin classification of congenital hand differences, RLD is categorized as a malformation of the radial-ulnar axis.[87] RLD is an uncommon condition, although it is the most common type of congenital longitudinal deficiency. A population-based study in Finland found RLD in nearly 1:5000 live births.[66]

Children with RLD should undergo thorough and serial examinations of both upper extremities. RLD is frequently bilateral and asymmetric, and manifestations may be subtle. Because the radius and many organ systems develop at the same time, a systemic workup is required. RLD is commonly associated with several congenital syndromes, such that only a third of patients with RLD present with an isolated upper extremity malformation (Table 38.1).[44] Therefore, a complete physical examination must be performed and consultation with a clinical geneticist is recommended. In addition, radiographic and serologic tests mentioned in the following are required.

Although children with bilateral and severe RLD have functional impairment as a result of thumb dysfunction, wrist instability, and short upper extremities, there is no difference in long-term activity and participation levels between those with mild versus severe RLD.[51] For some children with RLD, independent performance of activities of daily living, such as fastening buttons and zippers or accomplishing personal hygiene, may be difficult, prompting consideration for surgery.

Radiographs tend show the degree of involvement of the radius, thumb, and carpus dependent upon the degree of ossification and/or previous surgical intervention. Classification of the RLD is by radiographic studies.[55] Spine x-rays, renal ultrasound, and echocardiography are required to assess for associated anomalies.[44]

Persons with RLD have a high incidence of medical and musculoskeletal anomalies which escalate with increasing severity of the deficiency.[44] In addition to genetic counseling, testing for Fanconi anemia is recommended.[123] We recommend a chromosomal breakage test for all children with deficiencies of the thumb and radial border of the forearm. Additional findings, such as abnormal skin pigmentation (*café au lait spots*), kidney abnormalities, growth retardation, and microcephaly, add to the suspicion of Fanconi anemia. Failure to ascertain the diagnosis of Fanconi anemia will have lifelong ramifications for the child, family, and physician. Fanconi anemia can be diagnosed before the onset of bone marrow failure. Timely diagnosis allows for years of preparation to search for an appropriate bone marrow match that may prevent the child from dying from aplastic anemia. Innovative techniques, such as preimplantation genetic determination, allow the parents to have another child with matching blood characteristics and without Fanconi anemia. At birth, the cord blood can be harvested and used as a donor for the affected Fanconi anemia child. Numerous hand surgeons and pediatricians fail to consider the diagnosis of Fanconi anemia in children with RLD, leaving the child and the family to suffer the consequences of a painful terminal illness that could otherwise have been treated.

RLD is associated with other upper extremity anomalies, including humeral hypoplasia, proximal radioulnar synostosis, congenital radial head dislocation, and finger stiffness. Less common associations include metacarpal synostoses and syndactyly.[56] Infrequent findings are contralateral radial polydactyly[102] and phocomelia.[42]

PERTINENT ANATOMY

Bayne and Klug classified RLD into four types based on the radiographic severity of the radial deficiency (Table 38.2).[10] James and associates modified this classification to include patients with deficiency of the thumb or carpus in the presence of a radius of normal length (Figure 38.1).[57] This classification is used in combination with the modified Blauth scheme for classifying thumb hypoplasia.[55]

Types of Operations

Indications for treatment vary with the severity of the deformity and the age of the patient. Children with type 0 or 1 or mild type 2 radial deficiencies may require only stretching and splinting. When considerable radial deviation is present, tendon transfers and soft tissue releases may be indicated.[83] Severe type 2 radial deficiency is difficult to treat. Lengthening of the radius may be possible,[75] or centralization of the carpus on the end of the ulna may be performed to achieve stability and improve the likelihood that the child will be able to use a reconstructed thumb. A recent large study found that patients with RLD who underwent centralization showed improvements in both subjective measurements (such as appearance) and objective measurements (such as alignment, grip strength, and finger and wrist range of motion) compared with patients who did not undergo surgery.[67]

We have previously recommended bony centralization, including (if necessary) carpal resection and ulnar epiphyseal shaving, to correct the wrist instability and radial deviation in types 3 and 4 RLD. Although bony centralization is still performed by some surgeons, others prefer not to resect the carpus or shave the distal ulna because of the high rate of recurrent deformity and complications such as wrist stiffness and forearm growth impairment that may be caused by iatrogenic damage to the ulnar physis.

The best results of centralization are obtained when aberrant radial wrist extensors can be transferred to help maintain the new position and the centralization is done before 1 year of age (as long as general anesthesia is not precluded by other manifestations of the child's syndrome such as cardiac problems or thrombocytopenia). Before centralization, serial casting or application of a distraction device, or both, facilitates stretching of the taut radial soft tissue structures, thereby diminishing the soft tissue tension and the likelihood that bony resection will be required during centralization.[43,117] Preliminary external distraction is most helpful for older children with untreated type 3 or 4 radial deficiency. A bilobed skin flap or dorsal rotation flap may help redistribute excess tissue from the ulnar to the radial side of the wrist.[32,120]

With unilateral type 3 or 4 involvement, the affected forearm is usually only half as long as the unaffected forearm. This deficit in length has been surgically addressed by ulnar lengthening via distraction osteogenesis.[93] Lengthening can be performed in older children after centralization. However, lengthening procedures may affect the future growth of the ulna, such that repeated lengthenings will be required to maintain the relative gain in length.[137]

Vilkki described the combination of soft tissue distraction and microvascular epiphyseal transfer for the treatment of type 4 radial deficiency (Figure 38.2).[125] Historically, attempts to treat radial deficiency by surgical transfer of nonvascularized growing bone were unsuccessful because the graft failed to grow. Although Vilkki's early results are promising, the technique is technically demanding and the outcome at skeletal maturity is not yet known.

Preliminary Soft Tissue Distraction

Unilateral and circumferential fixators have been used successfully to distract the radial soft tissues before centralization (Figure 38.3).[43,117] The fixator is applied across the wrist via an open technique for pin placement to protect the anomalous

TABLE 38.1 Syndromes Associated With Radial Deficiency

Syndrome	Other Anomalies	Inheritance
VACTERL	Spinal, renal, gastrointestinal, cardiac	Sporadic
Holt-Oram	Cardiac (septal defects); other upper extremity malformations	Autosomal dominant
TAR	Thrombocytopenia, anemia; radius absent but thumb present	Autosomal recessive
Fanconi anemia	Pancytopenia	Autosomal recessive
Chromosome aberrations (trisomies 13 and 18)	Multiple	Sporadic
Nager, Rothmund-Thomson, IVIC	Craniofacial	Varies with the syndrome

IVIC, Instituto Venzolano de Investigaciones Cientificas; *TAR*, thrombocytopenia–absent radius; *VACTERL*, vertebral, anal, cardiac, tracheoesophageal, renal/radial, limb.

TABLE 38.2 Modified Bayne Classification of Radial Longitudinal Deficiency

Type	Thumb	Carpus	Distal Radius	Proximal Radius
N	Hypoplastic or absent	Normal	Normal	Normal
0	Hypoplastic or absent	Absence, hypoplasia, or coalition	Normal	Normal, radioulnar synostosis, or congenital dislocation of the radial head
1	Hypoplastic or absent	Absence, hypoplasia, or coalition	>2 mm shorter than the ulna	Normal, radioulnar synostosis, or congenital dislocation of the radial head
2	Hypoplastic or absent	Absence, hypoplasia, or coalition	Hypoplasia	Hypoplasia
3	Hypoplastic or absent	Absence, hypoplasia, or coalition	Physis absent	Variable hypoplasia
4	Hypoplastic or absent	Absence, hypoplasia, or coalition	Absent	Absent

Modified from Bayne LG, Klug MS: Long-term review of the surgical treatment of radial deficiencies. *J Hand Surg [Am]* 12:169–179, 1987; and James MA, McCarroll HR, Jr, Manske PR: The spectrum of radial longitudinal deficiency: a modified classification. *J Hand Surg [Am]* 24:1145–1155, 1999.

anatomy and gradually distracted until the wrist can be centralized without residual radial deviation after the external fixator is loosened or removed (Figure 38.4).

Centralization

Although the wrist and forearm are profoundly abnormal in a radially deficient limb, the anomalies are predictable. All the radial forearm structures are deficient to varying degrees. The radial wrist extensors and extrinsic thumb motors are usually absent or aberrant. The radial nerve is generally absent below the elbow. The median nerve is always present and is frequently the most prominent structure on the radial side of the wrist. The radial artery is usually absent.[120] Occasionally, a child with RLD has an elbow extension contracture. In this case, centralization is contraindicated, as wrist radial deviation is needed for the child's hand to reach the face.

The incision begins at the level of the distal end of the ulna just radial to the midline, extends toward the ulna in a transverse direction, and then forms an ellipse to excise excess skin and subcutaneous tissue, or alternately, excess tissue is rotated from the ulnar to the radial side.[120] The dorsal ulnar sensory nerve is preserved, and the extensor retinaculum is exposed. The extensor carpi ulnaris is isolated as it inserts into the base of the fifth metacarpal. The extensor retinaculum is raised as a radially based flap and the finger extensor tendons are retracted radially. The radial wrist extensors are generally absent or adherent to the dorsal capsule and devoid of proximal musculature; their remnants are isolated and elevated with a piece of dorsal capsule.

The wrist capsule is incised in a transverse direction over the ulnocarpal joint to expose the distal end of the ulna (Figure 38.5). The carpal bones are often palmar and radial to

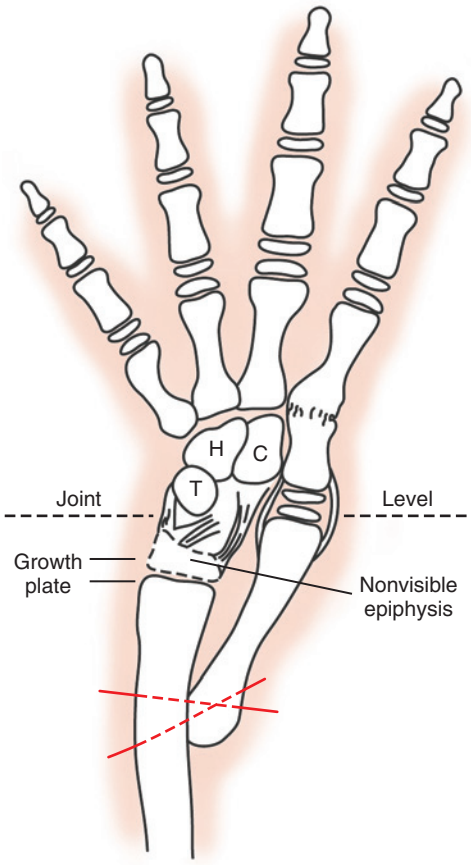

FIGURE 38.2 Diagram of free toe transfer to support the radial side of the wrist. The proximal phalanx of the toe is fused to the base of the second metacarpal, and the proximal metatarsal is affixed to the side of the distal ulna. *C*, Capitate; *H*, hamate; *T*, triquetrum.

the distal ulna. The ulna is freed from its soft tissue attachments distal to the physis, and the carpal bones are detached from the palmar capsule. The carpus is then reduced onto the distal ulna. If reduction cannot be achieved, the radial structures are examined for any persistent taut tissue. In severe cases without preliminary distraction, adequate reduction cannot be achieved and alternative measures are necessary. Surgical options include carpectomy or limited shaving of the distal ulnar epiphysis while avoiding injury to the growth plate or the application of an external fixator, postoperative distraction, and delayed formal centralization.

The reduction is maintained by placing a Kirschner wire through the carpus and third metacarpal into the ulnar shaft. If the ulnar angulation is greater than 30 degrees, a closing wedge osteotomy is performed at the apex of the deformity and secured with the same Kirschner wire. In severe deformity, separate Kirschner wires are often necessary. The wrist capsule is imbricated, and, if present, the radial wrist extensors are transferred into the extensor carpi ulnaris tendon. The extensor carpi ulnaris is tightened by detaching and advancing the tendon or imbrication to increase soft tissue tension on the ulnar side. The retinacular flap is passed underneath the finger extensors to reinforce the wrist capsule. Excess skin and subcutaneous tissue are excised, and the wound is closed with absorbable suture. A long-arm bulky compressive dressing is applied and covered with a long-arm fiberglass splint or cast.

Soft Tissue Release and Balancing

If the carpus cannot be passively reduced onto the end of the ulna, a soft tissue release and balancing procedure is performed instead of a formal centralization (Figure 38.6). The major difference between these two operations is that carpectomy and

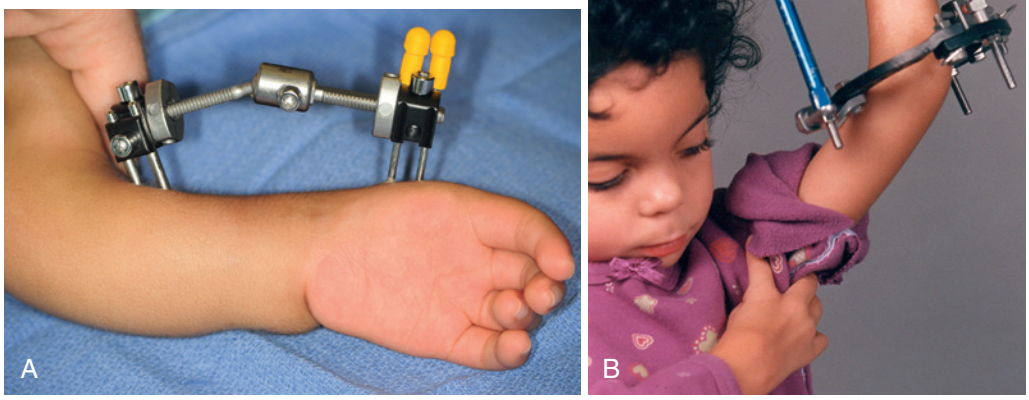

FIGURE 38.3 Radial deficiency with rigid deformity is often treated with preliminary soft tissue distraction, **A,** Uniplanar device along the radial side of the forearm. **B,** Multiplanar device for additional control of hand and forearm. shaving of the distal ulnar epiphysis are not performed, and the hand and carpus are either not pinned or are pinned in the best position possible, accepting some translocation or dislocation.

Ulnar Lengthening

This procedure is rarely indicated. When it is performed, the principles of distraction lengthening are followed (Figure 38.7).[93] A uniplane or multiplane fixator is used, depending on any concomitant angular bony correction needed. For application of a circumferential frame, two half-pins and one transfixion wire are used proximal to the osteotomy. One half-pin and two transfixion wires (one in the ulna and one in the metacarpals) are placed distal to the osteotomy. For a uniplane fixator, two pins each are placed proximal and distal to the osteotomy. We prefer a uniplane fixator with a hinge at the midpoint, to allow correction of the radial bow at the time of fixator application. Any residual radial deviation is corrected at the time of fixator application or during the distraction. Acute bony correction can be achieved with a closing wedge osteotomy followed by distraction osteogenesis. Distraction is initiated approximately 1 week after application of the fixator and is continued at 1 mm/day divided into two to three increments. Radiographic progress of bone regeneration is monitored weekly. The rate of lengthening is slowed if regeneration is lagging. The child and family are taught lengthening techniques and exercises to maintain elbow and digit motion. The ulna can usually be lengthened by 30% to 50%. The fixator is maintained during consolidation of the bony regenerate, which generally takes twice as long as the lengthening phase. The fixator is not removed until a total of three cortices are visualized on the anteroposterior and lateral x-rays. Occasionally, supplemental bone grafting is necessary to augment union.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Range-of-motion exercises for soft tissue stretching are started shortly after birth. The parents are instructed in stretching exercises, to be performed with each diaper change. Once the child's arm is large enough for splinting, generally around 3 months of age, a custom-fabricated long-arm Orthoplast splint (North Coast Medical, Gilroy, CA) is made for nighttime use in addition to the daytime stretches (Figure 38.8). The parents are

FIGURE 38.8 An example of a custom thermoplastic splint for nighttime stretching.

instructed to continue stretching the wrist several times each day for at least the child's first year. In certain children, neither pollicization nor centralization is indicated. These children typically have a mobile and dexterous small finger along with a stiff index finger. Pinch and grasp are accomplished using the ulnar side of the hand (ulnar grasp pattern) and straightening the wrist would eliminate the ulnar digits from approaching objects. This shift in position may be detrimental to the child's overall function and independence.

If the child is a candidate for centralization and is able to safely undergo general anesthesia around age 1 year, surgical correction is planned. If the wrist can be passively reduced preoperatively, formal centralization is performed. If not, preliminary distraction is performed followed by centralization. If incompletely correctable at the time of surgery, soft tissue release and balancing may be warranted. Prolonged pin fixation followed by long-term splinting is necessary to minimize recurrence. Ulnar lengthening is reserved for mature older children or teenagers. Lengthening requires realistic expectations and emotional stamina on the part of the patient and family. Preoperative counseling and psychological assessment are helpful. The support of a limb-lengthening team, including a nurse, social worker, and occupational therapist, is also essential.

Expected Outcomes

Long-term follow-up studies of bony centralization report problems with recurrence and stiffness (Figure 38.9).[27] The wrists tend to be either flexible and deviated or stiff and straight. Centralization has been shown to improve the appearance of the extremity but has not been proved to routinely enhance function. Some experienced pediatric hand surgeons have abandoned formal centralization in favor of soft tissue reconstruction, such as a bilobed skin flap combined with musculotendinous releases and tendon transfers (Figure 38.10).[126a,127]

Postoperative Management and Expectations

After soft tissue balancing, the extremity is placed in a cast for at least 8 weeks. Subsequently, a long-arm splint, custom-fabricated to maintain the wrist position, is worn full time for 3 to 6 months and then at night until skeletal maturity is reached.

Complications of ulnar lengthening are common, especially pin tract infections, which usually resolve with local care and antibiotics. Finger stiffness may occur during the lengthening process and is treated by slowing the distraction rate and therapy. A second procedure to place bone graft at the osteotomy site is occasionally necessary to achieve union.

CRITICAL POINTS *Treatment of the Wrist in Radial Longitudinal Deficiency*

- The basic goals of treatment are to (1) correct the radial deviation of the wrist, (2) balance the wrist on the forearm, (3) maintain wrist and finger motion, (4) promote growth of the forearm, (5) reconstruct the thumb deficiency, and (6) improve the function of the extremity.
- Passive stretching and splinting of the taut radial structures are initiated during infancy.
- Centralization and/or soft tissue release combined with tendon transfer is indicated in children with radial wrist deviation and insufficient support of the carpus.
- Thumb hypoplasia is addressed at a second stage after wrist centralization.
- The incision for centralization is planned to allow excision of excess tissue.
- The extensor carpi ulnaris is tightened and the extensor retinaculum is preserved.
- After releasing the taut structures, the carpus is pinned to the end of the distal ulna, avoiding removal of the carpal bones or shaving of the ulnar epiphysis.
- If the surgeon elects to remove carpal bones or shave the ulnar epiphysis, great care should be taken to not damage the ulnar physis.
- Despite numerous technical modifications to preserve alignment, some recurrence of the radial deficiency is universal. Currently, long-term maintenance of the carpus on the end of the ulna without sacrificing wrist mobility or stunting forearm growth remains a daunting task.

ULNAR DEFICIENCY

Preoperative Evaluation

Ulnar deficiency occurs approximately once in 25,000 live births and is 4 to 10 times less common than radial deficiency.[66] Ulnar deficiency occurs sporadically and is not associated with systemic conditions as occurs in children with radial deficiency. It is, however, associated with other musculoskeletal abnormalities that warrant careful physical examination supplemented by radiographs.

Unilateral ulnar deficiency is more common than bilateral deficiency.[116] Children with ulnar deficiency have hypoplasia of the entire upper extremity. The elbow is malformed or fused (i.e., radiohumeral synostosis) in the majority of cases (Figure 38.11).[116] The ulna may be partially or completely absent, and a cartilaginous ulnar "anlage" may be present.[80] The hand and carpus are always affected; occasionally, isolated hand involvement is seen.[49] About 90% of hands are missing digits, 30% have syndactyly, and 70% have thumb abnormalities (Figure 38.12).[22,116]

The other musculoskeletal anomalies that may accompany ulnar deficiency include proximal femoral focal deficiency, fibular deficiency, phocomelia, and congenital scoliosis.[116]

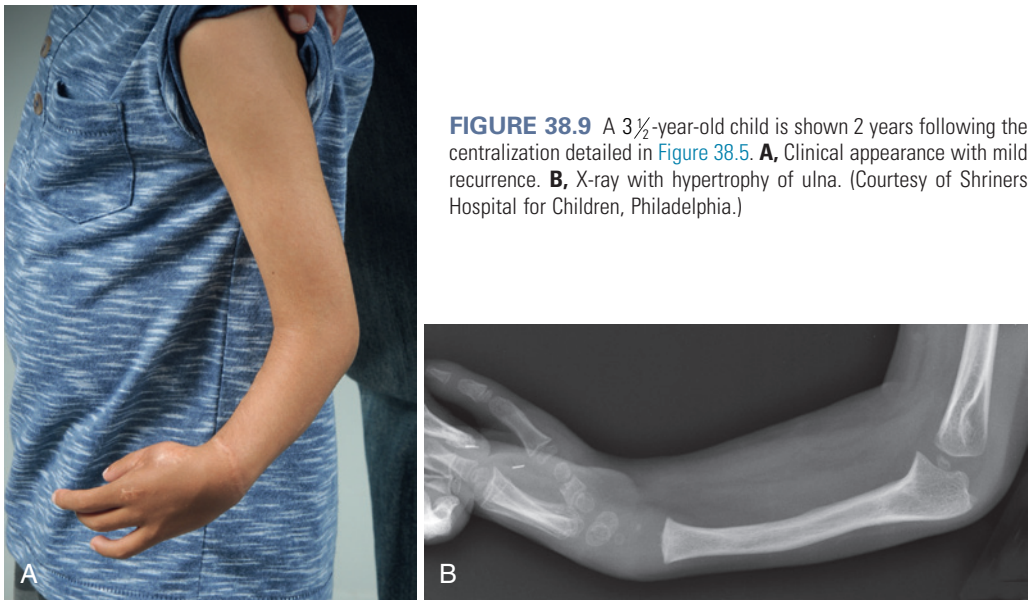

FIGURE 38.9 A 3½-year-old child is shown 2 years following the centralization detailed in Figure 38.5. **A,** Clinical appearance with mild recurrence. **B,** X-ray with hypertrophy of ulna. (Courtesy of Shriners Hospital for Children, Philadelphia.)

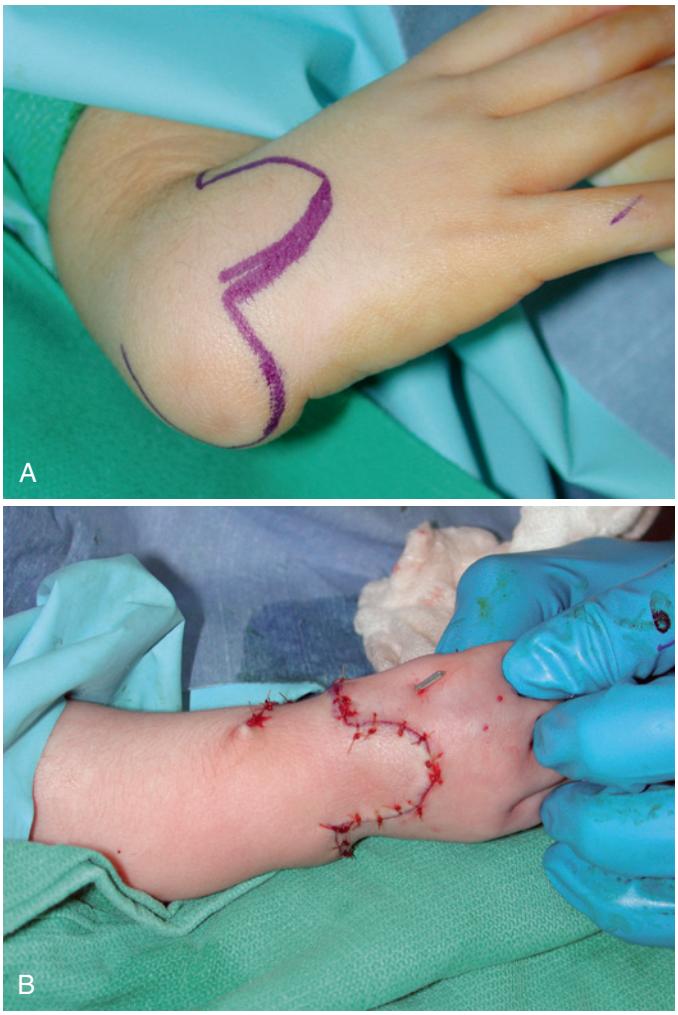

FIGURE 38.10 **A,** Bilobed rotational skin flap. **B,** Flap inset after musculotendinous releases and tendon transfers. (Courtesy of Marybeth Ezaki, MD.)

Radiographs should be taken of both upper extremities, both lower extremities, and the spine. Ulnar deficiency is rarely associated with anomalies of other organ systems.

PERTINENT ANATOMY

Most classification systems are based on elbow and forearm anomalies (Table 38.3).[80,116] To supplement these systems, Cole and Manske described a classification system based on thumb and first web anomalies (Table 38.4),[22] and Havenhill and colleagues included ulnar hand and carpal deficiencies without forearm or elbow involvement.[49]

Types of Operations

Surgical indications for many of the hand anomalies associated with ulnar deficiency are well established. Hand function is improved by release of the syndactyly and reconstruction of the thumb and first web deficiencies. Procedures that may be indicated include deepening of the first web space, opponensplasty, rotational osteotomy of the thumb metacarpal, and pollicization.[22]

With marked internal rotation of the limb combined with radiohumeral synostosis, the hand rests on the buttock or flank, and children may be unable to reach their mouth or place their hand on top of their head. Over time, children may compensate for this position and obtain adequate function (Figure 38.13). In recalcitrant cases, external rotation osteotomy of the humerus improves the position of the hand and the overall function of the limb.[80] Forearm rotational osteotomy is rarely necessary, even though the forearm is usually supinated. Rarely, the internal rotation deformity may recur with growth, necessitating a repeat external rotation osteotomy at skeletal maturity.

The indications for surgical treatment of ulnar deviation of the wrist and instability of the forearm are less certain. Several authors have reported that ulnar deviation at the wrist is due to tethering by the ulnar anlage, a fibrocartilaginous structure

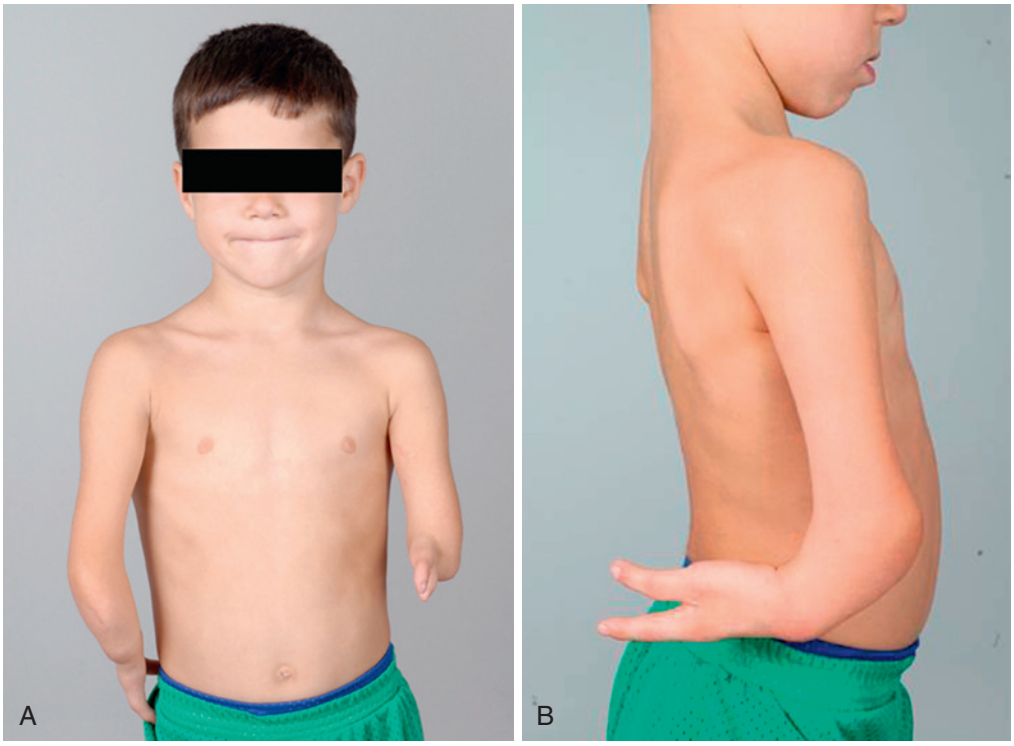

FIGURE 38.11 Four-year-old with bilateral ulnar deficiency. **A,** Frontal view showing asymmetric differences. **B,** Right hand in the classic "hand on flank" position. (Courtesy of Shriners Hospital for Children, Philadelphia.)

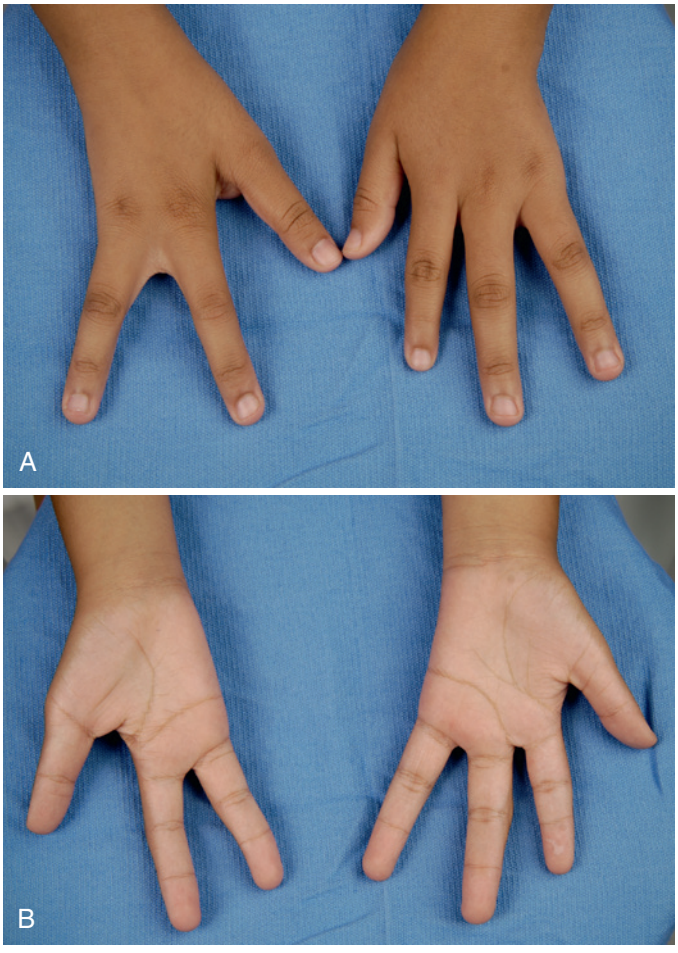

FIGURE 38.12 Nine-year-old with ulnar deficiency isolated to her hands. **A,** Dorsal view with three digits on the right hand and four digits on the left hand. **B,** Palmar view. (Courtesy of Shriners Hospital for Children, Philadelphia.)

occasionally found in the forearm of children with ulnar deficiency (Figure 38.14), hypothesizing that the ulnar anlage fails to grow with the radius and causes increasing ulnar deviation. Proponents of this theory have advocated early excision of the ulnar anlage to prevent progressive deformity.[16] Others, however, have shown that increasing ulnar deviation is uncommon, and therefore resection of the anlage should be reserved for documented progression.[80] The indications for surgical treatment of the forearm are even less defined. Some authors advocate surgical construction of a one-bone forearm to enhance forearm stability[108]; however, complete loss of forearm rotation may be detrimental to function.[16] The surgeon must remember that despite substantial differences, these children are adaptive and ingenious, especially with parental support and therapy guidance.

Thumb Reconstruction (Deepening of the First Web, Opponensplasty, Pollicization)

See Chapter 48.

Release of Syndactyly

See Chapter 36.

Excision of the Ulnar Anlage

The ulnar remnant is approached via a longitudinal incision along the ulnar border of the forearm (Figure 38.15). The ulnar extrinsic flexor muscles are often absent. The anlage will be adjacent to the ulnar neurovascular bundle, which must be protected as the anlage is dissected off its carpal attachment. The entire anlage need not be removed; removal of the distal third is adequate to release the tether. The subcutaneous tissue and skin are closed with absorbable suture and a long-arm cast is applied. The wrist is positioned as close to neutral as possible.

TABLE 38.3 Classifications of Ulnar Deficiency Based on Elbow and Forearm Anomalies

Characteristics	Kummel (1895)	Ogden et al (1976)	Riordan (1986)	Bayne (Dobyns 1993)	Swanson et al (1984)	Miller et al (1986)

TABLE 38.4 Classification of Ulnar Deficiency According to Thumb and First Web Anomalies

Type	Characteristics
A	Normal first web space and thumb
B	Mild first web and thumb deficiency
C	Moderate to severe first web and thumb deficiency; possible loss of opposition; malrotation of the thumb into the plane of the fingers; thumb/index finger syndactyly; absent extrinsic tendon function
D	Absent thumb

Modified from Cole RJ, Manske PR: Classification of ulnar deficiency according to the thumb and first web. *J Hand Surg [Am]* 22:479–488, 1997.

Casting is maintained for 6 weeks and followed by a short-arm splint that is worn at night until skeletal maturity.

Rotational Osteotomy of the Humerus

The distal end of the humerus is approached via a lateral incision.[80] Careful dissection is performed through the subcutaneous tissue, with care taken to visualize the radial nerve, which may be anomalous. The alignment of the humerus is marked by electrocautery or by inserting parallel Kirschner wires above and below the planned osteotomy site. A transverse osteotomy is performed, and the distal fragment is rotated until the hand can be placed in front of the trunk. Tight soft tissues may require bone shortening to prevent a traction injury to the neurovascular structures. The osteotomy is fixed with crossed Kirschner wires or a small plate. The subcutaneous tissue and skin are closed with absorbable suture. A well-fitted long-arm cast is applied and attached to the body with a Velpeau-type dressing.

Forearm Lengthening

This operation is rarely indicated (Figure 38.16).

Creation of a One-Bone Forearm

This operation is rarely indicated.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Excision of the ulnar anlage is reserved for children with progressive ulnar deviation of the wrist. The anlage may be resected at the same time as hand reconstruction, usually at around 1 year of age. Humeral rotational osteotomy is reserved for children who are impaired by inability to reach their hand to the

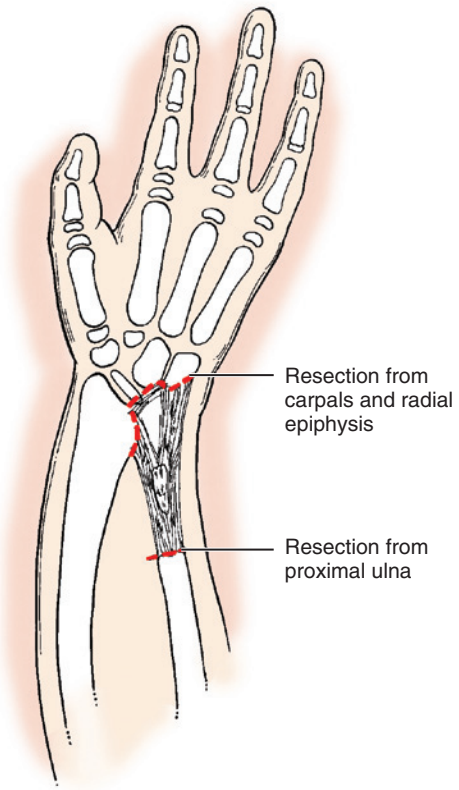

FIGURE 38.15 Excision of the ulnar anlage. This may prevent further ulnar deviation of the hand.

midline or to their face and head. Surgery is performed after children are old enough to evaluate their ability to perform activities of daily living. This age allows additional determination of the optimal limb position for function.

CRITICAL POINTS *Ulnar Deficiency*

- Ulnar deficiencies are associated with other musculoskeletal abnormalities that warrant careful physical examination supplemented by radiographs (e.g., congenital scoliosis).
- The forearm is difficult to manage and treatment should be individualized. Treatment is dependent on forearm stability, available elbow motion, and function. Surgery to restore motion for synostosis across the elbow or forearm (or both) is unsuccessful.
- Ulnar deficiencies may be accompanied by thumb anomalies ranging from a narrow web space to an absent thumb, which are a major predictor of function. The thumb deficiency limits prehensile activity and is treated by principles similar to those for isolated thumb hypoplasia.

Expected Outcomes

Children with unilateral ulnar deficiency generally function well, but those with radiohumeral synostosis, absent or stiff fingers, or bilateral deficiencies are more impaired.

MADELUNG DEFORMITY

Preoperative Evaluation

Madelung deformity consists of excessive radial and palmar angulation of the distal radius caused by a growth disturbance of the palmar and ulnar portion of the distal radial physis, although it may involve the entire radius.[138] The exact cause of this growth disturbance is still unknown. It may be due to a bony lesion in the ulnar portion of the distal radial physis and/or an abnormal palmar ligament tethering the lunate to the radius proximal to the physis (Vickers ligament) (Figure 38.17).[124] Madelung deformity is usually bilateral, and the deformity typically becomes clinically apparent in early adolescence. The underlying cause of this deformity is often Leri-Weill dyschondrosteosis, a genetic condition with a dominant inheritance pattern and 50% penetrance[79] that is due to a mutation in a short-stature homeobox-containing (*SHOX*) gene.[36] Repetitive loading of the wrist in a growing child may also cause partial physeal arrest. The resultant appearance is similar to Madelung deformity.[30]

The distal ulna of the affected wrist is dorsally prominent, and the distal radius appears to have a dorsal concavity in the lateral view (Figure 38.18). Ulnar deviation and extension may be decreased. The forearm is shorter than normal. Despite the clinical appearance, there is minimal functional impairment. In advanced cases, however, pain may limit function. Standard measurements have been established to characterize the severity of the deformity.[76]

Types of Operations

No treatment is necessary for painless deformities. However, physiolysis combined with release of the abnormal ligament should be considered for asymptomatic, skeletally immature patients. The most common motivation for surgery is appearance. Many patients dislike the distal forearm concavity and dorsal prominence of the distal ulna and request surgical correction.

A recalcitrant, painful deformity is an obvious indication for treatment. Physiolysis combined with release of the Vickers ligament[124] may reduce the pain and gradually improve the deformity during growth. However, most patients do not complain of pain until adolescence, when there is insufficient growth remaining for physiolysis to correct the deformity. In these instances, physiolysis and ligament resection may be combined with ulnar epiphyseodesis and/or a dome osteotomy of the radius.[48] In a skeletally mature patient with wrist pain, there are multiple options for correction of the deformity and relief of pain, including (1) ligament resection and dome osteotomy,[48] (2) radial closing wedge osteotomy and ulnar shortening,[95] (3) radial opening wedge osteotomy,[29] (4) radial osteotomy and distal ulnar resection,[95,128] and (5) radial osteotomy and the Sauvé-Kapandji procedure.[106]

For complex deformities in skeletally mature patients, three-dimensional modeling may be helpful to plan correction using multiple osteotomies. This technique is still in its early stages of development, but it seems to allow more precise correction than standard osteotomy techniques. To date, there is only one case report in the literature of using three-dimensional computer simulated bone modeling in Madelung deformity.[53]

Physiolysis

The radius is approached through a longitudinal palmar incision (Figure 38.19).[124] Exposure proceeds ulnar to the palmaris longus and flexor carpi radialis tendons to protect the radial artery and median nerve. The distal edge of the pronator

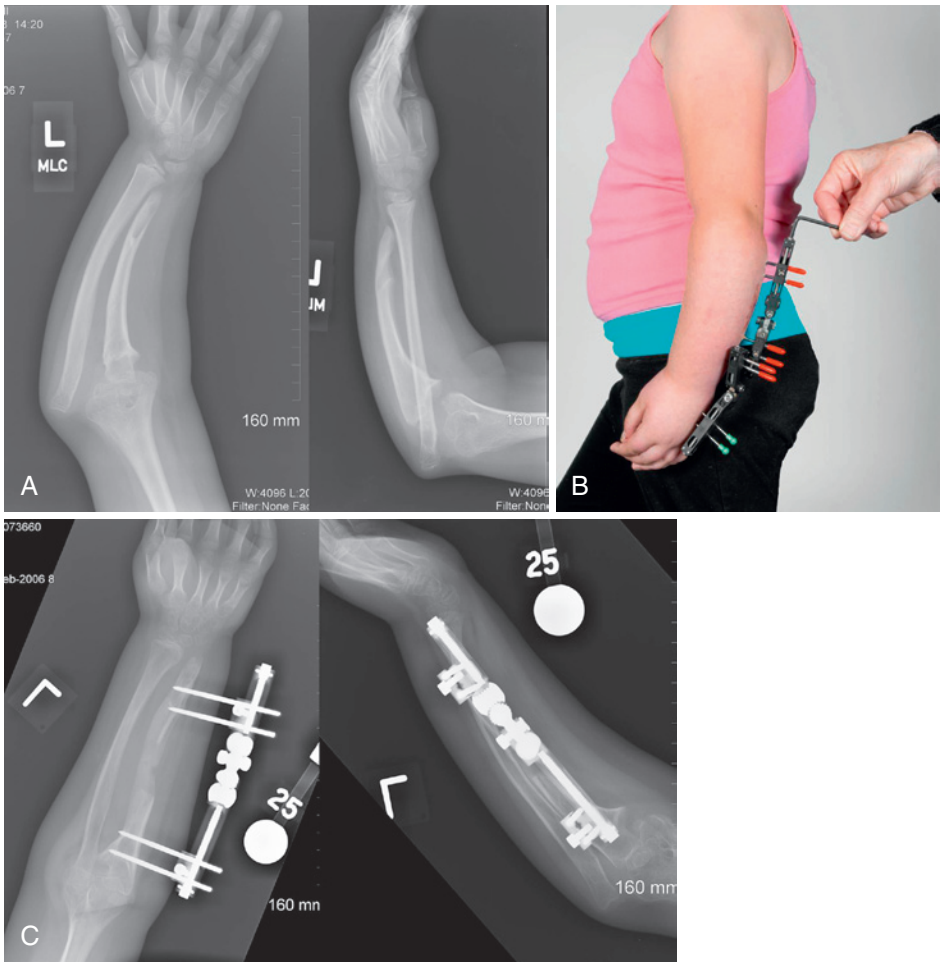

FIGURE 38.16 Ulnar lengthening for ulnar deficiency. **A,** Preoperative radiographs demonstrating significant dislocation of the radial head. **B,** Uniplanar external fixator in place. **C,** Postoperative radiographs demonstrating bone regeneration through the osteotomy site, with improved position of the radial head. Complete reduction of the radial head was not attempted given the long-standing nature of the deformity.

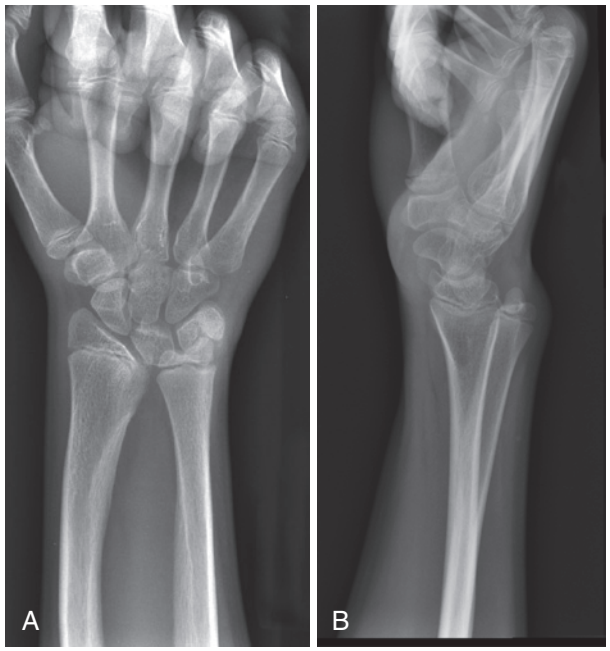
quadratus muscle is located. A flap of distal radial periosteum that includes the Vickers ligament is raised in a proximal to distal direction. The flap is elevated until the physis is identified, which appears narrow and wavy. The lunate is carefully protected. Any tethering fibrous tissue and bone about the physis are removed. A fat graft may be inserted into any physeal defect to inhibit bone formation. The fat graft is held in place by the surrounding soft tissue. The skin is closed with running absorbable suture, and the forearm is immobilized in a bulky compressive dressing with a removable wrist splint. A similar procedure can be done dorsally for reverse Madelung deformity.

Physiolysis and Dome Osteotomy

A longitudinal palmar incision is made starting just proximal to the wrist crease along the flexor carpi radialis tendon (Figure 38.20).[48] The radial artery is protected, and the pronator quadratus is incised near its radial border while leaving a cuff of tissue for later repair. Ulnar reflection of the pronator quadratus reveals the Vickers ligament, which is released from the radial metaphysis and reflected distally. The metaphysis of the distal radius is exposed. A biplanar dome osteotomy is performed with curved osteotomes or a curved oscillating saw. The dome osteotomy can be convex like a smile or concave like a frown depending upon surgeon preference. The distal radius fragment is manipulated from an anterior ulnar position to a dorsal ulnar position. The dome shape of the osteotomy makes this complex three-dimensional deformity easier to correct than with a simple wedge osteotomy. A Steinmann pin may be used as a joystick to position the distal fragment. The distal fragment is pinned to the proximal fragment after coverage of the lunate has been achieved. Definitive fixation can be accomplished by



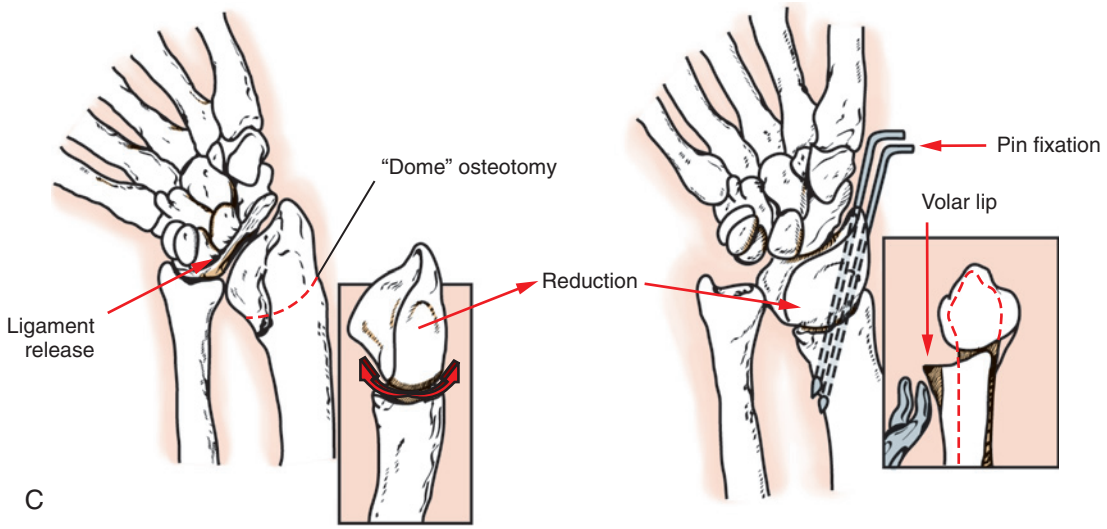


FIGURE 38.20 Eleven-year-old with Madelung deformity. **A,** Anteroposterior x-ray. **B,** Lateral x-ray. **C,** Technique of ligament release and dome osteotomy.

(Courtesy of Shriners Hospital for Children, Philadelphia.)

two parallel pins inserted from the radial styloid across the osteotomy site or a plate and screw construct contoured across the osteotomy. The palmar step-off of the proximal fragment is removed with a rongeur; the dorsal step-off will remodel after the osteotomy heals. If possible, the pronator is repaired. The subcutaneous tissue and skin are closed with absorbable suture. A long-arm splint or cast is applied. The pins are removed after 6 weeks, and the osteotomy is protected for an additional 4 to 6 weeks with a removable splint.

Dorsal Closing Wedge Osteotomy of the Distal Radius and Ulnar Shortening

The size and shape of the radial wedge osteotomy are planned according to the preoperative radiographs and amount of deformity.[95] The goal is to restore palmar and radial tilt. The osteotomy is performed at the point of maximum angulation through either a dorsal or volar approach. Plate fixation is preferred. The ulna is shortened with standard techniques. The goal is to obtain a neutral or slight ulnar-minus variance. Dynamic compression plate fixation is preferred.

Multiple Osteotomies Using Three-Dimensional Modeling

Three-dimensional imaging of the deformity is most easily achieved via computed tomography (CT) scanning with three-dimensional reconstruction. Because bilateral involvement is typical of the Madelung deformity, the use of the contralateral wrist as a model for comparison can be difficult. If the contralateral wrist is asymptomatic and not severely affected, it can be used as the comparison model. Other options for comparison models include generic bone models and those of prior patients. Using the appropriate computer software, the three-dimensional models of the affected bone are superimposed onto the goal model and osteotomies planned. From these data, physical bone models are fabricated using three-dimensional printing techniques, along with customized guides to assist with plate and screw placement and the pre-planned osteotomy sites.

Radial Opening Wedge Osteotomy

See the work of de Paula and colleagues.[29]

Distal Radial Osteotomy and Distal Ulnar Resection

See earlier for distal radial osteotomy, and see Watson and associates for details of distal ulnar resection.[128]

Distal Radial Osteotomy and the Sauvé-Kapandji Procedure

See earlier for distal radial osteotomy and Shroven and colleagues for details of the Sauvé-Kapandji procedure.[106]

❖ AUTHORS' PREFERRED TECHNIQUE

Physiolysis alone may provide satisfactory correction in a young patient with early Madelung deformity (Figure 38.21). However, when initially seen, most patients have considerable deformity and limited growth potential. Physiolysis combined with dome osteotomy is the most common procedure for mild to moderate deformity without distal radioulnar joint (DRUJ) degeneration. This can be done prior to skeletal maturity using smooth pins for fixation. Osteotomy of the radius in conjunction with some form of ulnar resection is warranted in older patients with DRUJ arthritis.

CRITICAL POINTS *Madelung Deformity*

- Madelung deformity is characterized by radial and palmar angulation of the distal radius caused by a growth disturbance in the palmar and ulnar portion of the distal radial physis (Figure 38.22).
- The growth disturbance may be due to a combination of a bony lesion in the ulnar portion of the distal radial physis and an abnormal palmar ligament tethering the lunate to the radius proximal to the physis (Vickers ligament).
- No treatment is necessary for a painless deformity. However, asymptomatic skeletally immature patients with progressive deformity should be considered for physiolysis and release of the abnormal ligament.
- Most patients are first seen in adolescence with limited growth potential and considerable deformity. In these cases, physiolysis and ligament resection are combined with osteotomy to realign the radius.

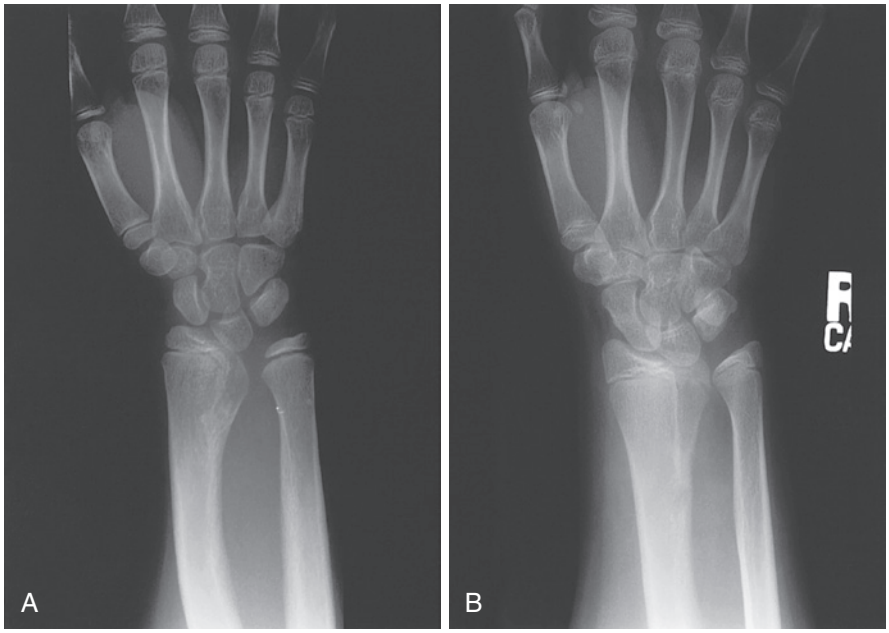

FIGURE 38.21 **A,** Preoperative radiograph showing Madelung deformity of the right wrist of a skeletally immature girl. **B,** Postoperative film of the same wrist 28 months after physiolysis. Longitudinal growth has been restored, and there has been no increase in deformity.

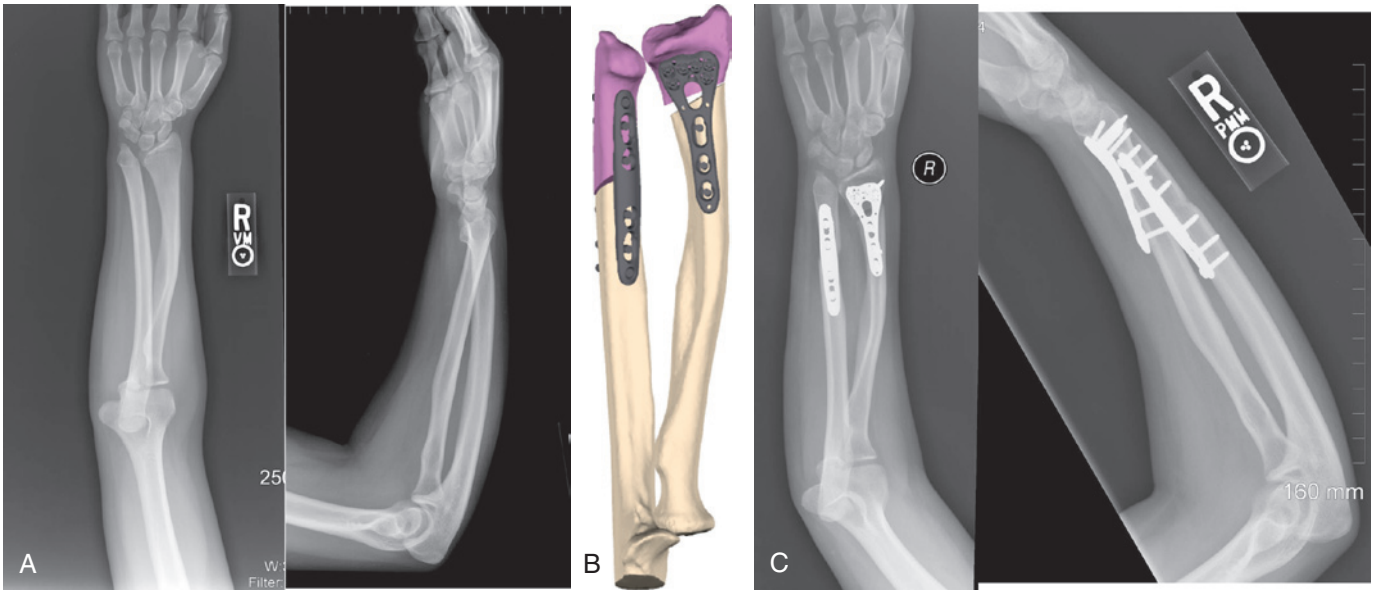

FIGURE 38.22 **A,** Preoperative radiograph showing severe Madelung deformity of the right wrist of a skeletally mature girl. **B,** Preoperative computer model demonstrating planned correction of the radius and ulna. **C,** Postoperative radiographs. FIGURE 38.23 **A,** Preoperative Madelung's deformity. **B,** Postoperative correction with a dome osteotomy through the distal radial metaphysis. (Courtesy of Shriners Hospital for Children, Northern California.)

Expected Outcomes

Physiolysis alone is unlikely to yield satisfactory correction except in young patients with mild deformity. In most cases, dorsal wrist pain is relieved by distal radial osteotomy and DRUJ pain by ulnar shortening, with several reports of good long-term results.[95] Both dome osteotomy and closing wedge radial osteotomy improve appearance by reducing the dorsal concavity associated with Madelung deformity (Figure 38.23). Ulnar shortening reduces the dorsal distal ulnar prominence. Three-dimensional modeling can be used to create a patient-specific plan of multiple osteotomies for precise correction of this complex deformity.

TRANSVERSE DEFICIENCY

Evaluation

Transverse deficiency, often inaccurately termed *congenital amputation*, occurs when the upper limb fails to form below a certain level. The most common level of failure of formation is at the proximal part of the forearm or below the elbow (Figure 38.24), followed by transcarpal, distal forearm, and through-humerus (above-elbow) failure. This condition is almost always unilateral.[134] In the previous edition of this chapter, this condition was referred to as "transverse failure of formation." It is now more commonly referred to as transverse deficiency and

FIGURE 38.24 A child with a right short, below-elbow transverse deficiency. (Courtesy of Shriners Hospital for Children, Northern California.)

categorized as a failure of axis formation or differentiation of the entire upper limb.[87]

Transverse deficiency is sporadic. The most prevalent theory of causation is vascular compromise of the developing limb bud or apical ectodermal ridge (see Chapter 35).[50] Risk factors include maternal use of misoprostol (Cytotec), alcohol, tobacco, or cocaine, as well as low maternal intake of riboflavin.[25,35,40,71,100] but for most cases the cause is unknown.

PERTINENT ANATOMY

The diagnosis is readily apparent, although there is variability in the length of the residual limb. The most common transverse deficiency is at the level of the proximal forearm. The elbow generally has full flexion and extension. Forearm rotation is frequently restricted by proximal radioulnar abnormalities. Finger nubbins are usually present at the distal end of the limb, which may be evidence of an intrauterine attempt at limb regeneration.[41] Elbow and forearm radiographs should be obtained.

Types of Operations

Some parents want their infant's nubbins removed, but older children with nubbins rarely request this procedure. Children with nubbins use them for sensory feedback and manipulation of small, light objects. Some surgeons remove these nubbins routinely, arguing that the resulting stump is more aesthetically pleasing and easier psychologically for the family, but this is not our current practice. We believe removal of finger nubbins from the distal end of the amputation stump is not indicated unless they frequently become infected or the small nails become problematic.

There have been isolated reports of forearm lengthening for transverse below-elbow deficiency.[2] However, this procedure has a high complication rate and has not been proven to help with function.

The Krukenberg procedure may be indicated in rare instances. The radius and ulna are separated and the muscles reattached such that the radius pinches against the ulna. This procedure is traditionally reserved for blind bilateral distal forearm amputees because it provides unilateral prehension with sensory feedback. However, it may occasionally be indicated for a sighted child with below-elbow deficiency and a long forearm.[64,68] To date there are few published data regarding functional improvements after this procedure, and the appearance of the Krukenberg forearm is strikingly abnormal.

Great improvements have been made in hand transplantation, such that more than 70 hand transplants have been performed for adults with upper extremity amputations due to trauma.[85] Parents of children with congenital limb deficiency may ask about this procedure. At this time, hand transplantation is contraindicated for children with transverse deficiency. They are unlikely to have formed muscles to move a transplanted hand, and the risks of prolonged immunosuppressive medications outweigh the potential benefits, as their level of functioning is extremely high.

❖ AUTHORS' PREFERRED TECHNIQUE

The greatest challenge in the treatment of children with transverse deficiency is helping parents adjust their often unrealistically high expectations of prosthetic technology. Good communication is important and should focus on numerous areas, including the remarkable abilities of the child with or without the prosthesis (Figure 38.25), the opportunity to try different prostheses as the child grows, and the need for improved prosthetic technology. Surgery is rarely required.

CRITICAL POINTS *Transverse Deficiency*

- Congenital transverse deficiency is classified according to the last remaining bone segment. A short below-elbow type of failure of formation is the most common transverse deficiency of the upper extremity.
- The residual limb is usually well cushioned, with rudimentary nubbins or dimpling often found on the end.
- These anomalies are generally unilateral, sporadic, and rarely associated with other anomalies.
- Prostheses have not been found to improve performance of everyday activities.
- Surgery is not usually indicated.

Expected Outcomes

Cognition and developmental milestones are generally normal, except that a child with a very short arm may not crawl. Children with unilateral below-elbow transverse deficiencies have few if any functional deficits. Prostheses do not improve performance of everyday activities[54] and are frequently abandoned.[28] Specialized prostheses may assist in the performance of higher-level activities, such as mountain bike riding or playing a violin.

FIGURE 38.25 Eight-year-old competitive swimmer with right below-elbow transverse deficiency. **A,** Clinical picture. **B,** Swimming prosthesis to facilitate competition. (Courtesy of Shriners Hospital for Children, Philadelphia).

CONGENITAL DISLOCATION OF THE RADIAL HEAD

Preoperative Evaluation

Congenital dislocation of the radial head (CDRH) is the most common congenital anomaly of the elbow and is usually bilateral.[97] CDRH may be sporadic or familial, but its cause is unknown. The radial head may be dislocated in an anterior, posterior, or lateral direction. Almquist and coworkers reported that 47% of dislocations are anterior, 43% are posterior, and 10% are lateral.[4] About 60% of congenital radial head dislocations are accompanied by other upper extremity congenital anomalies, whereas the remaining 40% are isolated findings.[81] CDRH is associated with congenital radioulnar synostosis[81] and numerous syndromes, including Klinefelter, Cornelia de Lange, Ehlers-Danlos, and nail-patella syndromes.

A delay in medical evaluation is common with CDRH. The lack of forearm rotation is unrecognized until the complexities of daily activities amplify the problem, such as catching a ball or eating soup. CDRH is often recognized after a perceived elbow injury and may be erroneously attributed to that injury. When unilateral, CDRH may be difficult to distinguish from chronic traumatic dislocation (Table 38.5).[65] The initial complaint usually involves prominence and restricted elbow and forearm motion. Elbow "popping" or pain with activity is uncommon before adolescence. Magnetic resonance imaging (MRI) can be helpful in distinguishing CDRH from a traumatic dislocation. In CDRH, the radial head generally remains intracapsular, whereas in a traumatic radial head dislocation, the radial head usually tears through the elbow joint capsule. Additionally, the shapes of the cartilaginous radial head and capitellum can be assessed using MRI. In CDRH, the radial head is generally convex instead of concave, and the capitellum is hypoplastic and ovoid instead of round.

TABLE 38.5 Congenital Versus Traumatic Radial Head Dislocation

Feature	Congenital	Traumatic
Trauma	Sometimes	Always
Radial head	Dome shaped, no central concavity (anterior dislocation) Elongated and narrow (posterior dislocation)	Normal shape with a concavity
Bilateral	Common	Rare
Other anomalies	Common	Rare
Ulna	Shortened; possible palmar bow (anterior dislocation) or dorsal bow (posterior dislocation)	Normal
Capitellum	Hypoplastic or absent	Normal

Data from Mardam-Bey T, Ger E: Congenital radial head dislocation. *J Hand Surg [Am]* 4:316–320, 1979; and Kelly DW: Congenital dislocation of the radial head: spectrum and natural history. *J Pediatr Orthop* 1:295–298, 1981.

An anteriorly dislocated radial head is palpable just distal to the cubital fossa, whereas a posteriorly dislocated radial head is palpable and visible lateral to the capitellum. Posterior CDRH usually impedes terminal extension (≤30 degrees), and anterior CDRH may limit full flexion (Figure 38.26). Diminished forearm rotation in both pronation and supination is common. Slight limitation of wrist motion may be present.

FIGURE 38.26 Seven-year-old with bilateral posterolateral radial head dislocation. **A,** Clinical picture. **B,** Prominent radial head. **C,** Lack of full elbow extension and restricted forearm supination. (Courtesy of Shriners Hospital for Children, Philadelphia.)

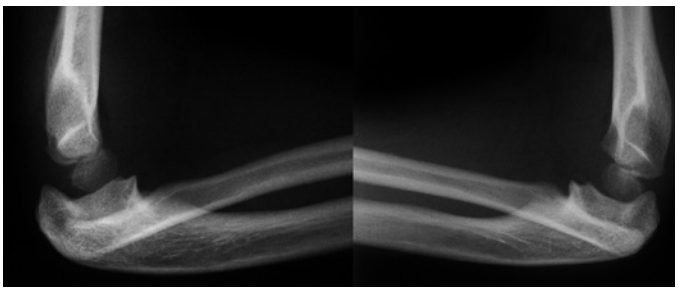

FIGURE 38.27 Lateral x-rays of a 7-year-old confirming bilateral posterolateral radial head dislocation. (Courtesy of Shriners Hospital for Children, Philadelphia.)

The limitation of elbow and forearm motion rarely causes considerable functional impairment. Certain activities that require the extremes of motion may be limited, such as accepting change and performing push-ups. In older children, erosions may develop between the radial head and capitellum and cause pain and additional loss of motion.

The diagnosis is generally confirmed by radiography (Figure 38.27). A line drawn through the longitudinal axis of the radial shaft does not bisect the capitellum. The radial head is dome shaped. The ulna bows, depending on the direction of the radial head dislocation. With anterior dislocations, the ulna bows into extension, whereas posterior dislocations cause a bow into flexion. Similar bowing, however, also occurs with unreduced Monteggia fracture-dislocations. Additional radiographic findings include dysplasia of the capitellum and ulnar-positive variance of the wrist.

Types of Operations

Surgical intervention is seldom necessary in childhood. Most children are asymptomatic and have minimal functional limitations.[31] Open reduction of a congenitally dislocated radial head with reconstruction of the annular ligament has not been consistently successful[4,81,104] and is not recommended at this time.

Radial Head Resection

In adolescence or adulthood, a dislocated radial head may become painful because of degenerative changes at the point of contact between the radial head and the distal humerus. This is the best indication for resection of the radial head, although appearance and limited forearm rotation are relative indications. In a small series with an average 10-year follow-up after surgery, Bengard and colleagues demonstrated that 25% of patients who underwent radial head excision for CDRH developed wrist pain requiring additional surgery.[11] For this reason, we recommend that radial head excision be reserved for patients with significant elbow pain, and that the operation be delayed until skeletal maturity whenever possible.

Excision of the radial head in posterior CDRH is performed using an approach through the interval between the extensor carpi ulnaris and the anconeus (Kocher approach) or directly over the prominent radial head (Figure 38.28). The capsule is incised with the forearm in maximum pronation. The capsular incision is not extended distal to the radial neck to avoid injuring the posterior interosseous nerve. Reverse retractors are placed around the radial neck. The radial head is excised with a saw perpendicular to the radial neck (Figures 38.29 and 38.30). The elbow is moved through a full range of motion to make sure that the proximal radius does not contact the distal humerus. Additional impingement requires further resection. The capsule is closed with nonabsorbable suture (Figure 38.31). The subcutaneous tissue and skin are closed, and the arm is placed in a long-arm splint with the elbow at 90 degrees and the forearm in neutral rotation for 7 to 10 days.

FIGURE 38.28 Lateral incision just anterior to the lateral epicondyle and extending in a distal direction over the radial head. A Freer elevator indicates the Kocher interval between the extensor carpi ulnaris and the anconeus. (Courtesy of Shriners Hospital for Children, Philadelphia.)

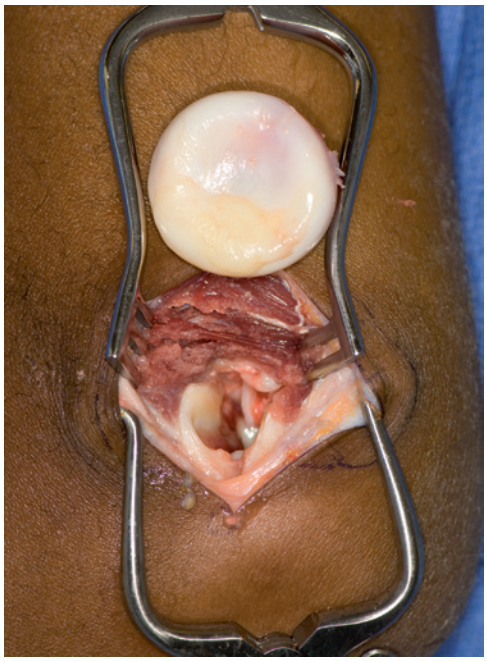

FIGURE 38.30 Radial head removed after osteotomy of the radial neck. (Courtesy of Shriners Hospital for Children, Philadelphia.)

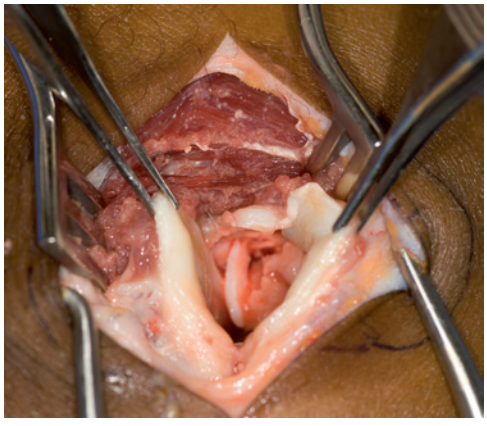

FIGURE 38.31 The capsule is carefully closed with nonabsorbable suture. (Courtesy of Shriners Hospital for Children, Philadelphia.)

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Because young children with CDRH are relatively asymptomatic, most cases are managed by observation. Open reduction with soft tissue reconstruction of the annular ligament to maintain the reduction is unreliable, frequently complicated by recurrent radial head dislocation and elbow stiffness. Although the newer literature on combining radial head reduction with corrective ulnar osteotomy, as done for chronic Monteggia fracture-dislocations, is intriguing, this procedure has yet to be proved effective for CDRH. The most unpredictable variable is the shape of the radial head. Even though MRI and arthrography may help assess head shape, it is difficult to maintain a reduction when the radial head is ovoid. In adolescents, pain and further restriction of motion may occur because of degenerative changes between the radial head and the distal humerus. Radial head excision reliably relieves pain, improves the appearance, and may increase the range of motion, although it may be complicated by wrist pain caused by incompetence of the interosseous membrane.

Expected Outcomes

Radial head excision for the treatment of CDRH reliably results in decreased elbow pain and improved rotation.[15] Complications include regrowth of the proximal radius, postoperative radioulnar synostosis, and cubitus valgus deformity.[15,62] Other potential complications include injury to the posterior interosseous nerve, proximal migration of the radius (Essex-Lopresti lesion), and wrist pain.[4,11,15]

PROXIMAL RADIOULNAR SYNOSTOSIS

Preoperative Evaluation

Congenital proximal radioulnar synostosis (PRUS) is an uncommon anomaly caused by failure of prenatal separation of

CRITICAL POINTS *Congenital Dislocation of the Radial Head*

- Dislocation of the radial head is usually bilateral. The radial head most commonly dislocates in an anterior or posterior direction. Lateral dislocation is less common.
- A delay in initial medical evaluation is frequent because the lack of forearm rotation is unrecognized until the complexities of daily activities amplify it, such as catching a ball or eating soup.
- The diagnosis is generally confirmed by radiography as the radial head fails to align with the capitellum. Other radiographic abnormalities include an ovoid shape of the radial head and hypoplasia of the capitellum.
- Surgery is seldom necessary in childhood. The limitation of elbow and forearm motion rarely causes considerable functional impairment.
- Open reduction of the radial head with reconstruction of the annular ligament has not been consistently successful. Ulnar distraction osteotomy may improve the odds of maintaining the reduction.
- In adolescence or adulthood, a dislocated radial head may become painful because of degenerative changes between the radial head and the distal humerus. Excision of the radial head reliably relieves pain and improves the appearance and may increase the range of motion, although it may cause wrist pain.

the radius and ulna, which normally occurs late in the first trimester.[103] PRUS is part of a spectrum of anomalies ranging from radial head abnormalities to complete synostosis and culminating in absence of the radial head.[103] PRUS may be sporadic or inherited as an autosomal dominant trait.[98] It is associated with other conditions in up to a third of affected children,[112] including thumb hypoplasia, carpal coalition, symphalangism, and clubfoot. Associated syndromes include Apert syndrome, arthrogryposis, fetal alcohol syndrome, and Klinefelter syndrome.[113]

Children with PRUS are usually seen initially between 2 and 6 years of age with painless absence of forearm rotation, the forearm fixed in pronation or supination (usually pronation), and a slight elbow flexion contracture (Figure 38.32).[112] Typically, a parent or teacher notices that the child has difficulty positioning the hand to catch a ball, drink from a cup, or accept small objects in an open palm or has trouble performing midline activities requiring the use of both hands (Figure 38.33). The delay in diagnosis is attributed to lack of requirement for forearm rotation in infants and the use of compensatory shoulder and wrist motion.[46,88] Forearm rotation must be assessed at the radial styloid and ulnar head to avoid measuring rotation through the radiocarpal, intercarpal, or carpometacarpal joints (Figure 38.34). Bilateral involvement is seen in approximately 60% of children, and the forearm is fixed in more than 60 degrees of pronation in approximately 40% of patients.[88,112] Children with bilateral involvement and forearms fixed in marked pronation have more functional limitations. In addition, PRUS is more often diagnosed during infancy in children whose arms are fixed in severe pronation and supination (Figure 38.35).

PRUS has been classified by Cleary and Omer into four types (Table 38.6). In children with PRUS and anterior dislocation of the radial head (type 4), an acute elbow flexion contracture may develop after either forced hyperflexion of the elbow or a prolonged period of flexion of the elbow,[73] possibly associated with an abnormal annular ligament–like structure.

PERTINENT ANATOMY

PRUS is initially cartilaginous and eventually ossifies, at which point it becomes visible on radiographs. The radial head may be dislocated. The synostosis is nearly always proximal, and the length of the synostosis varies.[103,112]

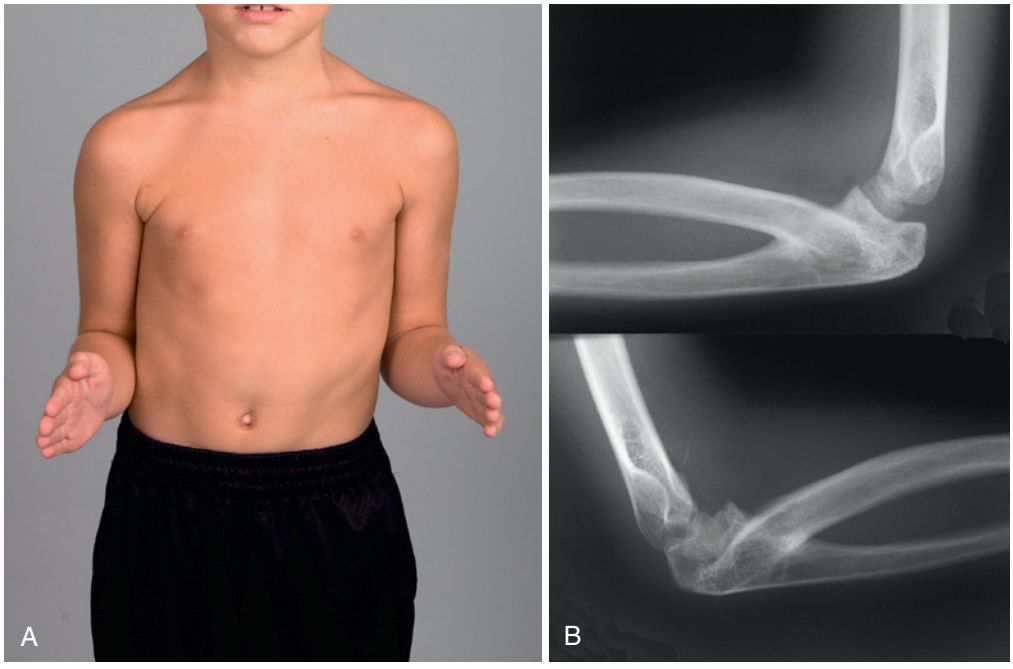

FIGURE 38.32 Seven-year-old with bilateral proximal radioulnar joint synostosis. **A,** Right forearm fused in neutral and left forearm fixed in slight pronation. **B,** X-rays confirming bilateral proximal radioulnar joint synostosis. (Courtesy of Shriners Hospital for Children, Philadelphia.)

Types of Operations

Resection of Synostosis

Surgery to restore forearm rotation by resection of the synostosis has uniformly been unsuccessful.[82] A review of the literature showed that resection of the synostosis and mobilization of the forearm failed in 22 of 23 forearms.[60] Interposition of a free vascularized fascial flap between the separated forearm bones may prevent recurrence of the synostosis,[59,60,61] but the amount of forearm rotation gained is small.

TABLE 38.6 Classification of Proximal Radioulnar Synostoses

Type	Radiographic Findings
1	Synostosis does not involve bone; radial head reduced
2	Visible osseous synostosis; radial head reduced
3	Visible osseous synostosis; radial head hypoplastic and posteriorly dislocated
4	Short osseous synostosis; radial head anteriorly dislocated and mushroom shaped

Derotation Osteotomy

Fixed extreme pronation (>60 degrees) that interferes with function is an indication for derotation osteotomy[84,112]; unilateral PRUS does not usually cause sufficient functional impairment to warrant surgical repositioning. The timing of surgery is controversial. Recommendations vary from before school age to waiting for the child to choose an intended occupation.[112] The child's preoperative rotational position should be carefully measured and recorded. The optimal rotational position of the forearm is also controversial because the best position varies with the task. Preoperative evaluation by an occupational therapist can help determine the individual child's functional deficits and optimal forearm position. Recommendations for surgical treatment of lateral synostosis have been to place the dominant forearm in 10 to 20 degrees of pronation and the nondominant forearm in neutral rotation; with the increasing use of technology requiring bilateral forearm pronation, many surgeons will now place both forearms in slight pronation, however. For unilateral PRUS, the forearm is generally placed in 0 to 15 degrees of pronation.[112] A study of the optimal rotational position for a one-bone forearm indicated that 30 degrees of pronation provides the best function for writing and working with small objects with the dominant arm.[20] In cultures where supination

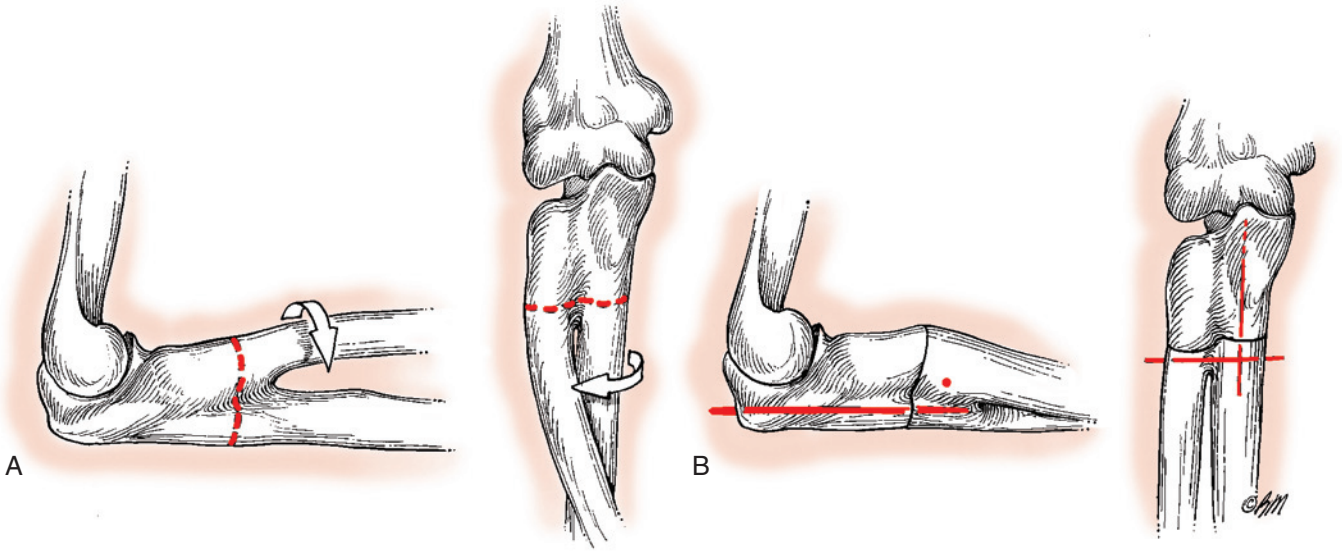

FIGURE 38.36 Rotational osteotomy for PRUS as described by Green and Mital. **A,** The desired position of rotation is attained by osteotomy through the synostosis mass. **B,** The new position is maintained by one longitudinal Kirschner wire and one transverse Kirschner wire that is incorporated into a cast. (Green WT, Mital MA: Congenital radioulnar synostosis: surgical treatment. *J Bone Joint Surg Am* 61:738–743, 1979.) (Copyright Elizabeth Martin.)

is more important for eating and hygiene, positioning the forearm in slight supination may be preferred.[111]

Derotation osteotomy is performed either through the fusion mass or through the proximal ulna and distal radius, and small Steinmann pins or a plate with screws is used for fixation (Figure 38.36).[46,82,88,112] Additional options include gradual correction with the Ilizarov method for severe deformity, two-stage osteoclasis without internal fixation, and osteotomy with bone morselization and cast immobilization.[13,34,70,84] If the desired amount of derotation is less than 30 degrees, an osteotomy at the distal radius alone may suffice.

A dorsal longitudinal incision is made along the subcutaneous border of the ulna at the level of the synostosis (Figure 38.37). The fusion mass is identified between the extensor and flexor carpi ulnaris muscles. Subperiosteal dissection is performed around the synostosis. A smooth Steinmann pin is placed from a percutaneous position through the olecranon apophysis into the intramedullary canal of the ulna under fluoroscopic guidance (Figure 38.38). The pin is positioned just proximal to the planned osteotomy site. A longitudinal mark is made across the osteotomy site to determine rotation. The osteotomy is performed with an oscillating saw through the fusion mass and distal to the coronoid process (Figure 38.39). The forearm is then rotated to the desired position. The osteotomy is transfixed with the longitudinal pin and an additional oblique pin (Figure 38.40). After closing the wound, the arm is placed in a splint or long-arm cast with the elbow flexed to 90 degrees. X-rays are taken to confirm fixation (Figure 38.41). The patient is admitted to the hospital overnight for strict elevation and neurovascular monitoring to check for compartment syndrome. The cast and pins are removed after bony union.

A substantial change in forearm rotation may result in traction injury to the posterior interosseous nerve or compartment syndrome. Methods to diminish neurovascular problems have been proposed, including resection of 5 mm of bone from the osteotomy site and prophylactic forearm fasciotomy.[18,88] Gradual sequential correction of severe forearm malposition with a two-stage osteoclasis technique[70,112] may also reduce this risk. One advantage of the procedure described above is that the oblique pin can be removed at bedside and the position of forearm rotation adjusted to diminish nerve traction; the morselization procedure also allows the position to be adjusted without reoperation if urgently indicated postoperatively.

Radial Head Excision

For the patient with an anteriorly dislocated radial head (Cleary and Omer type 4) who develops an acute elbow flexion contracture, radial head excision may reduce pain and restore motion.[121]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Surgery should be considered when the forearm is fixed in more than 60 degrees of pronation. Derotational osteotomy is the preferred method of treating this condition. Before deciding to pursue surgical correction, preoperative evaluation by a pediatric occupational therapist can help determine the individual child's functional deficits and optimal forearm position. Many children can compensate for lost forearm rotation by increased rotation through the radiocarpal and intercarpal joints, so accurate evaluation of forearm versus hand position in supination and pronation is important. The patient and parents need to realize that derotational osteotomy will only change the position of the synostosis, not increase forearm motion; this can be a difficult concept to explain to laypeople. The technique of derotational osteotomy is described earlier.

Postoperative Management and Expectations

Complication rates are high in reported series.[46,112] Wrist and elbow pain has been reported in adolescents after surgical treatment, but there are few reports with long-term follow-up.[63] The most serious complications are vascular compromise and compartment syndrome, which occur more frequently with changes of more than 85 degrees in rotational position. Immediate intervention is required to reduce the correction and release the forearm fascia.[103] In Simmons and colleagues' series of 22 patients, 4 required an emergency second operation to remanipulate the osteotomy because of poor vascularity of the forearm.[112] Green and Mital reported one patient with a Volkmann contracture postoperatively.[46] If excessive correction is needed, a two-stage operation or an ulnar-shortening osteotomy is safer. Other complications include posterior interosseous nerve palsy (as a result of either intraoperative damage or traction from rotational change), loss of correction, and nonunion.[70,84,103] Ogino and Hikino reported two radial nerve palsies occurring in 13 operations, with recovery at 4 and 8 weeks postoperatively.[88] Simmons and associates reported one posterior interosseous nerve palsy that recovered at 6 weeks and three patients who lost correction of 60, 50, and 20 degrees.[112] Green and Mital reported two patients who required repeat osteotomy.[46]

CRITICAL POINTS *Proximal Radioulnar Synostosis*

- In PRUS, forearm rotation is absent and the forearm is usually fixed in pronation.
- Children are generally first seen between 2 and 6 years of age with painless absence of forearm rotation and a slight elbow flexion contracture. The delay in diagnosis is attributed to lack of requirement for forearm rotation in infants and the use of compensatory shoulder and wrist motion.
- PRUS is usually visualized on radiographs, although the connection is initially cartilaginous and ossifies over time. The length of the synostosis varies, and a concomitant radial head dislocation may be present.
- Extreme pronation or supination that interferes with function is an indication for surgery. A forearm fixed in more than 60 degrees of pronation generally warrants correction.
- Surgery to restore forearm rotation has uniformly been unsuccessful.
- Corrective osteotomy, either through the fusion mass or in the distal radius and proximal ulna, is the preferred surgical treatment to better position the forearm. Complications are common after corrective osteotomy and include compartment syndrome, vascular compromise, radial nerve palsy, and loss of correction.

Expected Outcomes

Rotational osteotomy for PRUS is a reliable procedure for realigning the forearm.[88,112] Most children and parents note improvement in hand positioning for activities of daily living and midline activities. Rotational malalignment does not recur.[18]

CONGENITAL PSEUDARTHROSIS OF THE ULNA OR RADIUS

Preoperative Evaluation

Congenital pseudarthrosis of the ulna occurs when a segment of the ulna, usually in the distal or middle third, is replaced by fibrous tissue (Figure 38.42). This condition is rare and generally associated with neurofibromatosis. Seventy percent of persons with ulnar pseudarthrosis have neurofibromatosis.[23] Familial pseudarthrosis associated with neurofibromatosis has been reported but is unusual.[23]

FIGURE 38.42 Radiographs demonstrating congenital pseudarthrosis of the ulna. Note the large radiolucent defect, very little callus formation, and tapered bone ends. Radial head is dislocated.

Neurofibromatosis is an autosomal dominant trait with variable penetrance and a high rate of spontaneous mutation that occurs in approximately 1 in 3000 live births and is the most common single-gene disorder.[126] Congenital pseudarthrosis, most commonly in the tibia, develops in 5% to 10% of people with neurofibromatosis,[24,126] but its cause is unknown. In the majority of cases, the pseudarthrosis contains fibrous tissue and not a neurofibroma. Pseudarthrosis may occasionally involve both the radius and ulna or the radius alone (Figure 38.43).[96,107]

Congenital pseudarthrosis of the ulna causes a progressive forearm deformity, diminished rotation, instability, and weakness, and it may be painful. The forearm is short, and the radius bears the entire load of the forearm, which leads to radial bowing and eventually to radial head dislocation. The pseudarthrosis is diagnosed on radiographs, which also reveal the extent of radial bowing and position of the radial head (see Figure 38.42).

Types of Operations

The goals of surgical treatment are to achieve bony union, stabilize the adjacent distal radioulnar and ulnocarpal joints, and allow continued skeletal growth.[8] Similar to tibial pseudarthrosis, attempts to achieve union with nonvascularized bone

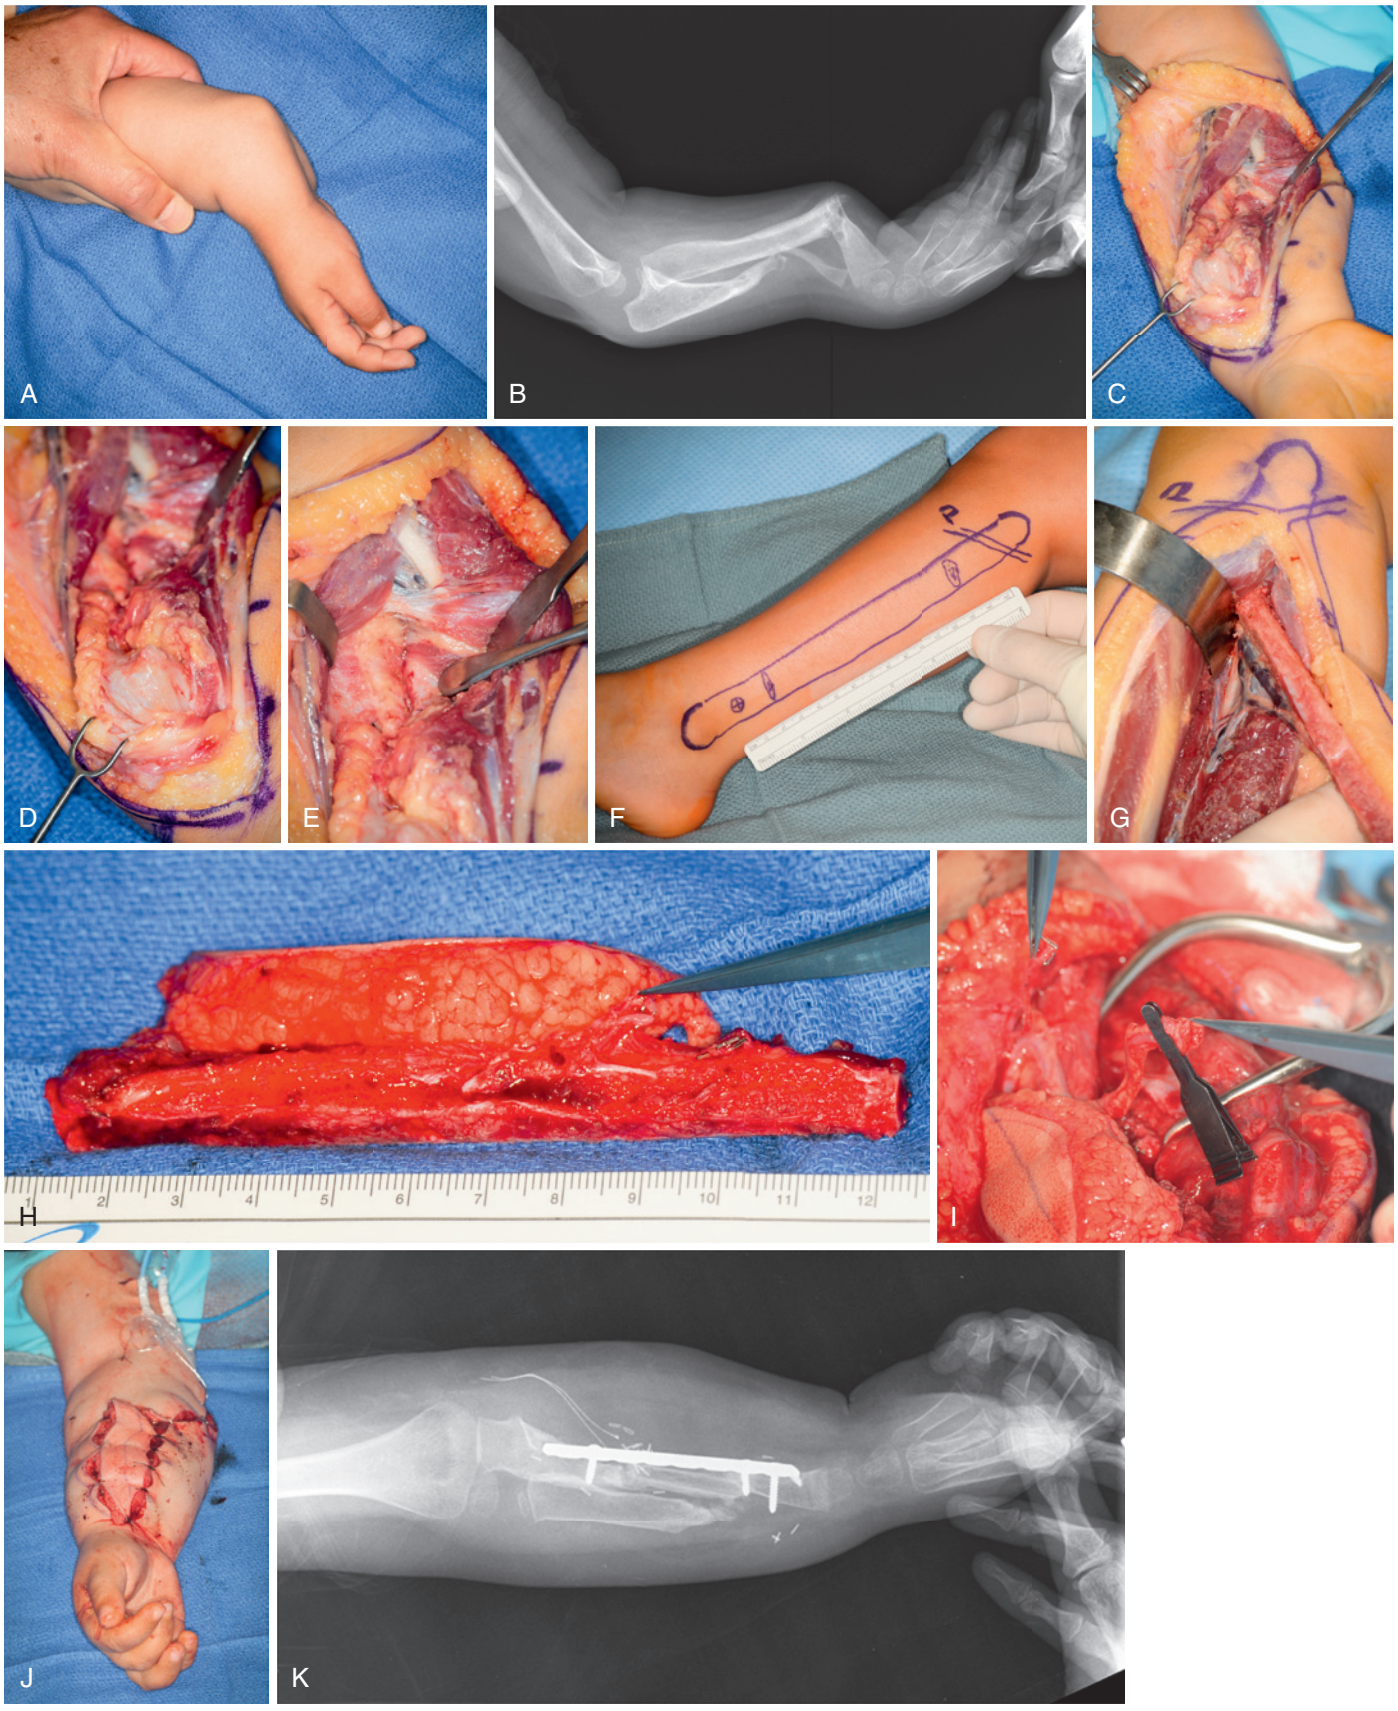

FIGURE 38.43 Four-year-old child with history of neurofibromatosis. He had fallen 1 year earlier and is presenting with persistent pain and deformity. **A,** Clinical picture of right forearm. **B,** X-ray with pseudarthrosis of the radius and ulna. **C,** Volar forearm exposure for free fibula from proximal ulna to distal radius. **D,** Distal radius exposure. **E,** Proximal ulna exposure. **F,** Free fibula preparation. **G,** Peroneal artery and venae comitantes. **H,** Free fibula with skin paddle. **I,** Radial artery for inflow. **J,** Loose closure and skin paddle. **K,** X-ray 3 months after surgery with early consolidation. grafting and immobilization usually fail.[89] Historically, creation of a one-bone forearm was the only option available to restore forearm stability.[92,126] Although external distraction techniques combined with compression across the pseudarthrosis may achieve short-term union in individuals with tibial pseudarthrosis,[91] in the forearm, differential lengthening of the paired bones results in loss of forearm rotation.

Resection of the pseudarthrosis and transfer of a free vascularized fibular graft to the defect reliably results in union. Preliminary distraction histogenesis may be necessary to achieve adequate soft tissue length. Fibular transfers maintain length and may preserve some forearm rotation.[3,74,96,107,130,135] A one-bone forearm may be necessary to restore forearm stability, especially when the pseudarthrosis affects both the radius and ulna (see Figure 38.43). Although follow-up of a large number of patients to skeletal maturity is pending, this technique is promising. In our series of five patients treated with this method, union occurred at an average of 10 months postoperatively, although one patient with a very distal pseudarthrosis of the ulna did require repeat surgery to achieve union.[9]

The donor fibula is contralateral to the pseudarthrosis to facilitate intraoperative positioning. Radiographs of both forearms and the donor leg are obtained. Preoperative arteriograms of the donor and recipient sites are not essential, but a preoperative Allen test is necessary to plan end-to-end versus end-to-side anastomosis of the ulnar artery to vascularize the fibular graft. The amount of fibular graft needed after resection of the pseudarthrosis is estimated. A minimum of the middle third of the fibula must be harvested to protect the nutrient artery. At least the middle half of the fibula can be harvested without knee or ankle instability. Some reports indicate that the distal 6 to 8 cm of fibula should be preserved to maintain ankle stability,[7,119,129] although other biomechanical studies indicate that only the distal 10% of the fibula is necessary to preserve ankle stability.[90] We prefer to perform a concomitant distal tibiofibular synostosis (Langenskiöld procedure) in children up to skeletal maturity to decrease the risk of valgus deformity at the ankle.

Two surgical teams are used to decrease operative time. The patient is placed in a floppy lateral decubitus position with the affected arm positioned along an arm board. The pseudarthrosis is exposed along the forearm, and the exposed neurovascular structures are isolated (see Figure 38.43, *C* to *E*). The entire pseudarthrosis is resected back to healthy bone at each end. The size of the defect determines the length of fibula resected.

Simultaneously, the fibula is harvested (see Figure 38.43, *F* to *H*). A longitudinal incision is made along the subcutaneous border of the fibula. The peroneal and soleus muscles are separated, and the fibular periosteum is left intact. The anterior tibial and peroneal vessels are isolated. Selection of the distal level for osteotomy is based on the amount of fibula required and the necessity to preserve ankle stability. After distal osteotomy, careful retraction of the fibula exposes the interosseous membrane, which is divided in its distal half. The proximal peroneal vessels and nerve are isolated. The proximal osteotomy is performed while protecting the neurovascular structures. At this point, the fibular segment can be externally rotated and the remaining interosseous membrane divided with preservation of the peroneal vessels adjacent to the middle third of the fibula.

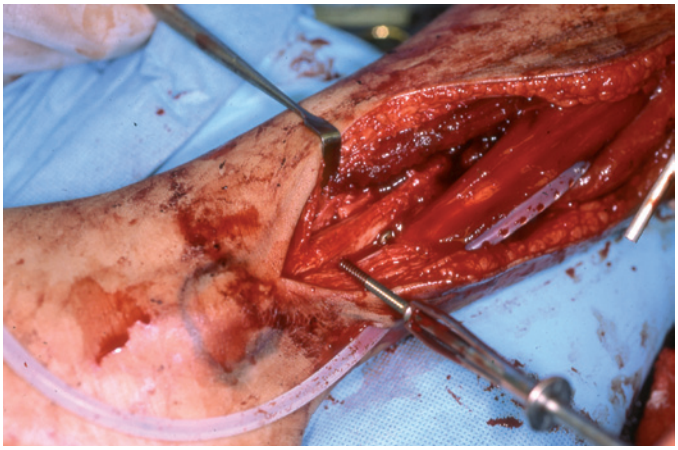

FIGURE 38.44 Distal tibiofibular synostosis performed to maintain ankle stability. (Courtesy of Shriners Hospital for Children, Philadelphia.)

The peroneal vessels are ligated at the level of the distal osteotomy. The tourniquet is deflated to ensure perfusion to the fibular segment. After the forearm is prepared, the peroneal artery and vein or veins are ligated proximally. The graft is passed to the arm and contoured to fit the deficit. Distal tibiofibular synostosis is performed to maintain ankle stability (Figure 38.44). Bone graft trimmed from the fibula or graft harvested from the iliac crest may be placed between the tibia and fibula. One or two syndesmosis screws are used for internal fixation. Care is taken to avoid placing screws through the distal tibial or fibular physis.

Internal fixation is used to secure the graft in place before vascular anastomosis. Both the recipient and donor bone are osteotomized in a step-cut or transverse fashion. The proximal osteotomy is always fixed with plate and screws. Frequently, the segment of distal metaphyseal bone that remains after resection of the pseudarthrosis is very short, thereby precluding plate fixation. Interfragmentary screw, Kirschner wire, or tension band fixation may be used to secure the graft distally. An end-to-end or end-to-side arterial anastomosis is performed between the peroneal and ulnar arteries. The peroneal veins are often larger than the venae comitantes and require anastomosis with subcutaneous veins about the forearm. Supplemental cancellous bone graft from the ends of the donor fibula or from the iliac crest can be placed at each end of the fibular graft to enhance union. The wound is closed with interrupted subcutaneous sutures and running absorbable skin sutures. A drain is placed if necessary. Long-arm and long-leg casts are applied.

In skeletally immature patients, Bae and associates proposed transferring the proximal fibular epiphysis with the vascularized fibular graft to allow subsequent skeletal growth.[8] Their series consisted of two children 3 and 5 years old in whom preoperative radiographs demonstrated atrophy, narrowing, and sclerosis of the entire distal ulna with obliteration of the intramedullary space and a paucity of callus formation. In these cases, the entire distal ulna was removed. To harvest the proximal fibular epiphysis, the proximal tibiofibular joint is opened and the lateral collateral ligament, biceps femoris, and peroneal muscle attachments are released. The peroneal nerve is isolated and protected. The graft is taken with both the peroneal and anterior tibial vascular pedicles to perfuse both the proximal

epiphysis and fibular diaphysis. This mandates vein graft reconstruction of the anterior tibial artery for two-vessel flow and adequate vascularity of the lower extremity. The triangular fibrocartilage and DRUJ capsules are repaired to the proximal fibular epiphysis. Follow-up of 33 months in one patient and 80 months in the other was reported to show skeletal growth matching radial growth. However, a recent report of two cases of epiphyseal transfer demonstrated premature physeal closure in both patients.[136]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Débridement of the pseudarthrosis and placement of a vascularized fibular graft successfully restore ulnar length and stability in most cases. The authors recommend performing this operation in younger children, before the radial head dislocates. Surgical tibiofibular synostosis is especially important in younger children to prevent progressive ankle valgus deformity.

Postoperative Management and Expectations

The patency of the anastomosis may be monitored at the surgeon's discretion; monitoring options include harvesting of the fibula with a skin paddle or implantable flow monitors. Postoperatively, the patient is kept warm, calm (with sedation if necessary), and at bed rest for 72 hours. One baby aspirin (81 mg) per day is administered for 7 to 14 days. Caffeine and cigarette smoke are avoided.

Weight bearing on the affected leg is not allowed for 6 weeks. Radiographs of both extremities are obtained with casts off at 6 weeks. Casting is then continued until radiographic union is apparent at each site. The decision between long-arm and short-arm casting is made based on the age of the child, the location of the pseudarthrosis, and the strength of the internal fixation.

A vascularized fibular graft achieves a higher rate of union than any other operative treatment of ulnar pseudarthrosis other than the one-bone forearm.[130] Unlike creation of a one-bone forearm, vascularized fibular grafting preserves motion. This operation is best performed early to reduce the chance of progressive forearm deformity.[130]

Suzuki and coauthors reported three patients with 5- to 8-year follow-up after vascularized fibular grafting for ulnar pseudarthrosis.[115] Anterior bowing of the ulna and anterior dislocation of the radial head developed in two, and the other had considerable shortening of the ulna at the wrist. The authors noted that although free vascularized fibular grafting is the treatment of choice for congenital ulnar pseudarthrosis, patients must be monitored radiographically during growth. No published studies have reported follow-up to skeletal maturity.

Donor site morbidity is a frequent occurrence. Progressive ankle valgus deformity may develop in skeletally immature patients after fibular resection.[38,90] This can be prevented or at least minimized by preserving adequate distal fibular length,[90] inserting a distal tibiofibular syndesmosis screw, creating a synostosis between the distal tibia and fibula (Langenskiöld procedure), or any combination of these measures.[38,90] Distal tibiofibular synostosis is the preferred method of stabilization of the fibula to prevent ankle valgus deformity. Other donor site problems include objective motor weakness, pain, and sensory abnormalities.[69,119]

CRITICAL POINTS *Pseudarthrosis of the Ulna or Radius*

- Congenital pseudarthrosis of the ulna occurs when a portion (usually the distal or middle third) has been replaced by fibrous tissue.
- Congenital pseudarthrosis is rare and is usually associated with neurofibromatosis, although the cause is unknown and the pseudarthrosis does not generally contain a neurofibroma.
- Pseudarthrosis causes forearm deformity, instability, and weakness.
- The goal of surgical treatment is to achieve bony union, restore forearm integrity, stabilize the adjacent distal radioulnar and ulnocarpal joints, and allow continued skeletal growth.
- Resection of the pseudarthrosis combined with transfer of a free vascularized fibular graft to the defect is the preferred technique; complications include anterior ulnar bowing with anterior dislocation of the radial head, instability of the DRUJ, and valgus instability of the ankle.

ELBOW AND FOREARM DEFORMITY CAUSED BY MULTIPLE HEREDITARY EXOSTOSES

Preoperative Evaluation

Multiple hereditary exostoses (MHE) is a disorder of enchondral bone growth, inherited in an autosomal dominant pattern with high penetrance[105] and variable expressivity. Cartilaginous exostoses, also called osteochondromas, grow from the physes of long bones and from the pelvis, ribs, scapula, and vertebrae.[5] Many different names have been used to describe MHE, including multiple cartilaginous exostoses, diaphyseal aclasis, dyschondroplasia, hereditary deforming chondrodysplasia, and osteochondromatosis.[132] MHE is frequently confused with multiple enchondromatosis (Ollier disease), an entirely different condition. Multiple exostoses can also occur in other conditions, such as metachondromatosis and Langer-Giedion syndrome.[77] The prevalence of MHE is approximately 1 in 50,000.[105] MHE has an equal prevalence in both sexes, although males tend to have more severe involvement (Figure 38.45).[77] The most common sites of involvement are the knee, humerus, hip, scapula, ribs, distal radius and ulna, ankle, elbow, hands, feet, and pelvis.[109,122] Approximately half of all patients with MHE have forearm involvement.[14,19,31,32,58,105,131,132]

Genetic studies of families with this condition have mapped the chromosomal abnormality to at least three different genes.[17,77,78] The genes are termed *EXT* genes and are located on different chromosomes.[39,47] Because the *EXT* genes are tumor suppressor genes,[27,94,122,133] MHE has been classified as a familial neoplastic syndrome.[94]

A clinical "bump search" on all long bones is indicated if MHE is suspected but the diagnosis has yet to be established. Shoulder, elbow, forearm, wrist, and digit range of motion should be measured. Serial measurements of forearm rotation are used to document progressive forearm deformity, and the length of the ulna can be measured clinically to derive the proportional ulnar length. Clement and Porter demonstrated that a shorter proportional ulnar length (the length of the ulna described as a percentage of the patient's height) is a risk factor for eventual radial head dislocation.[21] They described a cut-off of proportional ulnar length of 13% or less in males and 12% or less in females as the point at which forearm

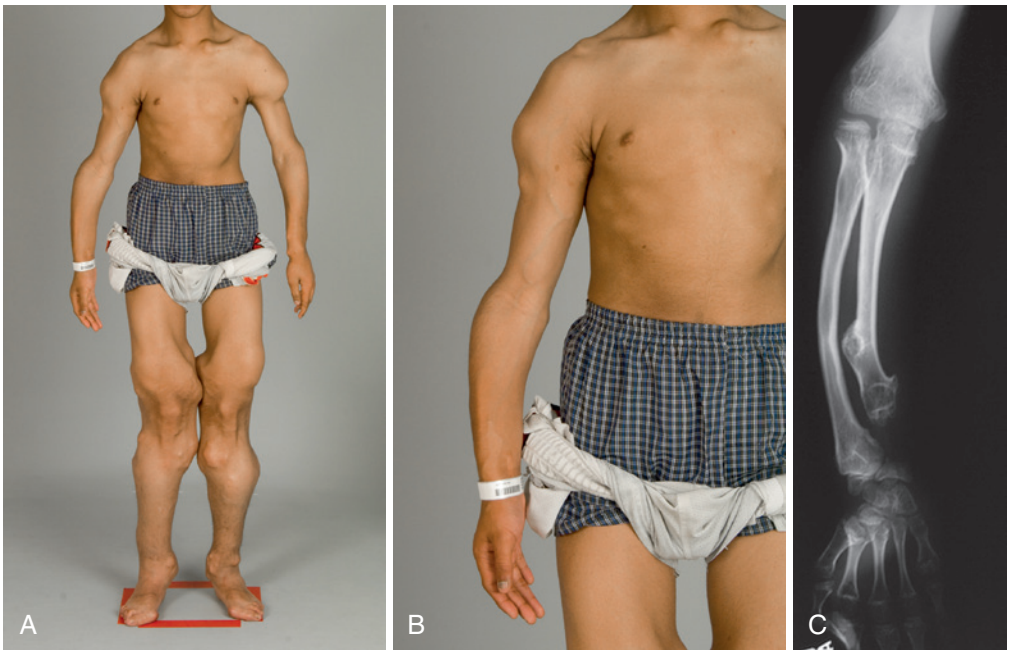

FIGURE 38.45 Sixteen-year-old boy with severe multiple hereditary exostoses. **A,** The upper and lower extremities are severely involved. **B,** Bowing of the right forearm. **C,** An x-ray shows ulnar shortening and radial bowing. The radiocapitellar joint is located. (Courtesy of Shriners Hospital for Children, Philadelphia.)

range of motion is likely to be below 100 degrees of rotation and thus limit activities of daily living. Radiographs should be obtained for any part of the extremity in which osteochondromas are suspected or that has a decreased range of motion. A thorough neurologic examination, including gait and reflexes, should be performed for all patients with MHE because intraspinal osteochondromas can lead to myelopathy.[6,99] Any neurologic abnormalities should prompt further workup. Occult intraspinal exostoses (without any neurologic symptoms) have been reported, in some instances leading to paralysis after minor trauma. In our practice, all patients with MHE undergo a screening spine MRI once they are able to do so without sedation, generally around the age of 5 or 6 years.

Most exostoses are asymptomatic and do not require removal. Exostoses removed before skeletal maturity may recur. However, exostoses may cause local discomfort, nerve or tendon impingement, decreased range of motion, and longitudinal and angulatory growth abnormalities.[17] Growth abnormalities may also occur in MHE in the absence of radiologically visible exostoses.[12] Several reports of adults with untreated forearm deformities secondary to MHE indicate that they maintain function and are comfortable with their appearance.[5,86,114] These reports question the role of aggressive surgical treatment to maintain or improve function. In evaluating the forearms of untreated adults with MHE, Noonan and colleagues demonstrated decreases in strength, motion, and function relative to controls; 77% were free of pain, only 13% thought that they were limited in performance of their jobs, and just 4% had evidence of osteoarthritis.[86] There were no radiographic measures that were associated with a poor outcome.

The exostosis may appear sessile (broad based) or pedunculated. More severe angular deformities appear to be associated with a predominance of sessile lesions.[17] Exostoses possess a cartilage cap and are larger than their radiographic appearance. MRI is not routinely performed but will reveal the size of the cartilaginous cap. It is the imaging technique of choice to evaluate for suspected malignant transformation.

Certain factors associated with exostosis about the forearm make the loss of forearm rotation over time more likely. On physical examination, reduced proportional ulna length is associated with radial head dislocation and diminished forearm rotation.[21] Radiographically, forearms with isolated osteochondromas of the distal ulna are more likely to develop radial head dislocation.[45] It is unknown if early ulnar lengthening has a long-term effect on forearm rotation.

Osteochondromas may cause local pain, visible deformity, and growth disturbance. Malignant transformation is uncommon. Local pain, caused by impingement of the osteochondroma on surrounding tissue, is a frequent indication for removal of the exostosis, which effectively relieves the pain. If forearm rotation is blocked by an exostosis, removal will often improve motion.

Forearm osteochondromas frequently cause a discrepancy in length of the radius and ulna.[109] The forearm deformities caused by growth arrest secondary to MHE are complex. Even when osteochondromas of the distal ulna are not visible on radiography, distal ulnar growth arrest is common; the ulnar physis appears to be especially susceptible to growth impairment, possibly because of its relatively small cross-sectional area. The resultant deformity is a length discrepancy between the two forearm bones. The radius becomes longer than the ulna and accepts the entire forearm load, which results in radial bowing, radial tilting, and dislocation of the radial head.[132] The increased radial inclination and lack of ulnar support position the wrist in ulnar deviation and cause the carpus to "slip" toward the

ulna.[14,21,109] The length discrepancy causes diminished forearm rotation.

Early removal of osteochondroma to retard or prevent progressive growth disturbances is controversial.[37,72] Hemiepiphyseal stapling of the radial side of the distal radius retards radial growth and allows correction of the radial articular angle and ulnar length discrepancy with growth.[132] Stapling may be performed in conjunction with ulnar lengthening in a skeletally immature child.[37] Ulnar lengthening may be performed in a single stage or by gradual distraction osteogenesis. Differential lengthening combined with angular correction can be used to reduce the radial head[52] because restoration of normal forearm anatomy may result in spontaneous reduction of the radial head. In patients with an isolated distal ulnar lesion, freeing the soft tissue tether between the ulna and ulnar-sided carpus and distal radius may prevent dislocation of the radial head. The dislocated radial head may become painful in adolescence; resection relieves the pain and removes the associated prominence.[5,72] Radial head resection may be indicated for pain, but it is delayed until skeletal maturity because removal of the radial head in a growing child may cause cubitus valgus or proximal radial overgrowth. Creation of a one-bone forearm may be used to salvage a severely disorganized forearm.[101]

In adults, an indication for excision of MHE is suspected malignant transformation. Symptoms and signs of malignant transformation include local pain and growth of an osteochondroma after skeletal maturity. Radiographic changes include internal lytic areas, erosion or destruction of the adjacent bone, and the presence of a soft tissue mass containing irregular calcifications.[122] Malignant transformation, however, is quite rare in the upper extremity.[118]

Contraindications to removal of osteochondromas are relative. Simple procedures, such as removal of symptomatic osteochondromas and dislocated radial heads, may improve the appearance and relieve pain with a low complication rate. Complicated procedures, such as forearm lengthening, are more likely to be associated with complications, but it is theoretically possible that ulnar lengthening may prevent radial head dislocation and loss of forearm rotation in selected patients.[1,21,45]

Careful preoperative neurologic and range-of-motion examinations and up-to-date radiographs are required before surgery. The patient, parents, and surgeon should agree on exactly which osteochondromas will be removed because there are often several present.

PERTINENT ANATOMY

Masada and associates developed a classification scheme for forearm deformities based on location of the osteochondromas.[58,72] This scheme is based on the location of the main forearm osteochondroma, the resultant deformity, and concomitant clinical problems. Type 1 is the most common form. The main osteochondroma is located in the distal ulna, which causes a short ulna and bowed radius (see Figure 38.45, *C*). The radial head remains located within the radiocapitellar joint. In type 2, the main osteochondroma is located in the distal ulna, which causes a short ulna, bowed radius, and dislocated radial head (Figure 38.46). Type 2 is subdivided into type 2a, with an osteochondroma on the proximal radial metaphysis, and type 2b, with no proximal radial osteochondroma. In type 3, the main osteochondroma is located in the distal radial metaphysis and the radius is relatively short.

Types of Operations

Removal of Osteochondroma

The osteochondroma is approached through a longitudinal incision centered over the tumor. The most readily available

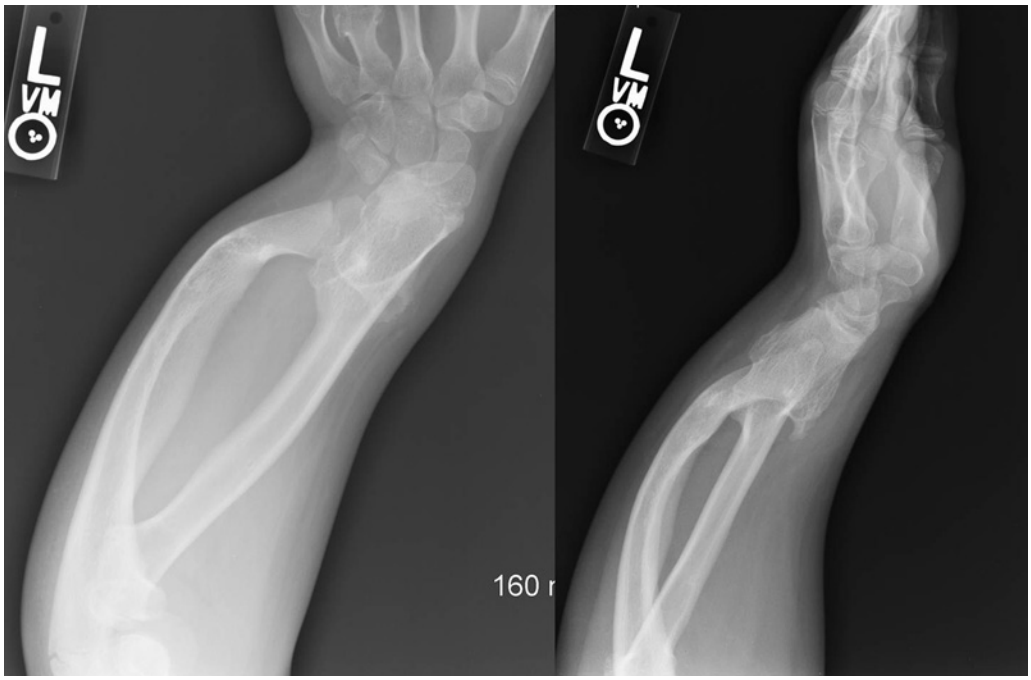

FIGURE 38.46 Radiographs of hereditary multiple exostoses of the right forearm. (Courtesy of Shriners Hospital for Children, Northern California.)

anatomic interval is used for the approach. Usually, the osteochondroma splits the surrounding structures and the approach is straightforward. Nerves or vessels (or both) may be wrapped around the pedicle of the tumor or flattened over its surface. These neurovascular structures are retracted, and the entire tumor, including the periosteum, is removed until a smooth bony contour remains. It is common for osteochondromas to be present on both the distal radius and ulna, such that both volar and dorsal approaches to the forearm may be required to fully remove the symptomatic tumors. In this case, prophylactic fasciotomy is recommended, and patients are admitted overnight to closely monitor their swelling.

Distal Radial Hemiepiphyseal Stapling

The radial aspect of the distal radial physis is approached through a transverse incision while taking care to avoid injuring the dorsal radial sensory nerve (Figure 38.47). Under radiographic guidance, three extraperiosteal staples are placed across the distal radial physis. Staples are placed on either side of the first dorsal compartment; usually there is room for 2 staples dorsal to the compartment, and one staple palmar to the compartment.[62a]

Radial Head Excision (Posterolateral Dislocation)

See the section on resection of the radial head under "Congenital Dislocation of the Radial Head." A substantial portion of the proximal radius may be dislocated in patients with MHE. In these cases, the posterior interosseous nerve should be visualized and protected to avoid injury.

Ulnar Distraction Lengthening

The ulna can be lengthened to maintain the relationship between the ulna and radius (Figure 38.48). Lengthening can also maintain radial head alignment and/or promote radial head reduction. Pins for a hinged uniplanar external fixation device are applied to the ulna, two pins proximal and two pins distal to the planned osteotomy site. The pins are placed perpendicular to the bone at each location, so that when the fixator is placed, the hinge can be straightened to eliminate any bowing of the ulna. Alternatively, an acute angular correction can be performed, followed by delayed distraction osteogenesis. Threaded bicortical pins are used. Once the pins are in place, the site of ulnar osteotomy is isolated. The periosteum is incised carefully. Retractors are used to protect the soft tissues, and a transverse osteotomy is made using an oscillating saw. The external fixator is applied. While the wound is still open, the device is used to lengthen and then recompress through the osteotomy site to ensure that there is no hindrance to lengthening. The osteotomy site is closed, including the periosteum. Patients return to the clinic in 5 to 7 days to start lengthening. Lengthening usually proceeds at 1 mm per day; patients return to the clinic weekly during the lengthening phase. Lengthening is slowed or stopped temporarily if there are any concerns about inadequate bone formation, excessive digital stiffness, or neurovascular problems. If the bone regenerates rapidly, lengthening can be temporarily sped up to 1.5 or 2 mm per day. Once the lengthening phase has been completed, the fixator remains in place until bone regeneration is complete, generally twice the time of the lengthening phase.

Differential Forearm Lengthening

This complex operation is uncommon and is beyond the scope of this text. See Dahl's detailed description of planning osteotomies, designing fixation, ulnar lengthening and angular correction, and radial head reduction.[26]

Ulnar Detethering

At times significant deformity can be present as a result of an ulnar tether, which is most often the sequela of premature ulnar

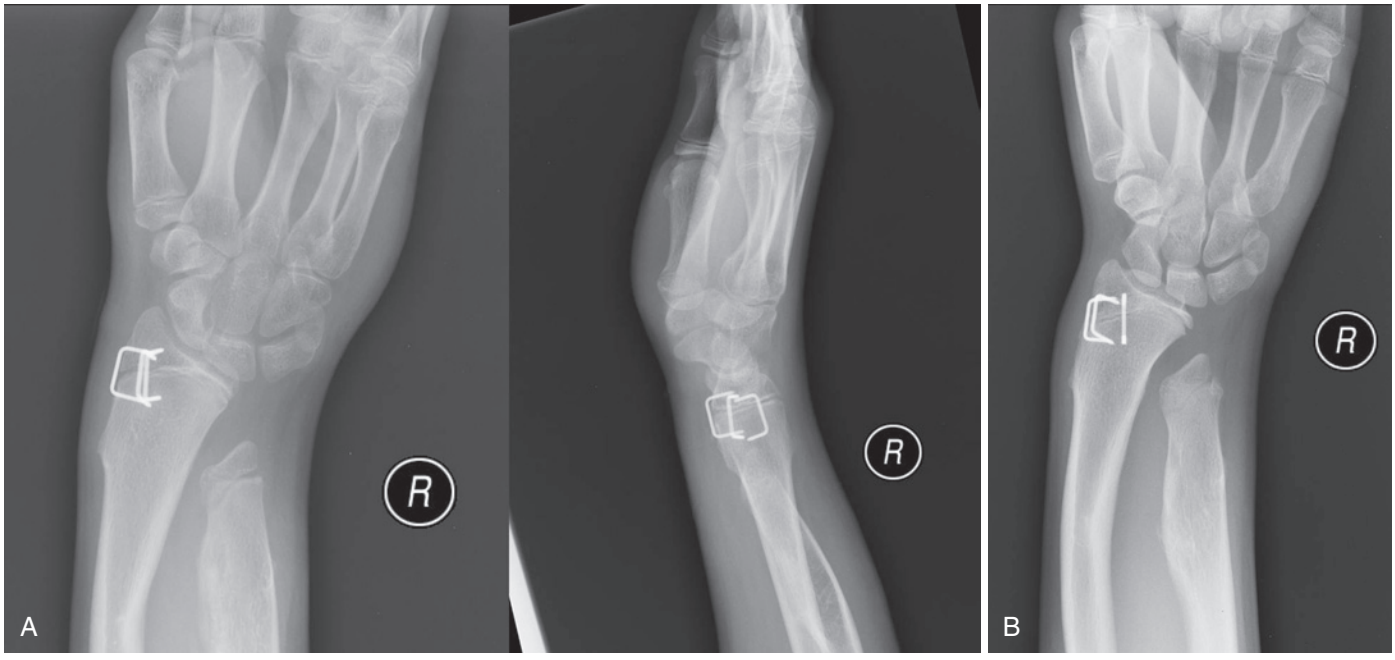

FIGURE 38.47 Distal radius hemiepiphyseal stapling. **A,** Anteroposterior and lateral radiographs after distal radius hemiepiphyseal stapling. **B,** Follow-up radiograph with correction of radial tilt.

physeal closure. To release this tether an incision is made over the area of the distal ulna, with release being accomplished by transecting the ulna through the epiphyseal or styloid area with the triangular fibrocartilage complex attached to the distal fragment. The extensor carpi ulnaris subsheath is also released because this can be an additional deforming force. At this point a corrective radial osteotomy can be performed, depending on the deformity present and/or growth potential remaining in the radius.

Postoperative Management and Expectations

For removal of distal forearm osteochondromas and distal radial hemiepiphyseal stapling, use of a soft dressing and wrist splint for 2 to 3 weeks is adequate immobilization. Radiographs of the distal radius should be obtained twice a year after hemiepiphyseal stapling, and the staples should be removed when the desired amount of radial tilt (usually 20 degrees) is attained.

Osteochondromas tend to grow until skeletal maturity. Recurrence is uncommon when resection is performed near

skeletal maturity. Hemiepiphyseal stapling can restore radial tilt when performed on patients with enough remaining growth. Radial head resection reliably relieves pain in persons with radial head dislocation. Differential forearm lengthening may improve the appearance and prevent radial head dislocation, but there is little evidence that function is improved.

Akita and coworkers reported the long-term results of surgery for forearm deformities in this condition.[1] Thirty-one forearms in 23 patients were monitored for an average of 13 years after surgery. The mean age at the time of surgery was 11 years. The most beneficial procedure was excision of the osteochondroma, which significantly improved forearm pronation and appearance. Corrective osteotomy and lengthening of the ulna were not found to be beneficial. Ulnar lengthening was the only surgery associated with complications, including nonunion, fracture of callus at the site of lengthening, and temporary radial nerve palsy. Although the radiographic parameters of ulnar variance, radial articular angle, and carpal slip were initially improved by the surgery, at final follow-up the deformities had progressed. In two patients with radial head dislocation before skeletal maturity, the radial head was reduced with corrective osteotomy of the radius, ulnar lengthening, and reconstruction of the annular ligament. At last follow-up, both had degenerative changes at the elbow and restricted forearm pronation. Two other patients with dislocation of the radial head at skeletal maturity were treated by radial head resection. Both had relief of pain and improvement in motion at follow-up. These authors concluded that forearm deformities are unrelated to function, and they no longer recommend corrective procedures for prevention of functional impairment.

Shin and colleagues reported outcomes after excision of the osteochondroma, ulnar lengthening, and the Sauvé-Kapandji procedure.[110] Although excision improved the range of motion of the forearm, the Sauvé-Kapandji procedure was shown to improve wrist stability, movement of the forearm, and radiographic appearance. The authors hypothesized that resection of the ulna reduces the tethering effect that the distal ulna has on the radial physis.

❖ AUTHORS' PREFERRED TECHNIQUE

Hemiepiphyseal stapling, resection of the osteochondroma, and removal of the radial head are simple operations with good results. Forearm rotation should be measured twice a year in children with MHE and forearm involvement. Progressive loss of forearm rotation is considered an indication for removal of osteochondromas. Freeing the tether between the radius and ulna, either by soft tissue release of the distal ulna, by ulnar osteotomy and lengthening, or with the Sauvé-Kapandji procedure, may prevent dislocation of the radial head when there is a solitary distal ulnar osteochondroma and progressive bowing of the radius. Early detection of radial head subluxation can be remedied with correction of the ulna via distraction osteogenesis. All children with MHE should be screened for intraspinal osteochondromas with a thorough neurologic examination; it is our preference to also obtain a screening MRI of the spine once the child is old enough to tolerate an MRI without sedation.

CRITICAL POINTS *Hereditary Multiple Exostoses*

- MHE is inherited in an autosomal dominant pattern with high penetrance. Cartilaginous exostoses (osteochondromas) grow from the physes of long bones and from the pelvis, ribs, scapula, and vertebrae.
- Most exostoses are asymptomatic and do not require removal. Early removal of osteochondromas with corrective osteotomies to retard or prevent progressive growth disturbances is controversial.
- Large exostoses may cause local pain from irritation of surrounding tissues. Simple removal is recommended. The risk of recurrence after removal is higher in younger children.
- Forearm deformities are common in MHE and are based on the location of the osteochondromas, although the forearm deformities are complex and not well understood.
- Hemiepiphyseal stapling of the radial side of the distal radius retards radial growth and allows correction of the radial articular angle and ulnar length discrepancy with growth.
- Ulnar lengthening may be performed in a single stage or by using gradual distraction osteogenesis. Differential lengthening combined with angular correction can be used to reduce the radial head.
- Malignant transformation is uncommon.

CASE STUDY 38.1

A boy with left type 4 radial deficiency was initially seen at 2 months of age. Stretching and splinting were instituted when he was 1½ years old (eFigure 38.1, *A* and *B*), and radiographs were taken at that time (eFigure 38.2). Treatment began with preliminary distraction (eFigure 38.3, *A* and *B*). Next, centralization was performed (eFigure 38.4, *A* to *J*). The final result is shown in eFigure 38.5, *A* and *B*. Pollicization was then performed (eFigure 38.6). The 2-year outcome is shown in eFigure 38.7.

39.1 Stiletto flap metacarpophalangeal joint chondrodesis for the clasped thumb

Any child with congenital joint contractures in two or more limbs can be classified as having *arthrogryposis multiplex congenita (AMC)*; the term does not specify any certain cause for the contractures. Arthrogryposis can result from environmental or genetic causes but is most often idiopathic. *Amyoplasia* is an idiopathic disorder with a wide range of levels of severity and anatomic involvement (Figure 39.1). *Distal arthrogryposes (DAs)* are genetic disorders with 11 discrete patterns, each with variable penetrance (Figures 39.2 to 39.4, Table 39.1).[3,15] The most common DAs are types 1, 2A, and 2B (DA1, DA2A, and DA2B). Arthrogryposis can also result from myriad disorders that compromise the central or peripheral nervous system or the musculature; currently, over 300 types have been identified.[9]

Although the cause of amyoplasia is unknown, the clinical findings result from a localized or generalized neuromuscular system underdevelopment. Muscles are either absent or hypoplastic, often replaced by fibrofatty tissue. Tendons and overlying fascia are often preserved even when no muscle is present, leading to tethering at the joints. It is not clear whether the primary insult is at the central nervous system (motor cortex), the peripheral nervous system (anterior horn cells), or the target organ (muscles), or a combination of the three, because aplasia or hypoplasia of any of these systems alone in utero would result in concomitant loss of the other systems. Maternal bicornuate uterus and oligohydramnios have been historically thought to increase the risk of amyoplasia,[20] yet recent studies have not found such a link.[9,13]

Children with amyoplasia have a characteristic appearance with high cheeks and button noses and "stork bite" hemangiomas over the occiput and the bridge of the nose.[14] Interestingly, there are a few identical twins in our practice with indistinguishable facial features, yet only one displays clinical signs and symptoms of amyoplasia. The hemangiomas are usually flat and small (Figure 39.5) but can be protuberant and even extend through the skull into the cranium. Even though the lesions are benign and most resolve or diminish over time, raised lesions should be imaged to evaluate for intracranial extension. Despite or perhaps as a result of diminution of the motor cortex, children tend to have average to above average intelligence.

PREOPERATIVE EVALUATION

History

Most children with arthrogryposis have no other medical conditions. Some, however, may have respiratory and gastrointestinal system involvement. A small percentage of children will have bowel atresia, abdominal wall defects, or gastroschisis. Approximately the same number will require mechanical ventilation at birth; they can typically be weaned to a tracheostomy and supplemental oxygen by their second or third year. Terminal limb deficits are more common in amyoplasia patients than in the general population. The family history is usually positive in DA and in other inheritable neuromuscular conditions, but it is otherwise negative. Quite a few children are adopted because their biologic parent is unable or unwilling to care for them, and the family history is therefore unavailable. The history should gauge the depth and resilience of the family support structure and the resources available.

Physical Examination

Building trust is critical to coaxing a meaningful examination from any child but doubly so for children with arthrogryposis, most of whom have already been traumatized by extensive medical interventions before ever seeing the upper extremity specialist. Begin with a global assessment of the child's cognitive, social, and physical abilities. Some children are quite affected, requiring feeding tubes and mechanical ventilation. A thorough intake worksheet can help to obtain a more complete picture of the child's needs (Figure 39.6). All of the joints of the upper limb should be examined for both active and passive motion. Watching the child play with a variety of differently shaped and sized toys is an effective way of judging the child's function. If possible, observe how the child eats finger foods or drinks from a bottle. There is no substitute for spending a few minutes playing with the child to gain a good understanding of who the child is as a person and what the child requires as a patient.

A more methodical examination of the upper limbs, when possible and age appropriate, proceeds from the shoulder to the fingertips. For the child who is unable or unwilling to respond to commands, having the child reach for toys and stickers followed by object manipulation may be the only way to examine the child. Assess every joint bilaterally in both active and passive motion as well as in the resting position. Internal rotation and adduction contractures of the shoulder are common; children with more than 90 degrees of active abduction and active external rotation past neutral rarely require any intervention about the shoulder.

Elbow flexion and/or extension contractures are also common and often suggest that there are underlying elbow flexors and extensors. The triceps is most often preserved and the elbow flexors are deficient, resulting in the more common elbow extension contractures. Occasionally, the triceps is weak or absent, causing an elbow flexion contracture. Finding the axis of rotation of the elbow in a child with less than 30 degrees of passive elbow flexion can be extremely difficult. Although historically the forearm has been thought to be in pronation in the majority of these children, most often the forearm is in neutral to slight pronation. The illusion of a pronation contracture is created by the internal rotation contracture of the shoulder combined with an extended elbow.

FIGURE 39.1 A child with amyoplasia demonstrating characteristic shoulders internally rotated with the elbows in extension and the wrists in flexion.

In patients with DA, the wrist is often in extension. Patients with amyoplasia typically have fixed wrist flexion contractures (see Figure 39.1). In the absence of active wrist extensors, some children will use the viable extensor digitorum communis (EDC) tendons to extend the wrist. This results in active extension to just shy of neutral but with concomitant metacarpophalangeal (MP) joints.

Hand function is highly variable, with intrinsic thumb flexion usually preserved even in the absence of other digital motion. There are several different patterns of hand deformities, some more commonly seen in specific AMC subtypes (Table 39.2).

Children with arthrogryposis often have lower limb involvement as well. A thorough examination of the lower limbs should be carried out by a pediatric orthopedic surgeon familiar with this disorder. The state of current and potential future ambulatory status is critical to the overall treatment strategy.

Children with arthrogryposis will typically visit the operating room several times for spine, upper extremity, and/or lower extremity correction before the age at which they become good candidates for muscle/tendon transfers (usually 6 years old or older). If the child is undergoing any procedures requiring sedation, an examination under anesthesia can be performed at the same time to determine the true extent of contractures. Percutaneous needle stimulation of individual muscles can be used to determine the suitability of the pectoralis major, latissimus dorsi, and gracilis for muscle transfer.

Diagnostic Imaging

Routine radiographs are unnecessary for patients with arthrogryposis. Some experts advocate lateral finger radiographs to evaluate phalangeal condyle hypoplasia in cases of camptodactyly. Neither computed tomography nor magnetic resonance imaging is necessary for the diagnosis or treatment of AMC. Electrodiagnostic studies are rarely necessary other than in evaluating specific neurogenic contracture syndromes. Muscle biopsy rarely yields useful information unless a specific, unusual diagnosis is being pursued.

PERTINENT ANATOMY

Arthrogryposis affects the entire musculoskeletal system. Children with arthrogryposis have absent or hypotrophic muscles but may retain the associated tendons and overlying fascia. As the child grows, these noncontractile tissues can tether the joints, which may lead to joint contractures. Because the bones do not have the normal load of muscle activity or weight bearing, they may be severely osteopenic. Cortices in these children tend to be quite thick, but the bones are of small diameter and the medullary canal is nearly absent. The motor and mixed nerves are also small in caliber compared with those in other children of the same size. With thin bones and a hypoplastic musculature, the subcutaneous fat encompasses a larger than expected percentage of the bulk of the arms.

Historical Review

A historical review of milestones in the treatment of AMC is shown in Table 39.3.

TABLE 39.1 Distal Arthrogryposis Types

Distal Arthrogryposis Types	Other Name(s)	Label	Characteristic Findings
Distal arthrogryposis type 1	Common or typical	DA1	Camptodactyly, clasped thumb, clubfoot
Distal arthrogryposis type 2A	Freeman-Sheldon syndrome	DA2A	Whistling face, camptodactyly, clasped thumb, clubfoot, scoliosis
Distal arthrogryposis type 2B	Sheldon-Hall syndrome	DA2B	Prominent nasolabial folds, down-slanting palpebral fissures, small mouth, camptodactyly, clasped thumb, clubfoot
Distal arthrogryposis type 3	Gordon syndrome	DA3	Short stature, cleft palate
Distal arthrogryposis type 4	Scoliosis	DA4	Scoliosis, camptodactyly
Distal arthrogryposis type 5	Ophthalmoplegia, ptosis	DA5	Ptosis, strabismus, restrictive lung disease
Distal arthrogryposis type 6	Sensorineural hearing loss	DA6	Hearing loss, camptodactyly
Distal arthrogryposis type 7	Trismus-pseudocamptodactyly	DA7	Trismus, pseudocamptodactyly, short stature
Distal arthrogryposis type 8	Autosomal dominant multiple pterygium syndrome, Escobar syndrome	DA8	Multiple pterygia, camptodactyly, scoliosis, ptosis, down-slanting palpebral fissures
Distal arthrogryposis type 9	Beals syndrome (congenital contractural arachnodactyly)	DA9	Camptodactyly, arachnodactyly, kinked upper earlobe, tall stature
Distal arthrogryposis type 10	Congenital plantar contractures	DA10	Plantar contractures

TABLE 39.2 Classification of Thumb Contractures in Children With Arthrogryposis*

	JOINT POSITION	
Classification	CMC	MCP
Type 1	Extended	Flexed
Type 2	Flexed	Extended
Type 3	Flexed	Flexed

*Subtype A is passively correctable, and subtype B is not correctable.
CMC, Carpometacarpal; *MCP*, metacarpophalangeal.

SURGICAL PROCEDURES

The goal of any treatment plan for a child with arthrogryposis is to maximize functional independence for that child. For the lower extremities, the goals are ambulation and sitting. Traditionally, ambulation has trumped all other treatment goals. In many centers, the lack of expertise and familiarity with upper limb surgery relegates upper limb function to an afterthought. This dismissal is a disservice to these children and to the adults who care for them. Basic upper limb function is just as important to the well-being of these children as ambulation. For the upper extremity, the primary goals are to have "one hand to eat and one to wipe." They can be the same hand. The rate-limiting step in optimizing the child's independence is always finger and thumb motion. Independent self-feeding requires at least some hand function. The child must be able to acquire the food, grip it firmly enough to bring it to the mouth, and release it. Beyond that, the wrist and the elbow combined must have enough extension to reach the plate or the table and sufficient flexion to allow the hand to reach the mouth. Forearm and shoulder rotation need to allow the hand to face the plate and then the mouth. In very impaired children, independent feeding may be an unrealistic goal. A skilled therapist and the use of adaptive equipment may achieve some independence (Figure 39.7).

Perineal care can be performed through the legs or around the back. Both require sufficient hand function to hold toilet paper firmly. Children who wipe their buttocks through the legs require wrist flexion, elbow extension, and shoulder internal rotation. Children who wipe their buttocks around the back require forearm supination, elbow extension, and shoulder extension.

The next priorities on the functional ladder are bathing and dressing, followed by food preparation, driving, and other activities of daily living. Recreational activities and sports participation may be achievable in mildly affected children.

Humeral External Rotation Osteotomy

Indications

Children with arthrogryposis typically present with internal rotation and adduction contractures. Elbow extension contractures can create the appearance of a pronation contracture, but most often the posture results from internal rotation at the shoulder with the forearm most often in neutral. The deltoid, rotator cuff, pectoralis, latissimus dorsi, and periscapular muscles may be weak or absent. Although rarely responsive to passive stretching, a course of therapy is recommended. Capsular releases have not been effective. Internal rotation contractures are best treated with a humeral external rotation osteotomy. The medial approach requires visualization and retraction of the median and ulnar nerves but is more cosmetic and provides a better bony surface for plate application than the deltopectoral approach.[18] For the child with a severe elbow extension contracture, distinguishing between an internal rotation contracture at the elbow and a pronation contracture at the forearm can be difficult. For these children, we will perform an elbow release first, followed by a humeral rotational osteotomy if needed. We rarely perform bilateral procedures in these children because the margin of error is so small for losing midline function.

Contraindications

Relative contraindications include (1) insufficient internal rotation for perineal care, (2) older age with established crossover

Upper Extremity Arthrogryposis Assessment

Chief Complaint	_____

1985	Bennett JB, Hansen PE, Granberry WM, Cain TE: Surgical management of arthrogryposis in the upper extremity, *J Pediatr Orthop* 5:281-286, 1985	Created surgical treatment algorithm for the upper extremity that serves as the basis for current treatment paradigm
1985	Palmer PM, MacEwen GD, Bowen JR, Mathews PA: Passive motion therapy for infants with arthrogryposis, *Clin Orthop Relat Res* 194:54-59, 1985	Early passive stretching and serial splinting improved motion and function

grasp (Figure 39.8), and (3) absence of pectoralis function. Children who lack pectoralis function but retain triceps function will use an obligatory crossover grasp pattern that requires internal rotation.

Preoperative Planning

Plates and screws of the appropriate size are required and are often a size smaller than what would be expected for a humerus of an unaffected child of the same age.

Technique

Place the patient supine on a standard operating room table with a hand table. Regional anesthesia may be used to control postoperative pain along with general anesthesia. If a tourniquet is used, the Hemaclear tourniquet (Hemaclear, OHK Medical Devices, Grandville, MI) allows sufficient proximal exposure. If a tourniquet is not used, inject bupivacaine with epinephrine subcutaneously along the length of the intended incision. Prepare and drape the arm to the axilla.

Incise the skin and raise full-thickness subcutaneous flaps while preserving the medial brachial and antebrachial cutaneous nerves, as well as the basilic vein. Incise the fascia between the median and ulnar nerves along the intermuscular septum. Regular palpation is required to feel the humerus because muscle planes may not be clearly delineated. Using a periosteal elevator, expose the humerus extraperiosteally to a length sufficient to place a plate. Plates of 2.4 mm to 3.5 mm are used for this operation and should be appropriate for the size of the bone. Gently precontour the plate so as to provide compression on the far side of the bone.

Apply the plate provisionally to the proximal osteotomy fragment as far anterior as the soft tissues will allow. Remove the plate. Split the periosteum longitudinally and apply Hohmann retractors to protect the surrounding neurovascular structures. Perform a transverse osteotomy using a reciprocating saw while preserving the periosteal sleeve. Reapply the plate to the proximal fragment. Place a fracture reduction clamp around the distal fragment and the plate. Externally rotate the arm to the desired position of between neutral and 15 degrees of internal rotation. Provisionally clamp the distal humeral fragment to the plate and reassess the rotation of the arm. Sufficient internal rotation should be preserved to allow for midline function, such as perineal care. Fix the plate to the distal fragment with a single screw and reassess one more time (Figure 39.9, *A*). If the position of the arm is optimized, confirm the screw lengths and plate position using fluoroscopy (see Figure 39.9, *B*).

Close the subcutaneous layer and the skin in standard fashion. Place the elbow in 90 degrees of flexion and apply a sterile dressing followed by a long-arm splint with a side bar to prevent elbow extension. If the fixation was felt to be tenuous or the child is very active, a triangular wedge can be used to place the arm in a "gunslinger position" (Figure 39.10).

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Alternative approaches to a humeral osteotomy include the posterior and anterolateral approaches. The advantages of the medial approach are primarily cosmetic, because the majority of children keep the shoulders adducted and conceal the scar. We are currently evaluating concomitant elbow release and humeral rotational osteotomy, but early results are not promising. For the time being, it is better to perform the elbow release at a separate time.

FIGURE 39.8 Children without elbow flexion or who have inadequate shoulder external rotation will use a crossover grasp pattern. (Courtesy of Shriners Hospital for Children, Philadelphia.)

CRITICAL POINTS *Humeral External Rotation Osteotomy*

- Make sure that the patient has internal rotation to spare before considering an external rotation osteotomy.
- Make sure that the internal rotation/pronation posture is truly coming from the shoulder and not from the forearm.
- If there is less than 30 degrees of elbow flexion, consider an elbow release prior to humeral osteotomy.
- For the medial approach, identify and gently retract the ulnar and median nerves.
- Apply the plate proximally first to simplify the procedure before making the osteotomy.
- Protect the radial nerve with Hohmann retractors deep to the periosteum while making the osteotomy.
- Gently precontour the plate to provide far-side compression.
- Test the amount of rotation several times before final fixation to ensure an optimal position.
- Use a gunslinger brace if the child is prone to falling or if the fixation is suboptimal.
- Use a fracture brace after 4 weeks if the osteotomy has not healed.
- Beware of long-term periimplant fractures.

Postoperative Management and Expectations

Expected Outcomes. Union is typically achieved between 4 and 6 weeks, although occasionally it may take up to 10 weeks. Remove the splint 4 weeks after surgery and outfit the child with a fracture orthosis (Figure 39.11) if union has not been achieved. Begin a passive range-of-motion protocol while maintaining the orthosis at all other times until union. Patients can expect improvements in hand-to-mouth and hand-to-neck activities

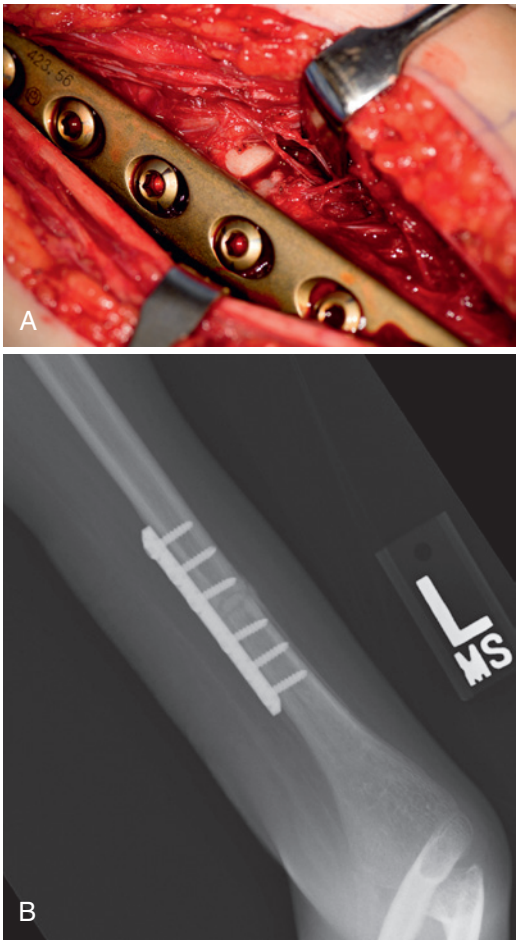

FIGURE 39.9 **A,** Intraoperative photograph and **B,** anteroposterior radiograph of a humeral rotational osteotomy performed via a medial approach. Note the relatively small caliber of the humerus compared with the length of the arm, as is commonly seen in children with amyoplasia.

FIGURE 39.10 A triangular wedge can be made out of rolls of cast padding to maintain the arm in a gunslinger position. (Adapted from Zlotolow DA, Thompson SJ: *Handbook of splinting and casting,* Philadelphia, 2011, Elsevier.)

FIGURE 39.11 A fracture orthosis can be used to protect the osteotomy site until union is achieved. (Courtesy of Shriners Hospital for Children, Philadelphia.)

if there is adequate elbow and shoulder motion. Bimanual tasks are also more easily performed because the hands should face each other after the osteotomy. Bilateral osteotomies may be required, but staging them is preferred.

Complications. Overrotation or underrotation is the most common complication. Typically, younger children will correct for overrotation but will not correct for underrotation. Older children, particularly those with minimal shoulder rotation, have a lesser margin for error. Neurapraxia of any of the major nerves can also occur, but more considerable nerve injuries are rare. If nerve function has not recovered after 2 to 3 months, electrodiagnostic studies are warranted. Infections and nonunions are rare, but delayed unions do occur, especially if there is a gap at the osteotomy site or if the periosteum was stripped. Fractures at the ends of the plate are an ongoing concern.

Elbow Extension Contracture Release

Indications

Most children with arthrogryposis lack adequate elbow flexion to oppose the working triceps, leading to extension contractures. Some children have active elbow flexion but no extension, leading to flexion contractures; pterygium is common in this group. Other children have only a jog of passive motion at the elbow. If the child cannot flex the elbow more than 30 degrees, the true axis of rotation of the elbow joint can be difficult to determine. Caretakers and health care professionals are discouraged from performing passive range of motion of these elbows because inadvertent collateral ligament damage or physeal injuries can result.

Impressive gains in elbow range of motion can be made in some children who can flex the elbow beyond 30 degrees. Progressive static splinting, as can be accomplished with an

FIGURE 39.12 An hourglass splint **(A)** can be used to help gain more elbow flexion both before and after surgery provided the patient has at least 60 degrees of flexion to begin with. Alternatives include an anteroposterior splint **(B)** or an adjustable static progressive splint **(C)**.

hourglass splint (Figure 39.12), will augment and preserve the gains made with therapy. Passive hand-to-mouth motion can allow the child to perform feeding and grooming tasks by pushing the arm against the knee or other arm, a desk, or a table, or by abducting the shoulder and allowing gravity to flex the elbow (Figure 39.13).

Indications for surgical release include less than 30 degrees of elbow flexion by 12 to 18 months of age and failure to achieve sufficient elbow flexion for self-feeding at any age.

Elbow flexion contractures are even more difficult to treat. The paradigm is the same initially, with passive range-of-motion exercises and splinting. Most children with elbow flexion contractures lack triceps function and some also lack active flexion. A pterygium across the antecubital fossa commonly accompanies elbow flexion contractures (Figure 39.14) and is a harbinger of a more recalcitrant problem. There is as yet no reliable surgical or nonsurgical technique to resolve these contractures.

Contraindications

Relative contraindications include (1) having a contralateral side elbow flexion contracture that prohibits perineal care and (2) a requirement of triceps function for ambulation.

Preoperative Planning

No specialized equipment is required.

Technique

Place the patient supine on a standard operating room table without a hand table. Prepare and drape the arm to the axilla. If a tourniquet is being used, a Hemaclear tourniquet (Hemaclear, OHK Medical Devices, Grandville, MI) allows sufficient proximal exposure. If a tourniquet is not being used, inject bupivacaine with epinephrine subcutaneously the length of the intended incision.

Define the anatomic landmarks of the elbow, beginning with the olecranon, by following the subcutaneous border of the ulna in a proximal direction. Confirm the position of the olecranon by identifying the medial and lateral epicondyles. If there is any doubt, fluoroscopic images are obtained.

The incision should run the entire length of the triceps tendon, at least midway up the brachium, curving ulnar to the olecranon. Raise full-thickness subcutaneous flaps both medially and laterally just past the level of the epicondyles. The ulnar nerve is identified just proximal to the cubital tunnel beneath a thick fasciotendinous band of the triceps that inserts onto the medial epicondyle and the ulnar side of the olecranon.

FIGURE 39.13 Children can use passive flexion of the elbow to feed themselves by pushing the forearm against the knee **(A)**, a table **(B)**, or the other arm **(C)** or by abducting the shoulder and allowing gravity to flex the elbow **(D)**.

Transpose the ulnar nerve anteriorly into a subcutaneous pocket, and suture the subcutaneous fat to the anterior aspect of the medial epicondyle to close the pocket (Figure 39.15, *A*). Make sure that the medial antebrachial cutaneous nerve and its branches are not sutured in the fat. After transposition, confirm that the ulnar nerve is not kinked or compressed anywhere along its new course.

Make a full-length triceps tendon incision in a distally based "V"-shape (see Figure 39.15, *B*), leaving enough tendon on the muscle to later perform a "V-to-Y" repair. Elevate the "V"-tendon flap off of the muscle using bipolar electrocautery up to the olecranon. Release any remaining triceps attachments to the medial and lateral epicondyles. Release the fat pad and the posterior capsule, keeping them in continuity with the proximal triceps muscle and tendon. Release the capsule along the medial and lateral gutters as distally as possible without destabilizing the medial and lateral ligaments (see Figure 39.15, *C*). Continue incremental releases until the elbow can flex past 90 degrees. The maximum flexion is usually 120 degrees. Forcing the elbow into flexion to gain additional motion not afforded by the release will lead to a transphyseal fracture of the distal humerus. If there is nothing left to release posteriorly or medially and laterally along the elbow but elbow flexion is still inadequate to reach the mouth, consider an anterior closing wedge humeral osteotomy just proximal to the olecranon fossa during this operation or at a later date, particularly if an external rotation osteotomy is required.

To optimize triceps excursion, elevate the medial head of the triceps off of the posterior humerus extraperiosteally to the level of the spiral groove (see Figure 39.15, *D*). Identify the radial nerve by following the lower lateral brachial cutaneous nerve to the spiral groove because the brachioradialis and brachialis are often absent and the nerve is usually hidden by fat in the lateral elbow and can be difficult to find.[28]

Repair the triceps in a "V-to-Y" procedure with the arm in maximal flexion using a braided nonabsorbable suture (see

FIGURE 39.14 Children with elbow flexion contractures often have a pterygium over the antecubital fossa.

Figure 39.15, *E*). If the length of the "V" is insufficient to allow for a primary repair, autograft or allograft may be used to bridge the gap. A properly planned triceps tendon flap and medial head elevation avoid this problem.

Reevaluate the ulnar nerve, and close the skin in layers. If there is a lot of tension on the wound, elbow extension can help as the wound is being closed. Apply a sterile dressing with the elbow in maximal flexion followed by a long-arm splint. If the soft tissue envelope is too edematous to allow for positioning of the elbow in maximal elbow flexion, flex the arm to the degree the soft tissues will tolerate and immobilize it in that position.

Remove the splint 2 weeks after surgery and outfit the arm with an hourglass splint (see Figure 39.15, *F*). Begin a passive range-of-motion protocol while maintaining the hourglass splint at all other times for 6 weeks. If soft tissue edema prevented splinting of the elbow past 90 degrees of flexion at the time of surgery, change the splint with the patient sedated 1 week after surgery to recover the missing flexion. Continue range-of-motion exercises through the fourth postoperative

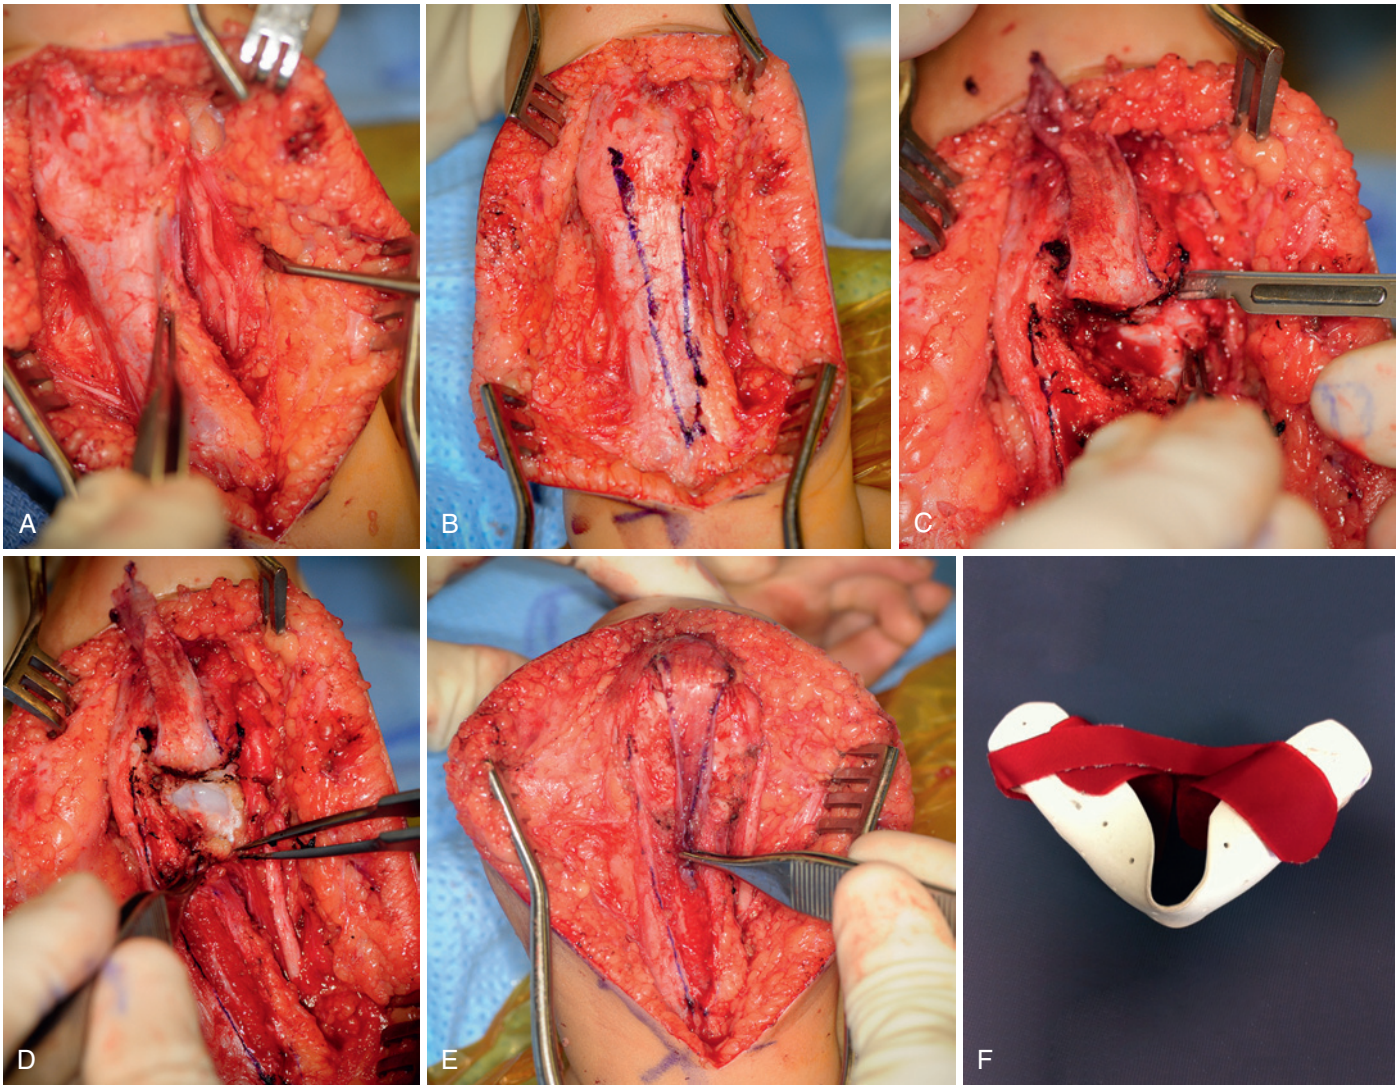

FIGURE 39.15 Releasing an elbow extension contracture requires transposition of the ulnar nerve **(A)**, creation of a "V"-shaped distally based triceps tendon flap **(B)**, release of the posterior capsule **(C)**, elevation of the medial head of the triceps **(D)**, and repair of the triceps in a "V-to-Y" fashion **(E)**. Postoperative splinting includes an hourglass splint **(F)**.

month while weaning the patient from the hourglass splint, so that it is used at night and during naps only. Alternate an elbow extension splint with the hourglass splint if elbow extension is difficult to recover.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

There are multiple ways to lengthen the triceps and release the capsule. Some surgeons prefer a "W"-type triceps tendon flap, and this has worked as well for their patients as the "V-to-Y" flap. I prefer the "Y" flap procedure because it is simpler to perform and requires fewer suture lines. The key is to make the flaps the length of the triceps tendon to allow adequate overlap once the elbow is flexed. If the ends do not meet, a turndown flap or allograft/autograft is required.

To augment excursion of the triceps muscle itself rather than simply elongate the tendon, I also perform a slide of the medial head of the triceps to the level of the spiral groove. The muscle origin is released from the humerus above the periosteum with a bipolar cautery or blunt dissection. This usually allows the medial head to reach the olecranon and enhances the tendon repair.

CRITICAL POINTS *Elbow Extension Contracture Release*

- Transpose the ulnar nerve first to minimize the risk to the nerve.
- Make a long "V" incision in the triceps tendon, leaving just enough of a tendinous cuff intact on the proximal side to allow for tendon repair.
- Beware of false planes when releasing the capsule from the medial and lateral gutters; the physeal cartilage can look like capsule.
- Release the posterior capsule over the medial and lateral epicondyles.
- Maintain the collateral ligaments.
- Try for 120 degrees of flexion but settle for 90 degrees rather than jeopardizing the integrity of the collateral ligaments.
- Avoid forceful passive elbow flexion because it may cause physeal separation.
- Release the medial head of the triceps off of its origin to allow it to slide in a distal direction.
- Repair the triceps with the elbow in maximal flexion.
- Begin passive range of motion after 2 weeks.
- Use both an elbow flexion splint and an elbow extension splint as needed until the patient's range of motion stabilizes in the desired arc.

Postoperative Management and Expectations

Expected Outcomes. The results of triceps lengthening, posterior capsular release, and ulnar nerve transposition have been promising.[24] Terminal extension loss and triceps weakness are possible, but most children achieve sufficient passive flexion to feed themselves. The results are most predictable in children under the age of 3 years, but releases in older children are still possible with variable outcomes.[29] Active elbow flexion has been seen in some children after a release without tendon or muscle transfer, but this is rare and should not be expected.

Because of the potential loss of elbow extension after a release, bilateral releases are discouraged. Begin with the arm most likely to have an adequate hand for feeding (i.e., the dominant hand). Do not release the nondominant side until the child demonstrates at least the potential to carry out perineal care with the arm that has already undergone a release. Remember the doctrine "one hand to wipe and one hand to eat," but it can be the same hand.

Complications. Complications such as ulnar and/or radial nerve injury are rare, but triceps insufficiency and elbow stiffness do occur.

Bipolar Latissimus Dorsi Transfer

Indications

Active elbow flexion is rarely achievable in children with arthrogryposis. On occasion, an elbow release alone will allow a previously restrained biceps or brachialis to flex the elbow. The "new" active flexor function is typically a grade 1 or a weak grade 2, and rarely provides enough active flexion to truly enhance function. In a child with passive motion who would benefit from active elbow flexion, there are several options for achieving active flexion. Transfer of the entire triceps to the biceps has proven to be a poor option, with many children developing elbow flexion contractures.[26]

Transferring only the long head of the triceps may avoid the flexion contracture that results from transferring the entire triceps. However, proponents of this technique have yet to demonstrate a substantial improvement in function from this transfer.[11a] More experience with this transfer is needed before it can be recommended for widespread use.

Other options for restoring active elbow flexion are a Steindler flexorplasty,[12] a unipolar or bipolar pectoralis major transfer,[6,7] a bipolar latissimus dorsi transfer,[27] and a free muscle transfer.[16] When present, the latissimus dorsi is the best choice for restoring active elbow flexion. The pectoralis major transfer has also been described; there is a possibility for functional loss and cosmetic disfigurement, however.[6,19] Transfer of only the sternocostal portion of the pectoralis major may be a better option from the standpoint of appearance, but it may not be of sufficient strength.

Contraindications

Poor triceps function is a contraindication to any transfer for active elbow flexion. Patients who have had a previous triceps lengthening typically have compromised triceps strength and are usually not candidates for active elbow flexion transfers. If the latissimus is difficult to palpate, it is probably not suitable for transfer. Poor passive elbow flexion of less than 90 degrees is another contraindication.

Preoperative Planning

No specialized equipment is necessary.

Technique

After inducing general anesthesia, place the patient on a bean bag in a lateral decubitus position (Figure 39.16). Pad all bony prominences and place an axillary roll. Drape out from the midline on the back to the nipple line on the front and from the base of the neck to the iliac crest. The peroneal nerve should be protected from compression at the level of the fibular head.

Make an incision in line with the lateral border of the muscle, from the posterior axillary fold to about the midpoint of the posterior iliac crest. We tend not to use a skin paddle to augment the skin. Children with arthrogryposis generally have a small latissimus dorsi and abundant skin and subcutaneous fat in the

FIGURE 39.16 Eight-year-old boy with arthrogryposis and no active elbow flexion. **A,** Good passive elbow flexion. **B,** Harvest of the bipolar latissimus dorsi muscle on a thoracodorsal neurovascular pedicle. **C,** Latissimus dorsi muscle transferred from the back to the anterior of the arm. **D,** Latissimus dorsi attached to the biceps to complete the flexorplasty. Acceptable elbow flexion for hand-to-mouth activity after latissimus flexorplasty. (**A** to **D,** Courtesy of Shriners Hospital for Children, Philadelphia.)

arm. If a skin paddle is used, it should be small enough to allow primary closure of the harvest site.

Dissect down to the level of the latissimus dorsi fascia. Release the muscle from its attachments, maintaining meticulous hemostasis (see Figure 39.16, *B*). Identify the thoracodorsal artery, vein, and nerve as they emerge deep to the latissimus and trace them back to the axillary artery and the brachial plexus. Ligate the vascular branches to the serratus to gain maximal length on the pedicle. Identify and preserve the long thoracic nerve to the serratus running near the vascular branches. More proximally, the circumflex scapular artery and veins may need to be ligated to increase the length to the pedicle.

Once the pedicle is isolated, separate the latissimus from the teres major and expose the insertion. If the teres major and latissimus share a conjoined insertional tendon, divide the latissimus tendon as close to the humerus as possible while maintaining the teres insertion to bone. The axillary nerve and posterior circumflex humeral vessels are deep to the latissimus and teres major near their insertions onto the humerus. Place a Penrose drain around the latissimus insertion and provisionally close the donor incision with a few staples or towel clamps to prevent desiccation of the wound.

Open the deltopectoral interval down to the coracoid with an incision large enough to pass the latissimus. Expose the coracoid and place two transosseous sutures into the coracoid for later tendon fixation using braided, nonabsorbable sutures in older children or polydioxanone monofilament suture in skeletally immature children. Make an "S"-shaped incision at

the antecubital fossa and dissect down to the biceps tendon. If the child has no active pronation, consider transferring the latissimus to the brachialis or directly into the ulna instead. Surprisingly, most children will have a biceps tendon that flexes the elbow when pulled in a proximal direction even though there is often no muscle present. Create a generous subcutaneous tunnel from the distal to the proximal arm incision and pass a Penrose drain to mark the tunnel.

Create a subcutaneous tunnel from the deltopectoral interval to the proximal arm incision. Mark the path of the tunnel with a Penrose drain. Detach the latissimus insertion off of the bone with a periosteal cuff, taking care not to injure the adjacent posterior circumflex humeral vessels. Before passing the muscle, reevaluate the length and freedom of the pedicle one final time. Pass the latissimus into the proximal arm wound. It is safer to pass the origin side first because the origin is further from the pedicle than the insertion and is therefore less likely to put tension on the pedicle.

Check the tension on the pedicle continuously as the muscle is transferred (see Figure 39.12, *C*). Provisionally place the insertion over the coracoid and recheck the tension on the pedicle. The muscle should be vascularized and the pedicle should be loose without having been rotated. If the muscle is questionable or the pedicle is tight, return the latissimus to the harvest wound and revisit the pedicle to achieve more length. There may be a tethering vessel or a traversing band of axillary fascia limiting pedicle excursion. The tunnel position may need to be revised to shorten the distance the pedicle must travel.

Affix the insertion of the latissimus to the coracoid using the previously passed sutures. Pass the origin of the latissimus into the distal wound through the subcutaneous tunnel. The length should be more than adequate to reach the biceps tendon or the proximal ulna if necessary. Remove any excess muscle and tubularize the latissimus and suture the end to the biceps tendon or directly to the ulna just distal to the coronoid. The tension should be set so that the elbow is difficult to extend past 30 degrees of flexion.

Recheck the pedicle and reevaluate the condition of the muscle. If a skin paddle is being used, it can evaluate the vascularity of the flap. Alternatively, a Cook-Swartz Doppler flow monitor system (Cook Medical, Bloomington, IN) can be assembled. However, if the pedicle is loose and the muscle is well perfused, there is little need for postoperative monitoring of muscle viability.

Close the wounds in standard fashion with one or two large drains in the back, maintaining the elbow in flexion during the closure. Apply a sterile dressing and splint the arm with a sling in 90 degrees of flexion.

After 4 to 6 weeks, remove the splint and outfit the patient with a hinged elbow brace. The brace should be used at all times except for bathing. It is initially locked to prevent extension past 90 degrees but allow full flexion. Each week, the extension is advanced by 15 degrees as long as active flexion is maintained. By around 3 months after surgery, full extension should be achieved and the brace can be removed. Begin strengthening exercises once motion is restored.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Most parents understandably wish for their child to achieve active elbow flexion. Unfortunately, this is not possible for the majority of patients. Partial triceps transfers and pectoralis transfers have their proponents, but the results are unpredictable. As long as the latissimus dorsi is in good condition, the bipolar latissimus muscle transfer is a fairly reliable technique for achieving active elbow flexion. Another viable option is a free gracilis with a spinal accessory nerve transfer. A gait study may be required to make sure that the gracilis harvest will not interfere with ambulation. Lidocaine injection of the gracilis prior to gait analysis can help in simulating ambulation following harvest.

CRITICAL POINTS *Bipolar Latissimus Dorsi Transfer*

- Identify the neurovascular pedicle working medial to lateral on the undersurface of the latissimus dorsi.
- Ligate the vessels to the serratus and isolate the pedicle to the latissimus all the way to the brachial plexus and the axillary artery.
- Expose the entire latissimus dorsi before releasing it from the origin.
- Maintain the humeral insertion to protect the neurovascular pedicle from traction during the anterior exposure.
- Transfer the muscle origin first through the deltopectoral interval.
- Sew the insertion to the coracoid in a position that minimizes pedicle tension.
- Attach the origin to the biceps or the ulna depending on the status of active pronation.
- Tension the elbow so that at rest the arm sits in at least 30 degrees of flexion.
- Apply a long-arm splint or cast for 4 to 6 weeks, followed by a graduated extension protocol.

Postoperative Management and Expectations

Expected Outcomes. Strong antigravity elbow flexion is rarely achieved. The best that parents can typically expect is grade 3 to 5 with antigravity flexion within the passive range (see Figure 39-16, *E*). Outcomes depend almost entirely on the quality of the latissimus muscle.

Complications. Loss of the latissimus is possible but rare as long as meticulous care is taken both to harvest the pedicle and limit tension on the pedicle. The posterior wound is prone to seroma formation, and this can be mitigated with the use of postoperative drains.

Radial Osteotomy With and Without Ulnar Osteotomy

Indications

Contrary to what has been described, it is unusual to see a pronation contracture in a child with arthrogryposis. Rather, most children have internal rotation contractures at the shoulder, creating the illusion of pronation at the forearm. The forearm is most often in neutral. However, because each child is unique, the rotation of the shoulder and the rotation of the forearm should be assessed independently. Forearm osteotomies have been mistakenly performed on children to correct shoulder rotation and humeral osteotomies to correct forearm malrotation. The risk of misdiagnosis is greatest when the elbow is contracted in full extension. Prior to humeral or forearm osteotomies in these children, we typically perform an elbow release that allows a better position to evaluate shoulder and

forearm rotation. If the malrotation is at the forearm, a separate surgical procedure is performed to correct the pronation at a later date.

Children with limited elbow flexion and forearm pronation struggle with self-feeding. This difficulty is worsened by ulnar deviation at the wrist. However, pronation can be an asset to a child who goes through the legs for perineal care. Supination straps and passive range-of-motion exercises are first-line treatments to improve supination. If these fail, surgical correction can be achieved by a radial osteotomy, ulnar and radial osteotomies, or a one-bone forearm. Rarely, if the child has an active biceps, biceps rerouting can be considered. A therapist who is familiar with the child can be very helpful in determining the best resting position for the forearm.

A radial osteotomy is usually sufficient for rotational correction below 45 degrees. Beyond that, an ulnar osteotomy can be added for corrections up to 90 degrees. Alternatively, a one-bone forearm is more predictable and easier to accomplish.

Alterations in forearm position can influence the elbow via retensioning the biceps tendon. Repositioning the forearm also reorients the wrist position. Pronation allows gravity-assisted wrist flexion, and supination augments gravity-assisted wrist extension.

Contraindications

A child who requires pronation for perineal care should not undergo a neutralization osteotomy of the forearm.

Preoperative Planning

Any standard hand plating system can be used for osteotomy fixation, with compression plates usually in the range of 2 to 2.4 mm. Minifluoroscopy is also recommended.

Technique

Place the patient supine on a standard operating room table without a hand table. Regional anesthesia may be used to control postoperative pain along with general anesthesia. Confirm that the patient is truly in pronation. If the shoulder is internally rotated on examination, consider a humeral osteotomy first and then reassess the forearm position.

The arm is prepared and draped to the axilla. Exsanguinate the limb and apply a tourniquet on the upper arm. Incise the skin along the flexor carpi radialis (FCR) tendon just proximal to the wrist crease. Raise full-thickness subcutaneous flaps medially and laterally. Beware of the palmar cutaneous branch of the median nerve. Mobilize the tendon and incise the floor of the FCR sheath. Elevate the flexor pollicis longus (FPL) and the proximal portion of the pronator quadratus to expose the distal radial diaphysis. Apply a contoured six-hole compression plate of appropriate size to the volar distal aspect of the radius with the distal three holes. Make sure that the plate is proximal to the volar metaphyseal flare to avoid physeal injury. Remove the plate.

Split the periosteum longitudinally and place Hohmann retractors deep to the periosteum. Cut the bone and reapply the plate to the distal fragment. Clamp the proximal fragment to the plate and reassess the rotation of the forearm. If there is some active wrist extension or the wrist is contracted in extension, supinate the radius to between neutral and 30 degrees of pronation. If the wrist has no active extension, place the forearm in neutral. Keep in mind the optimal forearm position for either wiping or eating, or if possible both. If the child has insufficient shoulder rotation, elbow movement, and wrist motion to achieve both tasks, then determine which function is best left to the contralateral hand, and optimize the opposite function for the surgical arm. This determination is done prior to surgical intervention. Fix the plate to the proximal fragment and reassess rotation a final time.

If the radial osteotomy was insufficient to provide the desired amount of rotational correction, add a proximal ulnar osteotomy or convert to a one-bone forearm. For the ulnar osteotomy, incise the subcutaneous border of the ulna distal to the level of the coronoid. Insert the proximal three screws of a six-hole plate. Remove the plate.

Split the periosteum longitudinally and place Hohmann retractors deep to the periosteum, keeping the periosteum in continuity. Cut the bone and reapply the plate to the proximal fragment. Rotate the ulna and clamp the distal fragment to the plate. Fix the plate to the distal fragment and reassess one more time. If the position of the arm is optimized, confirm screw lengths and plate position using fluoroscopy.

For a one-bone forearm, extend the FCR approach across the forearm to the ulna with an "S"-shaped incision. Dissect a path along the interosseous membrane for the radius to be reduced to the ulna. Make a transverse ulnar osteotomy 1 cm proximal to the radial osteotomy (Figure 39.17). The staggered osteotomies create bony overlap to encourage union. Reapply the plate to the distal fragment of the radius. Clamp the proximal fragment of the ulna to the plate and assess the rotation of the forearm. Fix the plate to the ulna and reassess one more time. If the position of the arm is optimized, confirm screw lengths and plate position using fluoroscopy.

Close the subcutaneous layer and the skin. Apply a sterile dressing with the elbow in flexion and the forearm in the desired position. Apply a sugar-tong splint or a long-arm cast to prevent forearm rotation.

Remove the splint 2 weeks after surgery and convert to a long-arm cast until union. Then begin a range-of-motion protocol while maintaining a Munster splint at all other times for an additional 6 weeks. Continue range-of-motion exercises through the third postoperative month while weaning the patient to wearing the splint at night and during naps only.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

A one-bone forearm is the most predictable operation for correcting forearm rotational deformities. Union in children is rapid and robust, and there is no risk of loss of correction over time. If a small amount of pronation is required and the child has an active supinator and a working biceps, biceps rerouting can be an effective technique and maintains motion. If a small amount of supination is required, a radial osteotomy can also be effective but may lose correction over time if there is no active supination.

Postoperative Management and Expectations

Expected Outcomes. Correction of a pronation deformity can be a life-changing event if it allows the child to self-feed for the first time. If it takes away or prohibits the acquisition of independence in the bathroom, loss of forearm pronation can have lifelong consequences.

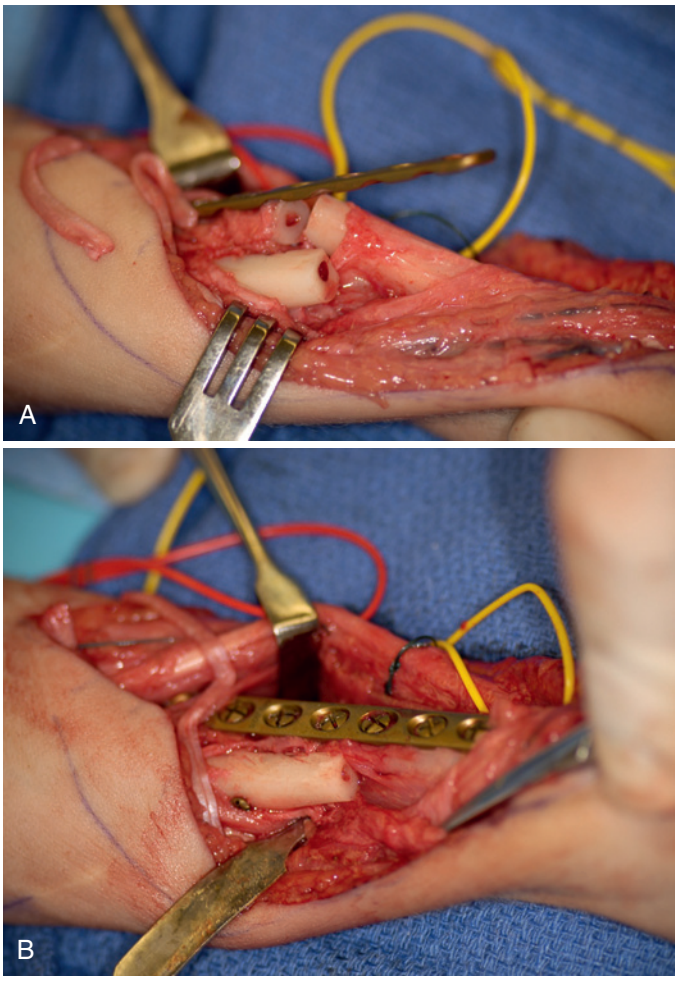

FIGURE 39.17 Creation of a one-bone forearm requires osteotomies of the radius and ulna. The ulnar osteotomy is made 1 cm proximal to the radial osteotomy **(A)** to allow for overlap of the cut bone ends once the distal radial fragment is fixed to the proximal ulnar fragment **(B)**.

CRITICAL POINTS *Radial Osteotomy With and Without Ulnar Osteotomy*

- Make sure that the deformity truly is in the forearm and not the shoulder before correcting forearm rotation.
- Confirm that self-feeding and perineal care will still be possible after the change in forearm position.
- Osteotomize just the radius for corrections of less than 45 degrees.
- For larger corrections, either create a one-bone forearm or perform dual radial and ulnar osteotomies.

Complications. Nonunion is rare, but malunions can occur from inadequate positioning in the operating room. Intraoperative reduction is confirmed by a careful intraoperative examination prior to definitive fixation. Malrotations of a few degrees are common, but more clinically important malrotations are rare.

Carpal Wedge Osteotomy

Indications

The carpal wedge osteotomy is a common upper limb procedure for children with arthrogryposis. However, the indications are few and the contraindications are many. More than for any other joint in the upper limb, decisions about altering a child's wrist position require a thorough assessment of the child's overall functional goals and limitations. In addition, the active and passive motions about the shoulder, elbow, forearm, and hand are critical components in the decision-making process.

The wrist position of children with arthrogryposis varies from child to child, with some children having one wrist in flexion and one in extension. Most patients with DA tend to have wrist extension contractures, whereas patients with amyoplasia have flexion contractures. Extension contractures at the wrist are well tolerated if the following criteria are met: (1) finger extension is sufficient to acquire and release objects, (2) forearm supination and elbow flexion are sufficient to get food to the mouth, and (3) forearm supination, shoulder extension, and elbow extension are sufficient to be able to wipe the perineum from behind. In some children, wrist flexion contractures can enhance function if the above noted criteria are not met.

Initial treatment consists of passive motion and night splinting. Unless splinting enhances function, splinting is avoided during the day to allow the child to play and to promote cortical/muscular development. Because surgical interventions in the wrist and hand have not been demonstrated to have better outcomes at a younger age, surgery can be delayed until the child's functional needs and capabilities are better defined.[11,25] Wait until the child fails to progress with therapy alone and perhaps even after the child is potty trained to determine the wrist flexion requirements. Because wrist flexion is so critical to being able to perform perineal care from the front, it is important for the child to be able to wipe from around the back before considering any procedure that limits wrist flexion.

Serial casting has not been shown to make a difference in the long term.[22] Extensor carpi ulnaris (ECU) to extensor carpi radialis brevis (ECRB) tendon transfers after serial casting may delay recurrence, but we have had minimal success with this strategy. The ECU muscle is often affected, particularly if the EDC is nonfunctional.

If the child has good finger extension, has sufficient pronation and elbow flexion to reach the mouth without the need of wrist flexion, and can perform perineal care around the back, the most reliable procedure to provide wrist extension is a carpal wedge osteotomy with ECU to ECRB transfer.[25] The best candidates have a reciprocal deformity of wrist flexion and MP extension (Figure 39.18). In cases where one hand is to be used for wiping and the other for eating, the eating hand can be considered for a carpal wedge osteotomy as long as finger extension, forearm pronation, and elbow flexion are adequate. The maximal amount of wrist extension that is desired is limited by the ability of the EDC to extend the fingers. Wrist extension past 30 degrees is unnecessary even if there is good finger extension beyond that amount of wrist extension.

Contraindications

Contraindications to correcting a child's wrist flexion contracture include (1) poor finger extension in maximal preoperative wrist extension, (2) obligatory wrist flexion for hand-to-mouth movement, (3) obligatory wrist flexion for perineal care, and (4) use of the back of the wrist for scooting along the

FIGURE 39.18 Children with limited wrist extension will use the extensor digitorum communis to extend the wrist, leading to a zigzag deformity of wrist flexion, metacarpophalangeal extension, and interphalangeal flexion. These patients are excellent candidates for a carpal wedge excision and tendon transfer for wrist extension.

ground for ambulation or for balance and support during standing or sitting. Most parents want their child to have their wrists in extension in the hopes of normalizing their appearance. However, the loss of the ability to ambulate, engage in perineal care, and self-feed is too high a price for aesthetic improvement.

Preoperative Planning

Large Kirschner wires and Steinmann pins should be available for fixation. A mini C-arm should be available.

Technique

Place the patient supine on a standard operating room table with a hand table. Regional anesthesia may be used to control postoperative pain along with general anesthesia. Apply a tourniquet to the upper arm.

Prepare and drape the arm to the tourniquet. Incise the skin either longitudinally or transversely across the dorsal wrist (Figure 39.19, *A*). The dorsal sensory branches from the radial and ulnar nerves are protected. Identify the ECU in its compartment and follow it out to its insertion at the base of the fifth metacarpal. Release the overlying sixth extensor compartment (see Figure 39.19, *B*). Make a separate incision just distal to the midforearm over the ECU muscle, approximately at the level of the ECU musculotendinous junction. Identify the ECU muscle and tendon. If there is no ECU muscle or the excursion is very limited, look for alternate tendons to transfer. Release the ECU from its insertion. Retrieve the tendon into the proximal wound and release the soft tissue adhesions from the forearm fascia to the ECU that may limit muscle excursion. Park the muscle in the proximal wound to keep it hydrated.

Mobilize the extensor pollicis longus (EPL) and elevate the second and fourth extensor compartments and their contents off of the wrist capsule and carpal bones. Divide the midcarpal joint capsule longitudinally and extend the incision along the capitate proximally and distally, staying out of the radiocarpal joint. Place a Hohmann retractor deep to the capsule on the medial and lateral carpal borders. In a child with minimal carpal ossification, use a knife to incise a dorsal and radially based carpal wedge. For older children, use a reciprocating saw. The cut should correct both wrist ulnar deviation and flexion (see Figure 39.19, *C*).

If there is any tension while placing the wrist in extension, make a longitudinal incision centered over the tight volar structures. Palpate the flexor compartment to identify tight structures, which usually includes the flexor carpi ulnaris. Lengthen the wrist flexors if there is muscle present, or resect the tendon and fascia of the wrist flexor if muscle is absent. If the ECU is inadequate, consider transferring one of the wrist flexors if present.

Once extension can more easily be achieved, augment fixation with Kirschner wires by inserting the wires through the osteotomy in an antegrade direction until they exit the distal hand (see Figure 39.19, *D*). Place transosseous sutures before closing the wedge (see Figure 39.19, *E*). Close the wedge and drive the Kirschner wires retrograde across the osteotomy. Crossing the radiocarpal joint with the Kirschner wires may be helpful to maintain the desired wrist posture but is usually not required. Tie the transosseous sutures if used (see Figure 39.19, *F*). Close the capsule.

Identify the ECRB tendon and open the second extensor compartment. Confirm that the tendon glides across the wrist and tenolyse the ECRB if there is no excursion. If there is no excursion even after tenolysis, cut the tendon proximally to be able to reroute it more effectively. Create a subcutaneous tunnel from the distal to the proximal wound and pass the ECU to the distal wound. Transfer the ECU to the ECRB using a modified Pulvertaft technique to minimize bulk (see Figure 39.19, *G*).[5] Bowstringing is not a concern, because the extension posture is only 30 degrees.

Close the wounds and apply a sterile dressing. Deflate the tourniquet and hold pressure for several minutes. Apply a short-arm splint or cast in maximal wrist extension.

If using a splint, convert to a cast after 2 weeks. Remove the cast and the pins 4 to 6 weeks after surgery, depending on the age of the child and the expected time to union. Children younger than 4 years of age typically heal in 4 weeks, whereas those older than 8 years require 6 weeks. If the carpal bones have not yet ossified, radiographs are not helpful in determining union of the chondrodesis.

Once the cast is removed, outfit the patient with an Orthoplast splint to be worn at all times except for bathing and therapy 3 to 5 times a day. Therapy consists of active and passive wrist extension and active wrist flexion. Passive wrist flexion is avoided. Digital motion should be encouraged. Two to 3 months after surgery, transition to just night-time splint use for another 3 to 4 months. Weight bearing is allowed at 3 months after surgery.

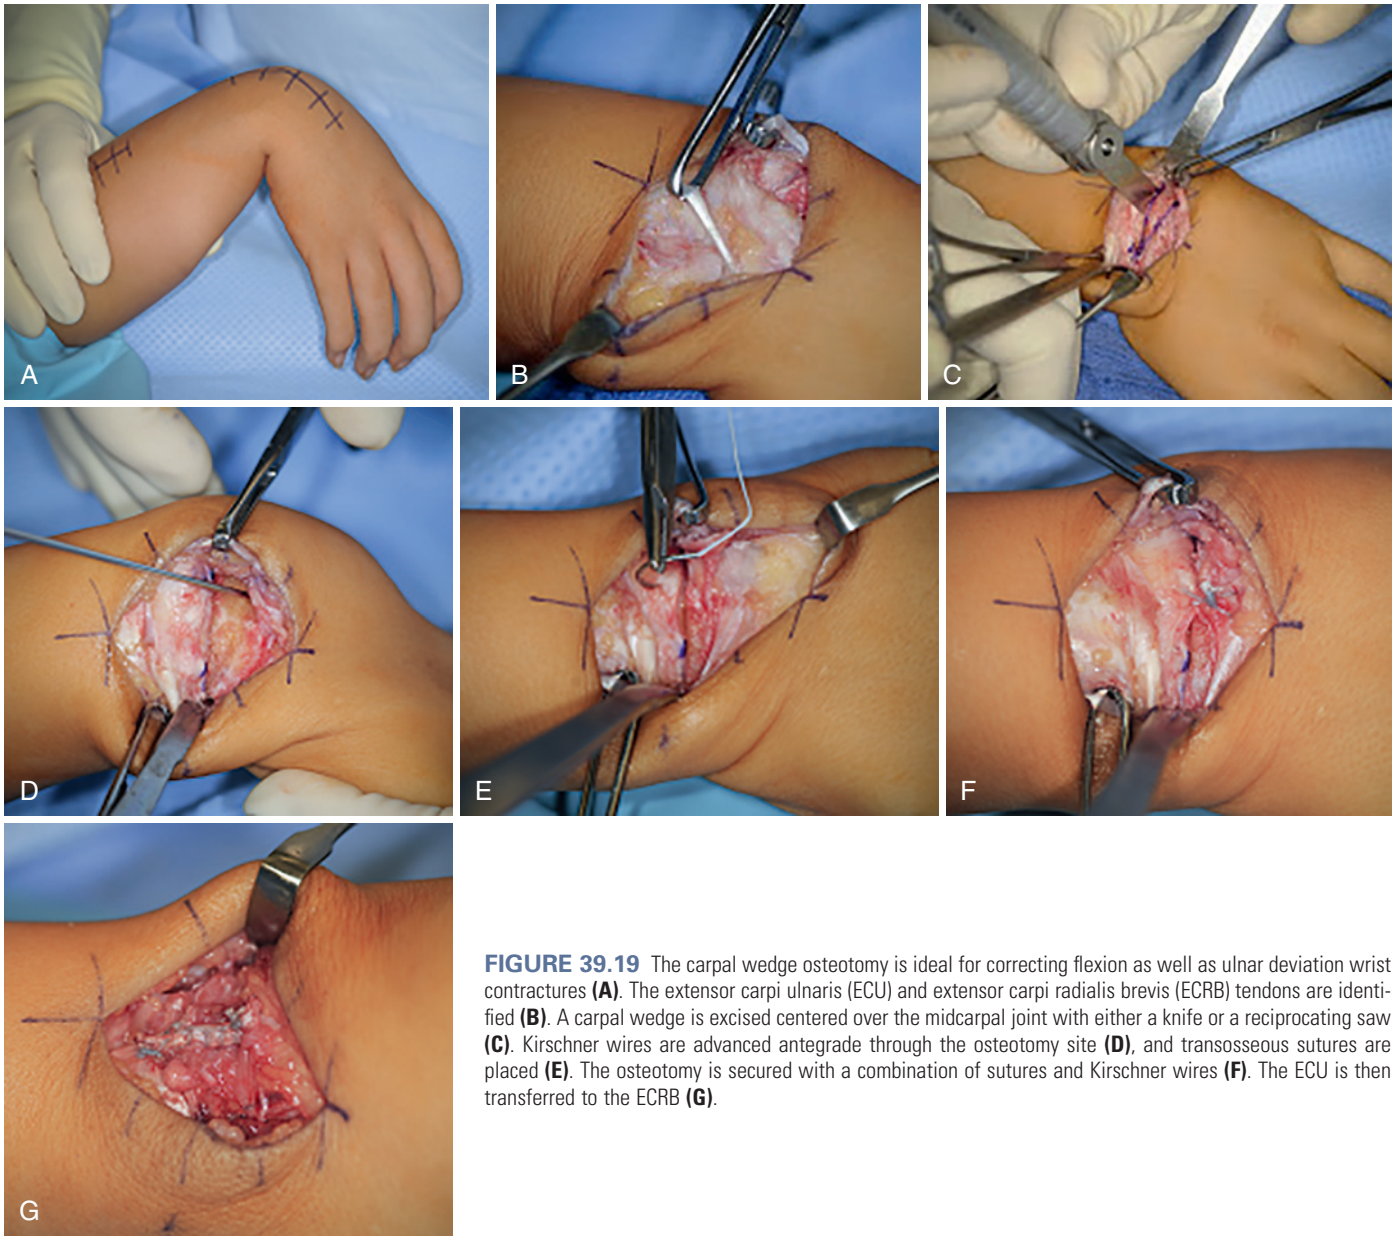

FIGURE 39.19 The carpal wedge osteotomy is ideal for correcting flexion as well as ulnar deviation wrist contractures **(A)**. The extensor carpi ulnaris (ECU) and extensor carpi radialis brevis (ECRB) tendons are identified **(B)**. A carpal wedge is excised centered over the midcarpal joint with either a knife or a reciprocating saw **(C)**. Kirschner wires are advanced antegrade through the osteotomy site **(D)**, and transosseous sutures are placed **(E)**. The osteotomy is secured with a combination of sutures and Kirschner wires **(F)**. The ECU is then transferred to the ECRB **(G)**.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

When indicated, the carpal wedge osteotomy and tendon transfer is the most predictable option for improving wrist extension. Radiocarpal fusions in this age group are notoriously difficult to achieve, and when they succeed they limit motion.

Postoperative Management and Expectations

Expected Outcomes. The wrist position is reliably improved so that there is more extension even if there is no active wrist extension transfer. However, the correction is underwhelming and can deteriorate over time if there is no active wrist extension.

Complications. Nonunions are rare, but undercorrections are common. Loss of finger extension and increased finger stiffness can also occur.

CRITICAL POINTS *Carpal Wedge Osteotomy*

- Confirm that there are no contraindications to extending the child's wrist.
- Release any volar structures that are tethering the joint into flexion.
- Design a biplanar osteotomy to correct both ulnar deviation and flexion.
- Use pins and transosseous sutures for improved fixation.
- Transfer the ECU or any other available expendable tendon to provide active wrist extension.
- Use a modified Pulvertaft technique with a single Pulvertaft pass to minimize tendon bulk.
- Continue night splinting for several months after the osteotomy has healed.

Thumb Reorientation Osteotomy and/or Metacarpophalangeal Chondrodesis

Indications

The classic clasped thumb in arthrogryposis consists of extension at the first carpometacarpal (CMC) joint and flexion at the MP joint. This is more commonly seen in distal arthrogryposis, however, as the CMC joint generally follows the position of the wrist. Children with wrist flexion contractures, as are more commonly seen with amyoplasia, typically have CMC joint flexion contractures with the MP joint in extension. The MP joint can either be passively correctable or fixed in flexion. Interphalangeal joint motion is typically limited but most often positioned in extension. A flexion posture at all three joints is less common (see Table 39.2).

In the postnatal period, initiate treatment in passive range of motion until the child is old enough to be fitted with a splint. We prefer nighttime splints, but daytime splints can be used in severe cases or if they enhance function. Splints should expand the first web space, correct the thumb posture, and provide simultaneous correction of wrist and finger contractures. Tremendous gains can be made with passive motion and splinting in infants, and the parents should be encouraged to be active participants in their child's care. Gains can be seen up to approximately 5 years of age, but most children plateau after their second birthday.

A thumb-to-palm pinch may be desirable for function if other pinch patterns are not possible even with surgical reorientation of the thumb. Surgical options should seek to place the thumb in a position where it can best provide pinch and/or grasp, regardless of appearance. The surgical algorithm (Figure 39.20) depends on the posture of the CMC and MP joints, as well as on the passive motion of the joints. In general, fixed contractures require a fusion whereas passively correctable contractures can be treated with a tendon transfer. The preferred donor for tendon transfers to augment thumb extension is the extensor indicis proprius, but alternate donors such as the palmaris longus, flexor digitorum superficialis (FDS), and brachioradialis can be used. If the CMC joint is in extension and the MP joint has a flexion contracture that is not correctable, MP chondrodesis is the best option.

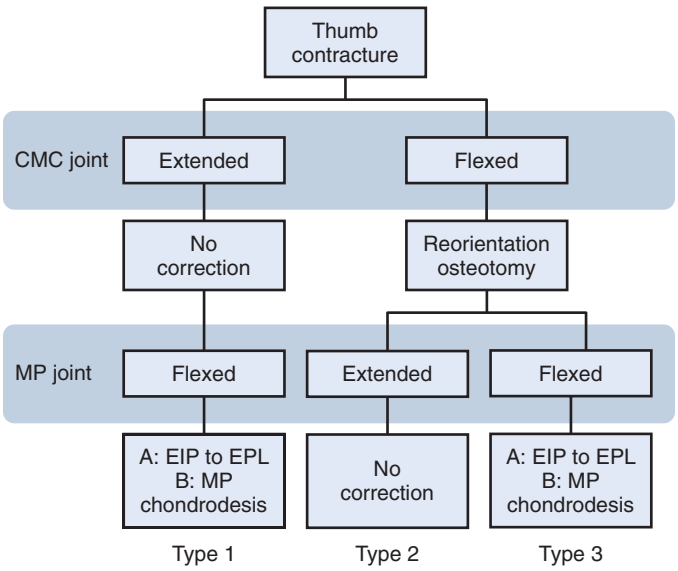

FIGURE 39.20 Surgical algorithm for thumb contractures in children with arthrogryposis. Subtype A is passively correctable, and subtype B is not correctable.

The more common thumb posture for children with amyoplasia is flexion at the CMC joint and extension at the MP joint. The thumb may oppose to one or several of the fingers, or typically only to the palm. Palm pinch is the only option if the fingers are stiff and fixed in extension. Some children have neither finger nor thumb active motion, and do not use their hands at all other than to push objects around. Patients with no digital motion usually lack any active motion in the upper extremity. If FPL function is preserved despite no other function, yet the thumb orientation prevents a useful prehension, the patient is a good candidate for a thumb reorientation osteotomy.[30] The goal of the osteotomy is to place the thumb into a position where it can best take advantage of the child's existing finger and thumb motion to provide pinch and/or grasp. The reorientation osteotomy typically results in a "sock puppet" type of position for the thumb, but other positions may be optimal depending on the child's needs and abilities.

Both type 1 and type 2 thumbs benefit from a first web space contracture release at the same time as a chondrodesis or reorientation osteotomy. Options for expanding the first web space include the four-flap Z-plasty, the Abdel Ghani dorsal rotation advancement flap,[1] and the index rotation (stiletto) flap.[8] For mild web space contractures with a passive extension at the MP joint, a four-flap Z-plasty will suffice (Figure 39.21, *A*). More severe web space contractures with no or minimal MP joint flexion contractures require the Abdel Ghani flap (see Figure 39.21, *B*). For patients with both fixed MP flexion and first web space contractures, the stiletto flap remains the best option (see Figure 39.21, *C*). When necessary, the stiletto flap can be extended into an Abdel Ghani type of flap to expand a very tight first web space (see Figure 39.21, *D*). Often, the first dorsal interosseous and adductor pollicis muscles are either tight or have been replaced with fibrous tissue and must be either lengthened or divided.

Contraindications

Contraindications include a fixed extension contracture at the CMC joint that would preclude opposition after the MP chondrodesis. Children with stiff fingers that would not reach the thumb even after reorientation or MP fusion are not candidates for thumb surgery.

Preoperative Planning

Kirschner wires and a reciprocating saw are required to perform both the reorientation osteotomy and the MP chondrodesis.

Technique

Place the patient supine on a standard operating room table with an arm table. Apply a tourniquet to the upper arm. Prepare and drape the arm to the tourniquet. Begin with a stiletto flap if appropriate (see Figure 39.21, *C*; Video 39.1). Mark the radial apex of the index finger's proximal interphalangeal (PIP) joint crease with a dot, and the entire thumb MP joint flexion crease with a line. Connect the dot to the most ulnar aspect of the line, and draw a divergent line from the dot to the dorsal aspect of

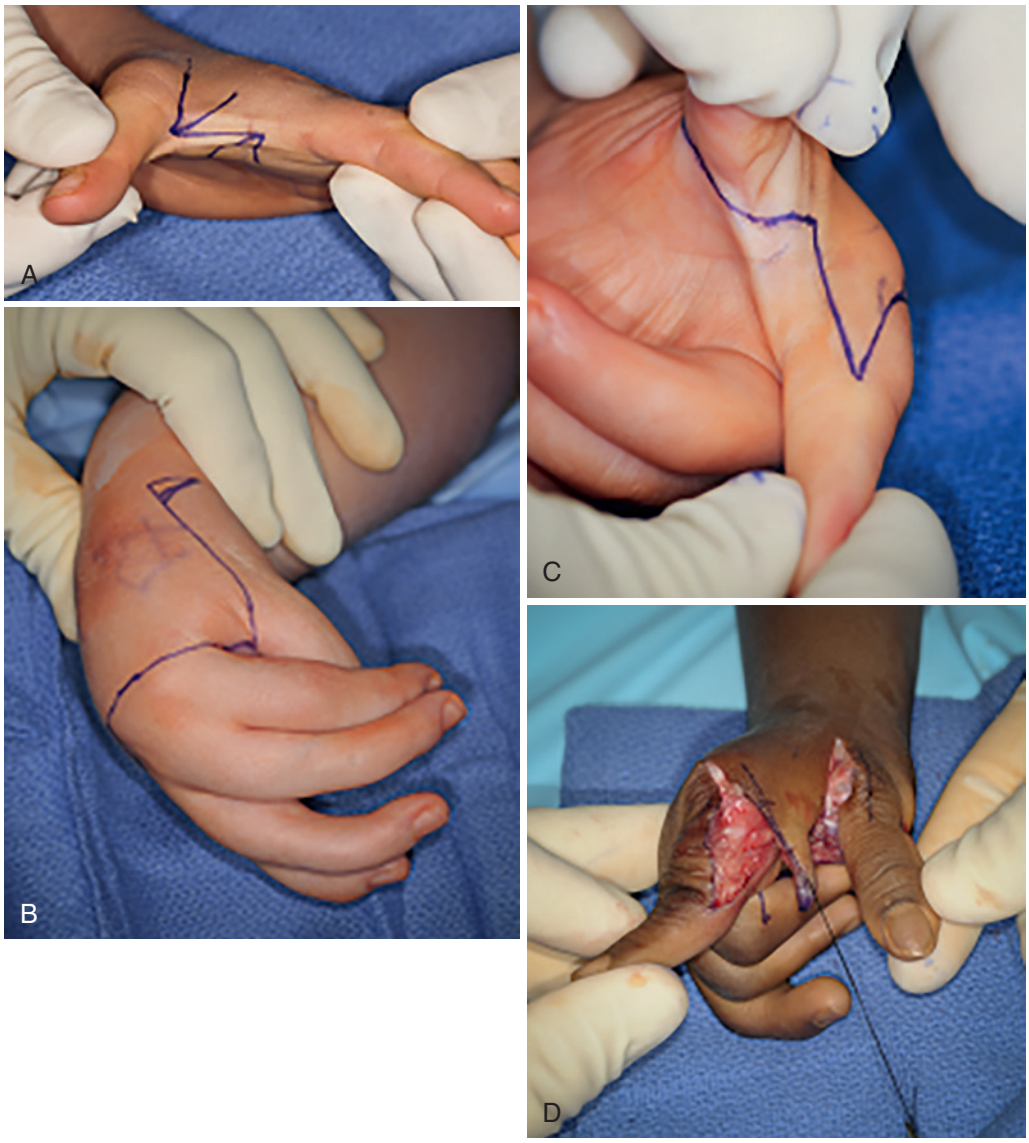

FIGURE 39.21 Multiple flap options exist for widening the first web space. The four-flap Z-plasty is reliable for mild contractures **(A)**. More severe contractures may benefit from a dorsal advancement flap **(B)**. If the thumb is clasped and the first web space is contracted, the index rotation (stiletto) flap is an excellent option **(C)**. If the web space is still tight after a stiletto flap, the flap can be extended into a dorsal advancement flap **(D)**.

the index MP joint. All limbs should be of equivalent lengths. It helps to imagine that the stiletto flap is merely a modified Z-plasty. Curving the more dorsal line provides a better contour for the web space along the thumb (Figure 39.22, *A*). Pinch the "V"-shaped flap together to confirm that there will be sufficient skin remaining on the index finger to close the donor site at the end.

Exsanguinate the arm and inflate the tourniquet. Incise the skin, keeping the stiletto flap in full thickness down to the fascial level. Preserve the dorsal sensory branch of the radial digital nerve to the index finger as it crosses deep to the flap. Identify and protect the princeps pollicis artery and its branches deep to the subcutaneous fat. Incise across the thumb MP joint crease, taking care not to injure the neurovascular bundles to the thumb (see Figure 39.22, *B*). Do not extend the MP joint while cutting across the MP flexion crease, because this places tension across the neurovascular bundles.

Release the fascia overlying the first dorsal interosseous and adductor pollicis muscles in the first web space (see Figure 39.22, *C*). If there is no muscle present, cut the vestigial tendons.

Make a separate longitudinal incision at the base of the thumb metacarpal between the extensor pollicis brevis (EPB) and EPL tendons. Split the periosteum longitudinally between the two tendons and retract the periosteum with two Hohmann retractors. The periosteum near the physis is adherent and should not be violated. Using a reciprocating saw, make an incomplete transverse osteotomy just distal to the physis. Referencing the thumbnail, make a second cut to create a dorsal closing wedge at the desired angle (Figure 39.23, *A*). Complete both cuts.

Pass two 0.035-inch or 0.045-inch Kirschner wires antegrade through the osteotomy site and down the thumb, keeping the wires as far from each other as possible at the osteotomy site to

FIGURE 39.22 The index rotation flap is the workhorse flap for the thumb in arthrogryposis. The limbs of the flap should be of equal length, with at most a 3:1 length-to-width ratio **(A)**. The metacarpophalangeal flexion crease is incised to create the space to inset the flap **(B)**. Divide the fascia over the first dorsal interosseous and adductor pollicis to allow expansion of the web space **(C)**.

maximize rotational control (see Figure 39.23, *B*). Leave the wires proud at the osteotomy site and use them to engage the canal of the metacarpal base. Reduce the osteotomy by extending, abducting, and pronating the thumb. Advance the Kirschner wires back across the osteotomy site. Make sure that the thumb is now in the optimal position to oppose to the fingers, typically in a "sock puppet" position (see Figure 39.23, *C*).

Alternatively, if the CMC joint is in extension and the MP joint is fixed in flexion, perform an MP chondrodesis instead of a reorientation osteotomy (Figure 39.24, *A*). Make an incision over the thumb MP joint between the EPB and EPL tendons. Split the capsule longitudinally between the tendons and cut the collateral ligaments (see Figure 39.24, *B*). Make a transverse cut just proximal to the articular surface of the metacarpal head (see Figure 39.24, *C*). Using a knife and a rongeur, resect the articular surface of the proximal phalanx to the level of the epiphyseal ossific nucleus but no further (see Figure 39.24, *D*). If the epiphysis has not begun to ossify, as is commonly the case in children under 3 years of age, resect only a minimal amount of articular surface so as not to damage the physis at the base of the proximal phalanx (see Figure 39.24, *E*). Provisionally reduce the chondrodesis to make sure that the thumb MP joint can be extended without undue tension on the volar neurovascular structures. Excessive tension can result in vasospasm or even intimal vessel injury that may lead to thumb ischemia or even necrosis. If there is tension, resect more of the metacarpal.

Once the chondrodesis reduces, pass one 0.045-inch Kirschner wire antegrade through the proximal phalanx and down the thumb, leaving the pin proud proximally. Reduce the chondrodesis and advance the Kirschner wire back across the joint. Make sure that the thumb is now in the optimal position to oppose to the fingers (see Figure 39.24, *F*) and adjust the fixation of the metacarpal osteotomy accordingly. Repair the extensor hood and joint capsule with slow absorbing suture. If the FPL is very tight, consider making a separate incision in the volar forearm and fractionally lengthening the FPL.

Wire placement can be confirmed either clinically or with the use of fluoroscopy. It is unnecessary to bury the pins. Rotate the stiletto flap into the thumb MP crease and close the wounds with absorbable suture. Apply a sterile dressing and deflate the tourniquet while holding pressure over the wound. Apply a short-arm thumb spica cast or splint.

Remove the cast 4 to 6 weeks after surgery, depending on the age of the child. Confirm union at the osteotomy site by x-ray and clinical examination (lack of tenderness) before removing the wires. Following pin removal, an Orthoplast thumb spica splint should be worn full time for a month except when bathing or doing range-of-motion exercises. Subsequently, transition to wearing the splint only at night for 2 months.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

For children with fixed thumb-in-palm deformities who can flex their fingers over the thumb, the standard operation is the thumb MP chondrodesis with first web space expansion. The functional and aesthetic gains are typically dramatic, and most patients will ask for the same operation on the contralateral side once they realize the results.

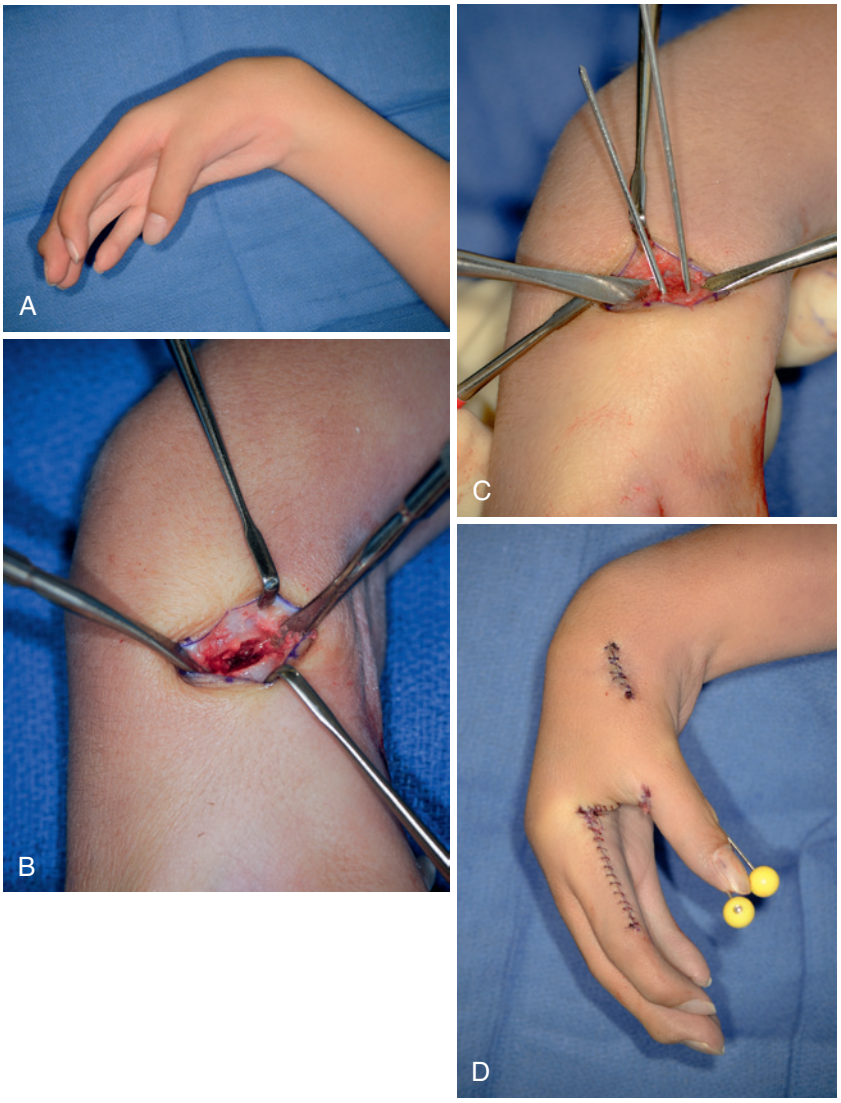

FIGURE 39.23 If the thumb and fingers are mobile but are not in a position to oppose to each other **(A)**, a thumb reorientation osteotomy can be considered. A skin flap, usually a stiletto, is used to open the first web space. The base of the metacarpal is osteotomized distal to the physis to place the carpometacarpal joint into an extension posture **(B)**. Two Kirschner wires are driven antegrade through the osteotomy site **(C)**. The thumb position is optimized into pronation, extension, and abduction and the osteotomy is secured with the two Kirschner wires. Closure of the skin flap completes the procedure **(D)**.

For children whose fingers do not reach the thumb and a thumb that does not reach the palm, pinch is not possible without reorientation of the thumb. The fingers must actively flex sufficiently to reach the thumb in its planned position in order to achieve postoperative pinch.

The stiletto flap is the workhorse flap for the thumb in arthrogryposis, allowing both expansion of the first web and resurfacing of the volar MP joint. It is rare in these children to require only first web space expansion, so a four-flap Z-plasty or an Abdel Ghani flap is less often used.

Postoperative Management and Expectations

Expected Outcomes. In the right patient, a thumb extension chondrodesis and first web space widening can increase function by improving pinch and grasp and can also dramatically improve the appearance of the hand. The thumb reorientation osteotomy in an older child can be similarly gratifying for the same reasons. However, children who undergo reorientation

CRITICAL POINTS *Thumb Reorientation Osteotomy and/or Metacarpophalangeal Chondrodesis*

- Ensure there is adequate finger flexion to merit a thumb reorientation or chondrodesis.
- Thumb reorientation osteotomy is used to correct CMC flexion.
- Thumb MP chondrodesis is used to correct MP flexion.
- MP chondrodesis alone will not address a CMC flexion contracture. A combination of MP chondrodesis and reorientation osteotomy may be required.
- Prior to surgery, assess the need for skin augmentation at the MP flexion crease and the first web space to choose the most appropriate skin flap.
- Release or lengthen the first dorsal interosseous and the adductor to allow expansion of the first web space and rotation of the first metacarpal.
- Make sure that the volar neurovascular bundles are not under tension after performing a chondrodesis.
- Lengthen the FPL if the interphalangeal joint remains tight after chondrodesis or reorientation.

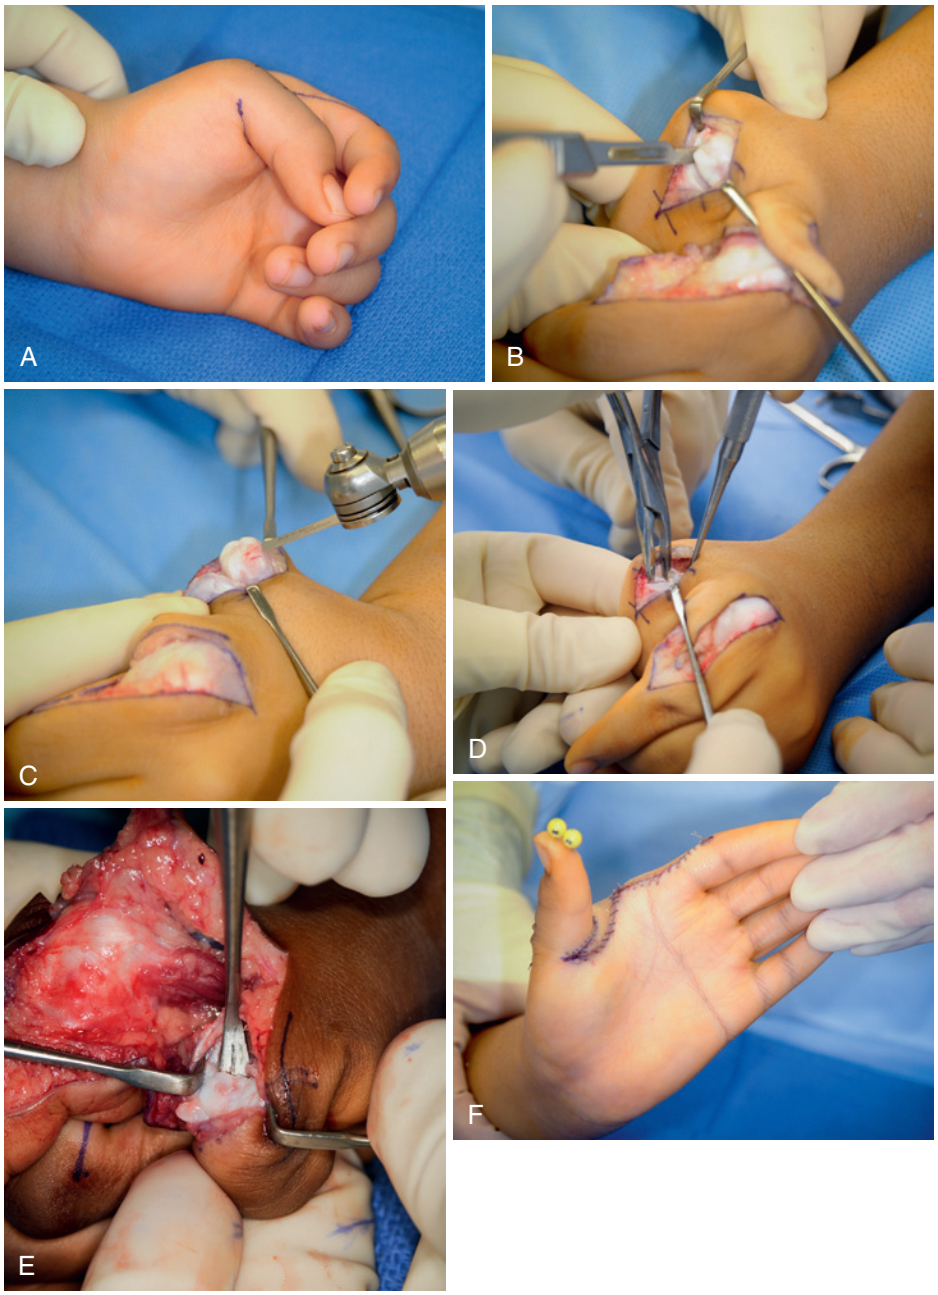

FIGURE 39.24 For type 1B thumbs, a metacarpophalangeal (MCP) chondrodesis and stiletto flap is a reliable option **(A)**. After elevating the stiletto flap, a separate incision is made over the thumb MCP joint. The joint is exposed between the extensor pollicis longus and extensor pollicis brevis tendons, and the collateral ligaments are divided **(B)**. The head of the metacarpal is removed with a reciprocating saw **(C)** followed by resection of the articular surface of the proximal phalanx **(D)**. In children older than 3 years of age, the ossific nucleus signals that the physis is near **(E)**. Fixation of the chondrodesis and closure of the skin flap dramatically improve the appearance of the hand **(F)**.

osteotomies typically have no hand function prior to surgery, and the functional gains are modest. Also, young children (<7 years) will often remodel their reorientation osteotomy over time and lose their correction.

Complications. Nonunion is rare in these cases. Malunions are possible and are usually the result of malrotation of the thumb. Nerve injury and vascular injury are rare. However, neurovascular injury can result in loss of the thumb. Great care should be taken not only to preserve the neurovascular structures during the dissection but to avoid excessive tension during joint reduction. If there is tension, resect more metacarpal prior to fixation.

Camptodactyly Release

Indications

Almost all children with upper extremity arthrogryposis have some degree of contracture of the fingers (Table 39.4). The fingers are typically rigid at the interphalangeal joints and fixed in extension. MC motion (at least, passive movement) is often preserved. Some children have reciprocal deformities with the wrist in flexion and the fingers in extension at the MP joints. Children with amyoplasia with no muscle function in the hands often present with symphalangism[2] fixed in extension (Figure 39.25). Rigid fingers function only to point or push objects

around a surface. There is currently no successful treatment for mobilizing stiff digits other than the occasional osteotomy to change the resting posture of the digits.

Camptodactyly is more common in DAs and can be a defining characteristic of specific syndromes such as *Beals syndrome* (contractural arachnodactyly). Camptodactyly can interfere with capturing objects in the hand, with some children developing a compensatory pinch-and-grasp pattern against the dorsum of the contracted fingers (Figure 39.26, *A*).

In the postnatal period, initiate treatment with passive range of motion until the child is old enough to be fitted with a splint. We prefer nighttime splints, but daytime splints can be used in severe cases or if they improve function. Splints should provide correction of wrist and finger contractures as well as simultaneous expansion of the first web space and improvement of the thumb posture. Gains can be made with passive motion and splinting, and parents should be encouraged to be active participants in their child's care.[4] Gains can typically be seen up to about 5 years of age, but most children plateau after their second birthday.

Radiographs are not useful for camptodactyly in young children. In older children, the condyles at the PIP joint will often appear hypotrophic (see Figure 39.26, *B*). Children with passively correctable camptodactyly are more likely to have well-formed condyles than children with fixed flexion contractures. In general, the more severe the condylar hypoplasia, the less correctable the deformity.

Many surgical schemes have been devised to correct camptodactyly.[10,17,23] Almost all surgical algorithms include a volar Z-plasty to release the tight pterygium at the PIP joint (see Figure 39.26, *C*). In addition to contributing to the contracture, the pterygium can make it difficult for the child to hold objects in the hand. Occasionally, the skin overlying the PIP joint is so tight that a full-thickness skin graft is needed to provide resurfacing instead of a Z-plasty.

The FDS is almost always tight and can be divided at the PIP joint (see Figure 39.26, *D*). If the camptodactyly is passively correctable and there is good FDS excursion, the FDS can be transferred to the lateral band to augment the extensor mechanism. However, FDS transfer may enhance digital extension at the expense of digital flexion (grasp). Another option is to use the FDS to enhance wrist extension, but this can only be done if there is sufficient finger extension to allow object acquisition and release with the wrist in neutral.

TABLE 39.4 Patterns of Hand Deformities in Arthrogryposis

Phenotype	Anatomic Findings	Typical Type of AMC
Clasped thumb	Contracted flexor pollicis longus and/or thenars, adductor, first dorsal interosseous, weak or absent extensors	All
Stiff straight thumb	Absence of thumb flexors and extensors	Amyoplasia
Windblown fingers	Ulnar deviation at metacarpophalangeal joints	Distal arthrogryposes
Claw fingers	Preserved extrinsic finger extensors, weak or absent intrinsics, weak wrist extensors	Amyoplasia
Camptodactyly	Contracted flexor digitorum superficialis, weak or absent extensor mechanism	All
Stiff straight fingers	Absence of finger flexors and extensors	Amyoplasia

AMC, Arthrogryposis multiplex congenita.

FIGURE 39.25 The typical position of the hand in a child with amyoplasia who has no hand function. The fingers are stiff and in nearly full extension. The thumb is a type 2B.

Contraindications

There are no practical contraindications to a volar Z-plasty. A relative contraindication for FDS tenotomy is lack of the flexor digitorum profundus (FDP) and intrinsic function.

Preoperative Planning

No special equipment is required.

Technique

Place the patient supine on the operating room table with an arm table. Apply a tourniquet to the upper arm. Begin with an examination under anesthesia. If the PIP joint itself is contracted, consider adding a joint release if the neurovascular structures allow. Determine if the FDS is tight by comparing the joint contracture in wrist flexion and extension. Lastly, look for any extensor mechanism tenodesis.

Prepare and drape the arm to the tourniquet. Inflate the tourniquet. Make a Z-plasty incision beginning along the ridge of maximal skin tension crossing the PIP flexion crease. Extend the incision in a "Z" shape to the apices of the PIP flexion creases at 60-degree angles. The "Z" should have equal length segments. Adjustments can be made to accommodate for more oblique lines of tension or for a more distal or proximal pterygium.

Identify the neurovascular bundles and retract them gently out of the way. Occasionally, the bundles may contribute to the contracture. Do not attempt to gain further passive extension

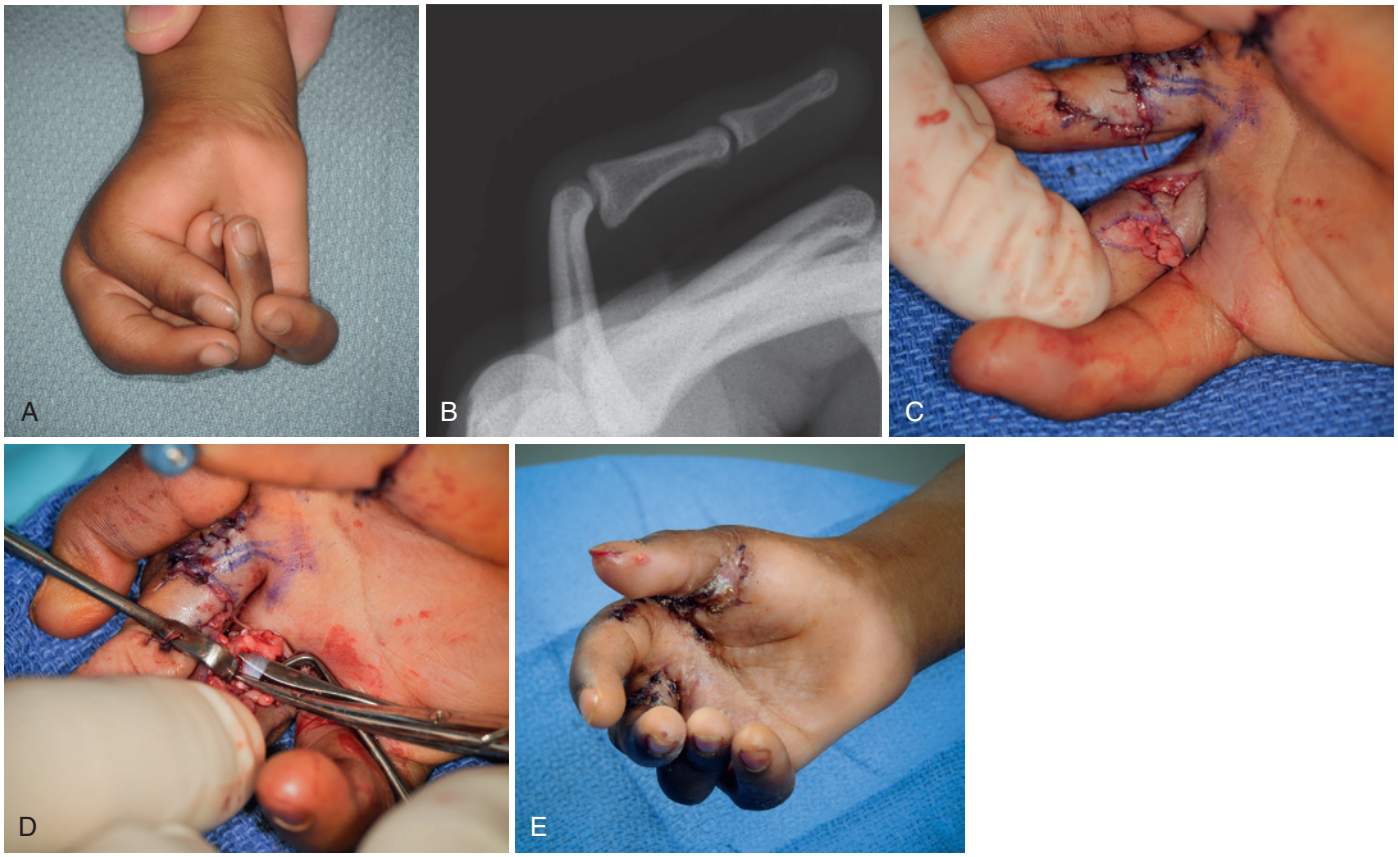

FIGURE 39.26 Camptodactyly can interfere with function, as seen in this child who was unable to place objects in his hand. His thumb opposed to the dorsum of his ring finger **(A)**. Radiographs typically demonstrate hypotrophic condyles at the proximal interphalangeal joint **(B)**. A thumb metacarpophalangeal chondrodesis and stiletto flap as well as camptodactyly releases of the long and ring fingers were performed. The Z-plasties were made along the lines of maximal tension **(C)**, and the flexor digitorum superficialis was released **(D)**. Clinical appearance at follow-up was improved **(E).**

than is allowed by the bundles. If the bundles can accommodate further PIP joint extension, test for FDS tightness by extending the wrist. If the child has a functioning FDP and a tight FDS, consider an FDS tenotomy just proximal to the fourth annular pulley.

In high-functioning patients with good FDS excursion and without an intrinsic PIP joint contracture, consider transferring the FDS to augment intrinsic function. Both a Zancolli lasso and a formal intrinsic-plasty have been described.[10,17,23]

After FDS release, any remaining contracture is likely from the joint itself. Depending on the tension of the neurovascular bundles, consider dividing the checkrein ligaments and the attachment of the accessory collateral ligament to the volar plate. Gently manipulate the joint to avoid a physeal fracture at the base of the middle phalanx. Application of a Kirschner wire is optional to hold the joint in maximal extension.

Close the wound with absorbable sutures and apply a sterile dressing. Deflate the tourniquet and check the finger for adequate perfusion. The arteries may be in spasm, and capillary refill may be delayed at first. If the fingers remain ischemic after 5 minutes, consider step-wise warming of the room, removing the dressings, blocking the sympathetic nerves with a lidocaine injection, and removing the pin (if used), in that order. Venous outflow is rarely an issue. Once perfusion is confirmed, apply a long-arm or short-arm cast or splint to maintain the fingers in extension.

Remove the splint or cast after 2 to 3 weeks, and remove the pin if used. Use an Orthoplast splint full time except during motion exercises and bathing for a further 6 weeks, followed by nighttime splinting until the contractures are stable.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Despite a few reports of good results with camptodactyly release overall, we have not had great success with anything other than releasing the pterygium and cutting the FDS. We have therefore decided that a Z-plasty is the standard treatment for camptodactyly, and we add an FDS tenotomy routinely if the FDP is functional and the FDS is tight.

If the child has the rare combination of inadequate active wrist extension, passive wrist extension past neutral, good finger extension, and camptodactlyly, the FDS can be transferred through the interosseous membrane to the ECRB tendon.

CRITICAL POINTS *Camptodactyly Release*

- Make the longitudinal portion of the Z-plasty along the crest of the pterygium in the line of maximal tension.
- Extend the digit only as much as the neurovascular bundles will allow.
- Tenotomize the FDS if the FDS is contributing to the contracture and the FDP is functional.
- Release the volar plate checkrein ligaments if the joint itself is tight.
- Pin the joint in maximal extension for 2 to 3 weeks following joint release.

Postoperative Management and Expectations

Expected Outcomes. The results of camptodactyly release are unpredictable, despite some favorable results in the literature.[10,17,23] It is rare that a patient will be worse off, unless one is attempting extensor mechanism augmentation. It is common, however, for the family to be underwhelmed by the degree of correction and to notice loss of correction over time.

Complications. Stiffness is the most common complication after any camptodactyly release. Digital nerve injury and vascular injury are possible and are most often traction injuries caused by straightening a bent finger.

SUMMARY

Arthrogryposis remains a challenging disease for the patient, the parents, and the treating practitioner. Fortunately, the initial joint contractures tend to improve over time with stretching and splinting. Each child follows his or her own path, however, with some returning to full function and other less fortunate children never developing any muscle tone. The type of arthrogryposis often suggests the nature and severity of the child's contractures, but each child is affected in a unique way and adapts to the limitations in a unique way. When a child is unable to adapt, guidance from an experienced therapist and communication with other children with arthrogryposis can help. The arthrogryposis community has accumulated many tricks to optimize function, with assistive devices and novel methods for achieving routine activities of daily living. The role of upper extremity treatment is to enhance the abilities of these children without compromising existing function. There is little margin for error in these children, and parents should be aware that any surgical intervention may risk compromising existing function. Surgery should be pursued only if the potential benefits in function outweigh the potential losses. Operating on one arm at a time provides a mechanism for the surgeon, patient, and family to judiciously assess the outcome.

Although the options are often limited and the results of surgery are not always predictable, helping these children transition from dependence to independence is tremendously rewarding. Sterling Bunnell's famous words, "to someone who has nothing, a little is a lot,"[21] particularly apply to these children.

This chapter discusses the diagnosis, treatment, and long-term expected outcomes of infants and children with neonatal brachial plexus palsies. Because the type and severity of neural injuries are variable, treatment and outcome are not uniform for all infants. In those children with mild neurapraxic lesions, spontaneous recovery is to be expected over the first several months of life, with complete recovery evident by age one.[60,63,179] In contrast, children with severe avulsion injuries experience a lifetime of disability despite extensive therapy and surgical management.[179]Although there have been many advances since Duchenne's (1872)[47] and Erb's (1874)[50] classic descriptions of infantile paralysis, many difficult challenges still remain. For instance, the treatment of severe injuries involving the entire brachial plexus with a combination of nerve ruptures and nerve avulsions remain insurmountable. Microsurgical reconstruction of the plexus in the first 3 to 9 months of life can improve the natural history. However, inability to directly repair avulsions of nerve roots from the spinal cord and the resulting relative paucity of donor nerves for reconstruction results in persistent and permanent impairment.[3,27,84,87,98,99,159]

Fortunately, the incidence of these multilevel avulsion and/or rupture injuries is relatively low (between 8% and 25%) for all brachial plexus birth palsies.[63,156,179] In addition, secondary musculoskeletal deformities are common in children with incomplete recovery in the first 1 to 3 years of life. Although nonoperative and operative intervention, such as contracture releases, tendon transfers, and osteotomies, may improve function, none can normalize limb function. The goal of this chapter is to explain the nature of the neurologic injury and its effect on the developing child. This knowledge will guide decision making regarding the initial neurological injury and its secondary musculoskeletal manifestations. Issues and controversies with incomplete evidence for decision making will also be addressed.

PERTINENT ANATOMY

Essential to any discussion of the natural history and treatment of a brachial plexus lesion is a thorough understanding of the anatomy. Therefore, a brief review of the pertinent anatomy is described (Figure 40.1).

The brachial plexus most commonly receives contributions contiguously from the fifth cervical (C5) through the first thoracic (T1) ventral spinal nerve roots. Prefixed cords (22%) receive an additional contribution from the C4 nerve root, whereas the much less common postfixed cords (1%) receive a contribution from T2.[9] The C5-6 nerve roots join to form the upper trunk, the C7 nerve root continues as the middle trunk, and the C8-T1 nerve roots combine to form the lower trunk. Each trunk bifurcates into anterior and posterior divisions. The posterior divisions of all three trunks make up the posterior cord. The anterior divisions of the upper and middle trunks form the lateral cord. Finally, the anterior division of the lower trunk forms the medial cord.

The major nerves of the upper extremity are terminal branches from the cords, with the ulnar nerve arising from the medial cord, the radial and axillary nerves from the posterior cord, the musculocutaneous nerve from the lateral cord, and the median nerve from branches of the medial and lateral cords. The other nerves to the upper extremity arise sequentially throughout the brachial plexus as illustrated in Figure 40.1. Of note, the dorsal scapular nerve arises from the C5 nerve root along with a branch to the phrenic nerve, the suprascapular nerve arises from the upper trunk, and the long thoracic nerve arises from the C5-7 nerve roots. In addition, the lateral pectoral nerve originates from the lateral cord and the medial pectoral from the medial cord. Finally, the thoracodorsal nerve and the upper and lower subscapularis nerves arise from the posterior cord. The proximal-to-distal orientation of the brachial plexus is nerve roots, trunks, divisions, cords, and terminal branches. The divisions are located behind the clavicle. Every muscle in the upper limb is innervated by the brachial plexus.

Surgical exploration and reconstruction of the brachial plexus require a thorough understanding of its three-dimensional anatomy. As noted, the brachial plexus extends proximally from the C5 to the T1 ventral nerve roots of the spinal cord and distally to the terminal branches in the upper brachium. In the neck, it is located between the anterior and middle scalene muscles. The plexus extends beneath the clavicle, superficial to the first rib, as it passes into the axilla. The plexus is divided into supraclavicular and infraclavicular portions. The brachial plexus is joined by the major blood vessels of the arm beneath the clavicle. As the plexus courses medial to the coracoid, the nerves are surrounded by the axillary artery.

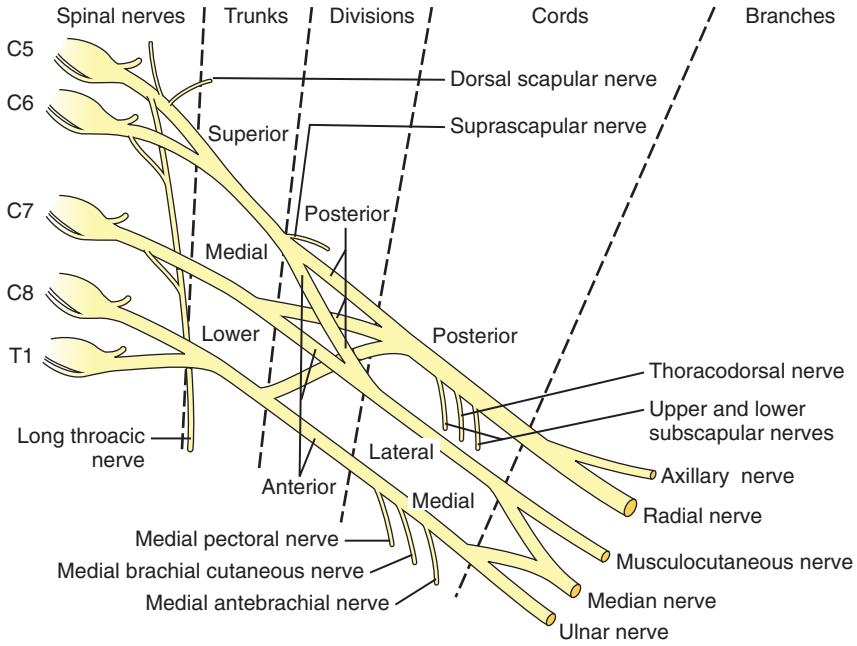

FIGURE 40.1 Normal anatomy of the brachial plexus.

The relationship of the cords to the artery gives them their appropriate medial, lateral, and posterior designations. Complete exposure of the brachial plexus often requires retraction or osteotomy of the clavicle, release of the muscular insertions to the coracoid, and release of the clavicular origin of the pectoralis major muscle.

PREOPERATIVE EVALUATION

Brachial plexus birth palsy has an incidence of 0.38 to 1.56 per 1000 live births.[55] The difference in incidence may depend on the type of obstetric care and the average birth weight of infants in different geographic regions.[87,149] Perinatal risk factors for brachial plexus palsy include large size for gestational age (macrosomia),[23,109,162] maternal diabetes, multiparous pregnancies, previous deliveries resulting in brachial plexus birth palsy,[8,159] prolonged labor, breech delivery,[57,159] shoulder dystocia,[77] and assisted (vacuum or forceps) and difficult deliveries.[77,164]

Maternal body mass index is on the rise in the United States and other well-developed countries of the world, and this is leading to increasing fetal size and a rising incidence of gestational diabetes. Both are risk factors for brachial plexus birth palsy.[112,188] Unfortunately, shoulder dystocia is often an unanticipated and unpredictable obstetric emergency.[58] Fetal distress may contribute to muscle hypotonia and provide less protection of the plexus from stretch or compression injury during delivery.[164]

Mechanically, shoulder dystocia[12,22,117,163] in vertex deliveries and difficult arm or head extraction in breech deliveries increase the risk for nerve injury.[57,159] The increased incidence of delivery by cesarean section may in part be due to an attempt to avoid dystocia and brachial plexus injuries. However, cesarean section does not guarantee prevention of a brachial plexus birth injury, although it decreases the incidence 100-fold.[11] Further complicating the etiology are reports citing evidence of intrauterine onset of paralysis.[80,134] Thus, prevention of the injury remains elusive, underscoring the importance of optimal treatment of the sequelae.

Most commonly, a brachial plexus birth palsy involves the upper trunk (C5-6 or Erb's palsy), potentially in combination with injury to C7 (extended Erb's palsy); less often, the entire plexus (C5-T1 or global palsy) is injured. Injuries are described classically as neurapraxia (Sunderland type I), axonotmesis (Sunderland types II to IV), neurotmesis (Sunderland type V), or avulsion (Figure 40.2). Mechanically, lesions have been described as stretch (Sunderland type I), varying degrees of rupture (Sunderland types II to V), and avulsion. Upper trunk extraforaminal ruptures are more common with vertex delivery and shoulder dystocia. The right upper limb is involved more often because of the more frequent left occiput anterior vertex presentation, which places the right shoulder behind the symphysis pubis. C5-6 root avulsions are particularly frequent with breech presentation and can at times be bilateral.[6,60,110] When the entire plexus is involved, a combination of stretch, rupture, and avulsion injuries can occur in various portions of the plexus.

A mechanical cause of infantile paralysis is the predominant theory on the etiology of brachial plexus birth palsy. The theory is based on extensive work that began with original descriptions of brachial plexopathy during delivery by Smellie[160] and Duchenne[47] and anatomic studies by Metaizeau.[113] However, there are rare reports of possible congenital causes of a birth palsy such as hypoplastic plexus.[61,134] In addition, it has been postulated that there may be abnormal in utero forces (maternal propulsive forces) acting on the posterior shoulder region and the plexus as the fetus passes over the sacral promontory before obstetric delivery. The pushing forces of uterine contractions in a dystocia situation have been studied to determine their contribution to neonatal nerve injury in these deliveries.[130]

Increased in utero pressure and subsequent traction across the plexus have been proposed as a possible root cause. In addition, the presence of an anomalous uterus, such as a bicornuate

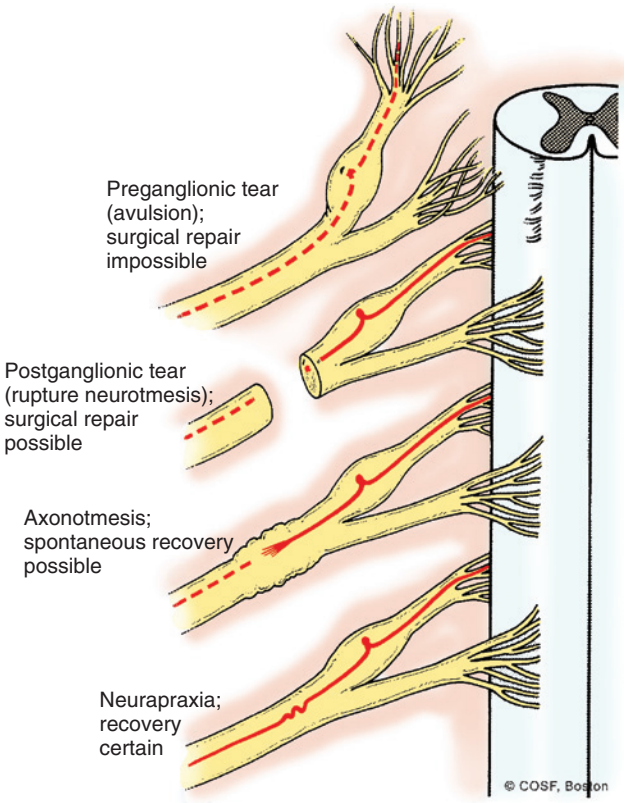

FIGURE 40.2 A severe traction injury to the brachial plexus may cause nerve injuries of varying severity in the same plexus. Such injuries include avulsion of the nerve root from the spinal cord (cannot be repaired), extraforaminal rupture of the root or trunk (can be surgically repaired), intraneural rupture of fascicles (some spontaneous recovery possible), and neurapraxia (recovery certain).

FIGURE 40.3 A 4-month-old child with left global brachial birth palsy and Horner syndrome. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

or fibroid one, may decrease the space available for the infant and lead to compression across the brachial plexus.[81] These alternative causes have become contentious issues in a litigious society because the presence of a brachial plexus birth palsy may result in a malpractice suit against everyone participating in the birth of that infant, including the obstetrician, midwife, labor nurse, hospital, and others.[79,130]

The diagnosis of a brachial plexus birth palsy is predominantly by physical examination. The differential diagnosis includes pseudoparalysis as a result of fracture or, less commonly, infection; injury to the central nervous system or cervical spinal cord; neuromuscular disorders; and congenital anomalies of the upper limb that result in limited motion and strength. Because fracture of the clavicle can occur concomitantly with a birth palsy, radiographs are clinically indicated. A humeral shaft fracture can mimic a brachial plexopathy, although the two injuries do not tend to coexist in the same limb. Instead, a severely displaced humeral shaft fracture results in an isolated radial nerve palsy.

Generally, the diagnosis of a brachial plexus palsy is readily apparent. The spectrum of clinical findings is dependent on the extent of nerve injury and the timing of examination. The presence of Horner syndrome (i.e., ptosis, myosis, enophthalmos, anhidrosis) is worrisome for an avulsion injury in the lower roots and a poor prognosis (Figure 40.3). The recovery after birth is often dynamic with changing physical findings over the first few weeks and months of life. Patience is required to perform a reliable examination of an infant (Video 40.1). Observation of spontaneous movement, testing of neonatal reflexes, and stimulation of motor activity are necessary for an accurate examination. The most important aspect of the examination is to determine the prognosis for recovery.[98,179] Therefore, serial examinations on a 1- to 3-month basis during infancy are critical for prediction of outcome and determination of indications for surgical intervention.[46]

Narakas and Slooff attempted to clinically categorize the continuum of brachial plexus palsy into four groups.[124,125,159] The mildest clinical group (I) is represented by the classic upper trunk C5-6 (Erb's) palsy,[50] with initial absence of shoulder abduction and external rotation, elbow flexion, and forearm supination. Wrist and digital flexion and extension are intact. Successful spontaneous recovery is believed to occur in as many as 90% of infants in this group.[159] Group II represents an extended upper trunk lesion and includes additional involvement of C7, with the absence of wrist and digital extension added to the limitations noted for group I. These infants have the classic "waiter's tip" posture of their hand and wrist. The prognosis is worse with C5-7 involvement. Group III consists of a flail extremity but without a Horner syndrome. The most severe involvement (group IV) is manifested as a flail extremity with a Horner syndrome. These infants may have an associated phrenic nerve palsy with an elevated hemidiaphragm.[10] This is best assessed via dynamic study such as a chest fluoroscopy or ultrasound during breathing. These infants have limited chance of meaningful spontaneous recovery.

For prognostic reasons, it is important to determine whether the level of injury is preganglionic or postganglionic (see Figure 40.2). Because of the proximity of the ganglion to the spinal cord and the fact that the motor cell body is in the spinal cord,

TABLE 40.1 Indicators of Avulsion Injuries and Poor Prognosis for Recovery

Finding	Implication
Paraspinal muscle injury	Dorsal rami injury
Rhomboid injury	Dorsal scapular nerve (C5)
Scapular winging	Long thoracic (C5, C7, C8) injury
Horner syndrome	Cervicothoracic sympathetic injury
Hemidiaphragm paralysis	Phrenic nerve injury
Pseudomeningocele	Dura and arachnoid avulsion injury

preganglionic lesions are avulsions from the cord that will not spontaneously recover. By assessing the function of several nerves that arise close to the midline and the ganglion, one can frequently determine the level of the lesion by physical examination (Table 40.1). Specifically, the presence of Horner syndrome (sympathetic chain), an elevated hemidiaphragm (phrenic nerve), and a winged scapula (long thoracic nerve) and the absence of rhomboid (dorsal scapular nerve), all raise concern about a preganglionic lesion.

Preganglionic lesions can be reconstructed only by nerve transfers,[123] most commonly with the thoracic intercostal nerves,[85,105,122] a branch of the spinal accessory nerve,[83] or partial peripheral nerve transfers. Postganglionic ruptures have reconstructible proximal and distal nerves beyond the zone of injury. Thus, a postganglionic injury is a complex peripheral nerve lesion that can be reconstructed with intercalary nerve grafts. Peripheral nerve transfers can also be used to reconstruct these injuries. However, functional spontaneous recovery is also possible in postganglionic injuries, likely due to partial ruptures and redundant innervation pathways present at birth.[177] Narakas group I and those in Narakas II with complete biceps recovery by 4 months have a high likelihood of full function. Infants in groups III and IV are unlikely to achieve full function without surgical intervention.[158]

The majority of neonatal brachial plexus injuries involve the upper trunk.[62] The classic Erb palsy involves C5-6 (46%). The next most common injury (an extended upper trunk lesion or extended Erb's palsy) involves C5-7 (29%); with these injuries, the pattern is most frequently postganglionic. When the lower plexus is involved, preganglionic avulsions of C8-T1 are most common. The exception to this situation is an upper trunk lesion seen with a breech delivery. These nerve injuries tend to be preganglionic C5-6 avulsions from the spinal cord.[57]

Most authors use the timing of specific motor function recovery and the absence of recovery as an indication for surgical intervention.[62,99] Wyeth and Sharpe in 1917 advised surgical intervention if no recovery was seen by 3 months of life.[190] Gilbert and Tassin concurred with the 3-month time interval and used recovery of antigravity biceps function as the key indicator of spontaneous recovery of the brachial plexus.[60] Waters similarly found biceps recovery to be statistically reliable.[179] Laurent and colleagues advised monitoring biceps, triceps, and deltoid function.[98]

Clarke and associates described the timing of return of elbow flexion and elbow, wrist, finger, and thumb extension as discriminators of outcome and used a combined threshold score of motor recovery of these muscles as an indication for nerve surgery.[36,116] Ultimately, Clarke advised that recovery at 9 months be assessed with a "cookie test" (i.e., inability to bring a cookie to the mouth with the arm at the side) to predict outcome and determine the need for microsurgical intervention in difficult cases.

Grading recovery of specific muscles in an infant is difficult. Many centers use the Medical Research Council (MRC) muscle grading system to define results. The schema classifies muscle strength as 0 (no contraction), 1 (trace contraction), 2 (active motion with gravity eliminated), 3 (active motion against gravity), 4 (active motion against gravity and resistance), and 5 (normal power). However, this system requires volitional contraction, which is not feasible in an infant and difficult in a young child. Understanding this, Gilbert and Tassin modified the MRC grading system to a four-grade one of 0 (no contracture), 1 (contracture without movement), 2 (movement with gravity eliminated), and 3 (complete movement against the corresponding weight of the extremity).[106] The modified Mallet classification (Figure 40.4) provides a more global motor function of the upper trunk as opposed to isolated muscle testing.[1]

A sixth category of "internal rotation" has been added to better balance the Mallet classification with regard to external and internal rotation. This global abduction system assesses external rotation of hand-to-mouth, hand-to-neck, hand-to-spine, and hand-to-belly activities on a scale of 1 to 5. A score of 1 is no function, 5 is normal function, and grades 2 to 4 denote progressive improved strength, as shown in Figure 40.4. The majority of late 20th century papers on infantile brachial plexus have used these classification schemes to determine the results of spontaneous recovery and surgical intervention.

More recently, Clarke and coworkers advocated use of the Hospital for Sick Children Active Movement Scale (AMS) (Table 40.2), a grading system that divides muscle strength into movement with gravity eliminated (grades 0-4) and movement against gravity (grades 5-7).[37] This system requires that full active motion with gravity eliminated occur (grade 4) before scoring antigravity muscle strength (5-7). Thus, the presence of contractures that limit joint passive range of motion can limit the progression from grade 4 to grade 5 despite the muscle strength being adequate to move the limb against gravity. The Toronto Test Score[115] is a similar grading of specific muscle functions at the elbow, wrist, and hand, is used only in infancy to predict the need for surgical nerve reconstruction, and is not designed to track progressive recovery over time (Table 40.3). Thus, no scoring system is without limitations.

The Mallet,[107] Toronto Test Score,[11] and AMS are statistically reliable in terms of interobserver and intraobserver analyses.[16,40] As might be expected, intraobserver reliability is better than interobserver, and less complicated systems (Mallet) have higher reliability than more complicated schemes (AMS). The Pediatric Outcomes Data Collection Instrument (PODCI), which assesses parent and patient-reported function, has also been shown to be a reliable tool for measuring baseline function in children with chronic brachial plexus injuries against normative per age data, as well as for assessing postoperative changes in these children.[16,78] However, parent reports of their child's function can be confounded by litigation against the delivery team,[48] as this injury carries with it a strong emotional component that affects perceptions of function.[48] This

Modified Mallet classification (grade I = no function, Grade V = normal function)						
		Grade I	Grade II	Grade III	Grade IV	Grade V
Global abduction	Not testable	No function	 <30°	 30° to 90°	 >90°	Normal
Global external rotation	Not testable	No function	 <0°	 0° to 20°	 >20°	Normal

information is critical for comparing results and for assessing multicenter studies of therapeutic interventions for brachial plexus birth palsy.

Recently, the recognition that objective measurements and legacy measures may not correlate with enhanced function has resulted in a paradigm shift in outcome assessments. The initiative toward patient- or caregiver-reported outcomes has resulted in the development of reliable subjective measures. For children with brachial plexus palsy, Shriners Hospitals for Children has invested millions of dollars into patient-reported outcomes using the computer adaptive test (CAT) approach.[120,121] This methodology has been shown to correlate with legacy measures, discriminate among brachial plexus impairment levels, possess minimal floor and ceiling effects, and be less burdensome compared to previous measurement systems.

Invasive radiographic studies, such as myelography, combined myelography and computed tomography (CT), and magnetic resonance imaging (MRI),[2,45,66,116,169,184,186,192] have been used in an attempt to distinguish between preganglionic avulsion injuries and postganglionic extraforaminal ruptures.[178] Kawai compared all three techniques with operative findings in infants.[86] Myelography had an 84% true-positive rate with 4% false-positive and 12% false-negative rates. The addition of CT to myelography increased the true-positive rate to 94%. The presence of small diverticula was only 60% accurate in diagnosing an avulsion; however, the presence of large diverticula or

frank meningoceles was universally diagnostic. MRI had a true-positive rate similar to that of CT myelography but also allowed extraforaminal assessment of the plexus.[107] MRI allows evaluation for possible double-crush injuries. High spin echo MRI,[56] MR myelography, and MR neurography improve the resolution of MR analysis.[174] MRI has the potential advantage of sedation only inasmuch as myelography requires general anesthesia for an infant.[68] These radiographic studies may improve the quality of preoperative planning, but the final decision regarding the presence or absence of an avulsion injury is determined at the time of surgery.

Electrodiagnostic studies with electromyography (EMG) and nerve conduction velocity (NCV) have also been used in an attempt to improve diagnostic accuracy of the severity of the nerve injury.[132] The presence of normal sensory nerve conduction in the absence of motor nerve conduction is diagnostic of root avulsion. Absence of reinnervation at 3 months is suggestive of an avulsion. The H-reflex has been shown to help prognosticate outcome.[82] Unfortunately, the presence of motor activity in a muscle has not been accurate in predicting an acceptable level of clinical motor recovery in that muscle. With EMG, the presence of partial reinnervation can confuse the clinical picture.[8,22,166]

Studies have shown that nearly normal findings on EMG can be seen in infants with a severe lesion or even root avulsion.[42,105,159,174] Frequently, there are substantial discrepancies between preoperative electrodiagnostic testing (EMG and nerve conduction), intraoperative somatosensory evoked potential testing, and surgical findings. A potential source of this discrepancy is the plasticity of the infantile nervous system.[25] For example, Slooff documented innervation of the deltoid and biceps from C7 in the presence of avulsions of C5 and C6.[159] At this stage, it is clear that neurophysiologic studies may underestimate the severity of injuries and provide a false optimism regarding recovery.[38,172,173] It has been estimated that 20 to 25% of infants with a brachial plexus birth palsy will require microsurgical intervention and that the clinical information is the decisive factor in determining indications for surgery.[32] At present, most centers and brachial plexus microsurgeons ultimately rely on the physical examination findings over time to assess recovery and decide on surgical intervention.

CRITICAL POINTS

- The most common brachial plexus birth palsy involves the upper trunk (C5-6) and is also known as Erb's palsy.
- The second most common pattern involves C5-7 and is known as extended Erb's palsy.
- Involvement of the entire plexus (C5-T1) is called global or total brachial plexus palsy. This is the least common pattern.
- Erb's palsy has the best prognosis for spontaneous recovery. In contrast, global palsy has the worst prognosis for spontaneous resolution.
- Despite difficulty in assessing muscle strength in infants, serial physical examinations remain the best method for predicting prognosis for recovery.
- Current electrodiagnostic studies have been unreliable in predicting recovery.

NATURAL HISTORY

The natural history of neonatal brachial plexus palsy was initially thought to be uniformly favorable; however, recent studies portend a more guarded prognosis. Assessing history is complicated by the lack of true natural history studies. In a systematic review of 76 studies discussing the natural history of BPBP,[142] no paper met all four established criteria for an unbiased study, and only two studies met even two criteria; in these papers, residual neurological deficits existed in 20 to 30% of children. Subsequently, the rate of permanent neurological deficit has been found to be as high as 40%.[54] A true natural history likely may never be elucidated as doing so would require withholding treatment that has become recognized as beneficial for optimal outcomes. Despite limitations in natural history studies, there is sufficient evidence to draw certain conclusions, as follows.

- The majority of brachial birth palsies are transient. Infants who recover partial antigravity upper trunk muscle strength during the first 2 months usually have a full and complete recovery over the first 1 to 2 years of life.
- Infants who do not recover antigravity biceps strength by 5 to 6 months of life should undergo microsurgical reconstruction because successful surgery would result in a better outcome than the natural history alone.
- Infants with partial recovery of C5-7 antigravity strength during months 3 to 6 of life will have permanent, progressive limitations in motion and strength, as well as risk for the development of joint contractures in the affected limb.
- Infants with global injuries and avulsion injuries of the lower trunk with have the worse prognosis and most limitations with lifelong dysfunction in the arm and hand.

The major clinical dilemma resulting from the uncertainty regarding spontaneous neurologic recovery is to determine whether infants without antigravity return of C5-7 function at 3, 4, 5, or 6 months of age warrant surgical exploration and nerve reconstruction. These infants have varying degrees of rupture (Sunderland types II to IV), and their ultimate neuromuscular recovery without intervention or with just tendon transfers has still not been compared with their recovery after microsurgery plus tendon transfers. Ideally, this question would be addressed in a prospective randomized clinical trial with sufficient enrollment[26]; however, such a study has been difficult to perform due to varying clinical practices and beliefs among surgeons at different centers.

Parents, primary care physicians, and therapists are under substantial emotional pressure to do what they believe is best for the affected infant.[153] Unfortunately, despite strong opinions and at times solicitous pressure from specific medical centers, data are still insufficient to definitively answer the question.[19] Comparative analysis has shown that elbow flexion alone is an insufficient criterion to warrant nonoperative care and that useful motor function has been observed in patients without elbow flexion at 3 months of age.[53,161]

Disagreement among surgeons is common regarding surgical indications.[23] This lack of clarity creates large regional variations in care and makes decision making difficult for parents. Accessing information from support groups and the Internet is common. This input affects parents' decision making regarding care of their child.[111,153] The quality of that information, however, can be variable. The long-term outcome with regard to function, activities of daily living, pain, career choice, and personal life is limited. The minimal data collected by support groups infer ongoing difficulties in performing activities of daily living.[13] Pain, as evidenced by self-mutilating behavior, is rare in infants, occurring about 3 to 4% of the time.[108] Chronic pain in adulthood is thought to be uncommon but the true incidence has yet to be documented.

NERVE SURGERY

The role, timing, and technique for nerve reconstruction are controversial issues.[141] The original surgical interventions on the brachial plexus at the turn of the 20th century consisted of resection of the neuroma and direct repair. Kennedy[87a] initially described three cases in 1903 with subsequent reports by Wyeth and Sharpe[184] in 1917 and Taylor[166a] in 1920. In a report on 1100 infants with brachial plexopathy in 1925, Sever was uncertain of the benefit of surgical intervention.[153] By the 1930s, brachial plexus nerve surgery had fallen out of favor. The advent of microsurgical techniques and extensive work in the 1970s and 1980s by Narakas,[123,124] Millesi,[116a-c] and Gilbert[59-61] in Europe, Kawabata[83-85] and others in Asia, and Boome and Kaye in South Africa[27] led to the resurgence in brachial plexus microsurgical reconstruction. At this time, medical centers throughout the world have plastic surgery, neurosurgery, and orthopedic surgery subspecialty brachial plexus centers actively performing brachial plexus nerve reconstruction.

The spectrum of nerve surgery includes neurolysis, neuroma resection and nerve grafting, and nerve transfers. Direct repair is rarely performed because of the extensive nature of the lesion and inability to achieve a tension-free nerve repair without grafting. Although neurolysis has been performed extensively,[98,156] most centers have abandoned its independent use.[3] Clearly, there is no role for neurolysis in the presence of an avulsion injury. Neurolysis has been shown to have results no different from the natural history following total plexopathy, and the evidence is similar (although less conclusive) for injuries involving upper trunk rupture.

Gilbert and Whitaker strongly believe there is no role for neurolysis alone.[61] Laurent and colleagues advocated its use in conjunction with intraoperative electrodiagnostic studies. A neuroma-in-continuity was maintained if greater than 50% of a muscle action potential was found after neurolysis. Otherwise, the neuroma was resected and grafted. However, recovery of muscle strength following nerve grafting was greater than with neurolysis despite the fact that the preoperative status of the neurolysis patients was better compared to those patients who underwent nerve grafting.[98]

Capek and associates described better long-term results after resection and grafting of both conducting and nonconducting neuromas than with neurolysis despite initial worsening of the situation with resection and grafting.[30] Superiority of nerve grafting over neurolysis has also been shown by others.[102] The topic of neurolysis has been recently revisited,[14] although without clear evidence that neurolysis alone affects the natural history as many children would have improved spontaneously without surgery. Based on the present information, neurolysis alone is viewed as having little therapeutic benefit.

The standard nerve reconstruction strategy is resection of the neuroma and sural nerve grafting with extraforaminal

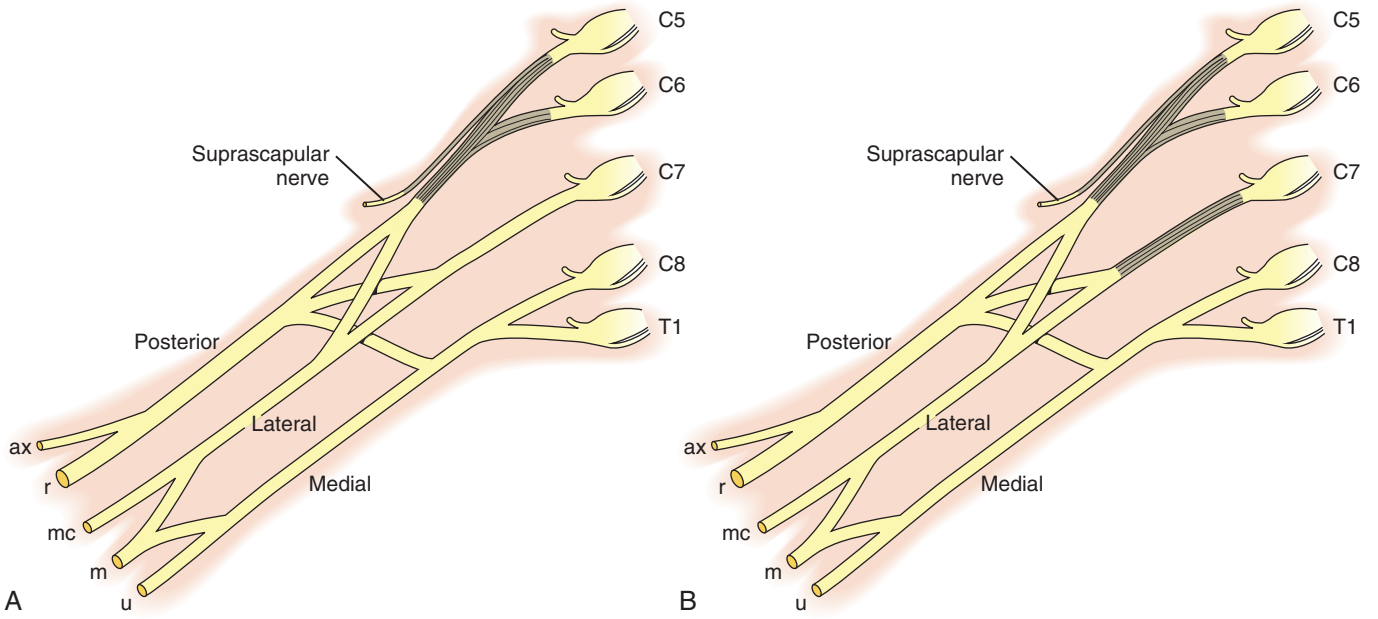

FIGURE 40.5 **A, B,** Nerve grafting strategies for upper trunk rupture. *ax*, Axillary; *m*, median; *mc*, musculocutaneous; *r*, radial; *u*, ulnar.

ruptures.[32] In an upper trunk (C5-6) rupture with an extraforaminal neuroma-in-continuity, resection of the neuroma and sural nerve grafting are performed from the C5 and C6 roots to the most proximal healthy nerve tissue of (1) the upper trunk anterior division, lateral cord, or musculocutaneous nerve; (2) the suprascapular nerve; or (3) the upper trunk posterior division, posterior cord, or axillary or radial nerves (Figure 40.5, *A*). If C7 is involved, additional grafting is necessary from C7 to the posterior cord (Figure 40.5, *B*). Nerve transfers are becoming more popular[4,25,129] for reconstruction of C5-6 and C5-7 injuries, with transfer of (1) the intercostals or partial ulnar nerve to the biceps motor branch, (2) a branch of the spinal accessory nerve to the suprascapular nerve, and (3) the radial nerve long head of the triceps motor branch to the axillary motor branch. Results of nerve transfers for upper plexus lesions appear to be equivalent to nerve grafting at the shoulder and elbow.[97,103]

In the case of ruptures and avulsions, nerve transfers in conjunction with nerve grafting are performed by using the thoracic intercostals (T2-4) (Figure 40.6) or a branch of the spinal accessory nerve (cranial nerve XI) after it innervates the trapezius (Figure 40.7). The spinal accessory can be harvested from an anterior or posterior approach (Figure 40.8). With total plexus avulsions, nerve transfers are the only reconstructive option and may include the intercostals, spinal accessory, contralateral C7, and even the hypoglossal nerve. Carlstedt and coworkers have done experimental and limited clinical work on direct reimplantation or grafting into the spinal cord,[31] but at present, the suboptimal results and the risk of causing cervical instability as a result of the laminotomy or injury to the nerves to uninvolved limbs does not warrant its use.

Gilbert and Whitaker as well as Slooff advocated that priority be given to microsurgical reconstruction of the hand in infants with extensive avulsions and limited nerve options.[61,159] Unlike adults, infants with brachial plexopathy have the potential to regain hand function after nerve grafting or nerve transfers, due to the shorter distance from the injury to the target muscles in the infant's upper limb. In each microsurgical case, the plan must be individualized depending on the time from injury, extent of the palsy, and available reconstructive options.

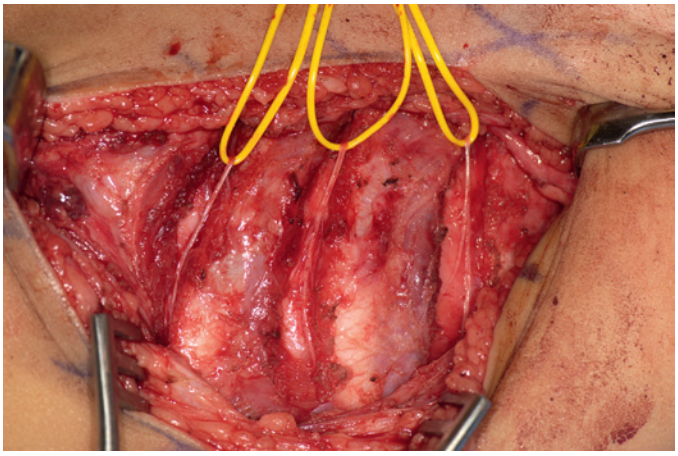

FIGURE 40.6 Nine-month-old with harvest of three intercostal nerves prior to transfer. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

Although there is ongoing debate about the timing of microsurgical intervention, the most common criterion is the absence of return of biceps muscle function associated with (1) total plexopathy and Horner syndrome at 2 to 3 months or (2) an upper trunk lesion at 5 to 6 months. Reconstruction is performed between 3 and 9 months of age at various centers. The degree of muscle recovery is open to debate and interobserver error makes comparative analysis difficult. Gilbert and others advocated for microsurgery when recovery of antigravity biceps function is not seen by 3 months of life.[27,34,123] The reasons for early intervention include less risk for irreversible loss of motor endplates because of prolonged denervation and better parental acceptance of surgical intervention if performed while the limb is still flail or has minimal motion.

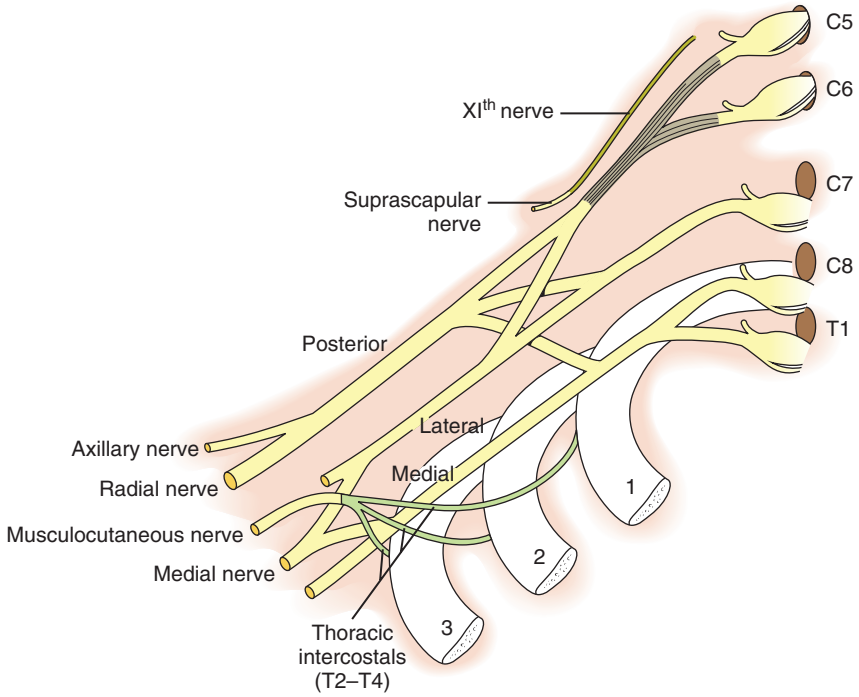

FIGURE 40.7 Nerve grafting strategies for nerve transfers and grafts.

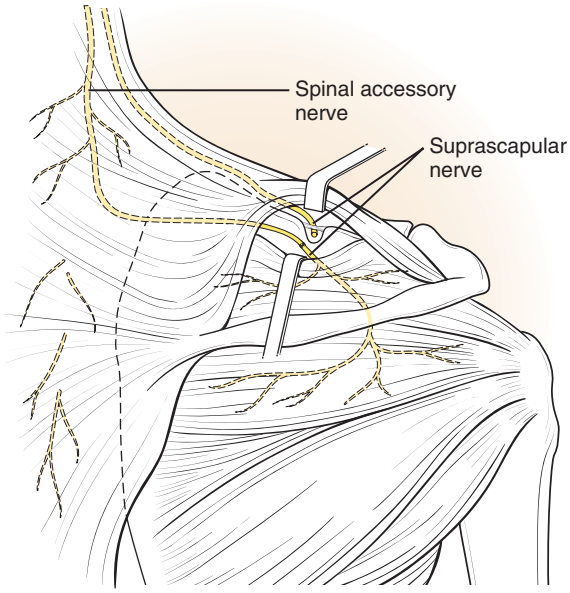

FIGURE 40.8 Schematic representation of a distal spinal accessory nerve transfer to the suprascapular nerve using the posterior approach. The proximal fibers innervating the superior and middle aspect of the trapezius muscle have been preserved, thus preventing a drooped shoulder.

Prospective studies by Al-Qattan[3] and Waters,[180] however, have indicated that recovery of antigravity biceps function by 4 and 5 months of age, respectively, results in outcomes that are equivalent to those of microsurgery, especially when combined with secondary tendon transfers to improve shoulder motion. Similarly, others have demonstrated functional results equivalent to nerve grafting in 12 to 55% of children treated conservatively despite lacking biceps function at 3 months old.[53,161] Finally, Clarke advocated microsurgery as late as 9 months for infants who fail the "cookie test" and thus have less than grade 6 biceps strength on the AMS. Microsurgical reconstruction at that relatively late time was overwhelmingly positive. Therefore, either the motor endplates of infants may be more resilient to irreversible demise than those of adults, or incomplete denervation of the affected muscles due to redundant innervation preserves motor endplate integrity.

Ultimately, the best time for microsurgical intervention in children with extraforaminal nerve rupture is still unknown. Comparative analysis indicates that biceps function alone is an insufficient criterion for operative management as some patients without biceps function by 3 months old recover useful limb function without microsurgery.[53,115,161] There is little consensus regarding the timing and type of procedures performed. Economic analysis indicates that microsurgical intervention at 3 months for nerve rupture is unlikely to be successful enough to produce cost savings for the payor.[28] Most centers and surgeons recommend that nerve surgery be indicated at 3 months for total plexus lesions and rarely indicated for an isolated rupture of the upper plexus.[35]

The problem with reviewing the results of microsurgery is that few patients (1) have long-term follow-up or (2) undergo microsurgery alone. Gilbert and Tassin's original study[60] compared microsurgery with spontaneous recovery. For C5-6 lesions, 100% recovered grade III shoulder motion spontaneously. In the nerve surgery cohort, 37% regained grade III and 63% obtained grade IV. With C5-7 lesions, 30% recovered grade II and 70% grade III with observation. With nerve surgery, 35% were grade II, 42% were grade III, and 22% were grade IV. Later, Gilbert and Whitaker[61] reported 81% shoulder function following C5-6 reconstruction in children with Mallet scores of III, IV, or V for abduction and 64% shoulder function in children who underwent total plexus reconstruction with Mallet scores of grade III or IV at greater than 2-year follow-up.[62]

When combined with secondary shoulder reconstruction, at 5 years these results increased to 70% shoulder function following C5-6 reconstruction with Mallet abduction class IV or V. Similarly, with total plexopathy reconstructions in which the hand was prioritized, at 2-year follow-up there were only 25% with grade III or IV shoulder function; 70% with grade III, IV, or V elbow function; and 35% with grade III or IV hand function using Gilbert's classification scheme. With the addition of secondary shoulder and hand procedures, this increased to 77% in the shoulder and 75% in the hand at 6-year follow-up. Gilbert maintains that nerve surgery not only improves function over natural history in selected patients but also increases the possibility for secondary tendon transfers. Long-term data from Sweden indicate that microsurgical patients still have deficiencies that may require assistance in activities of daily living.[89] The more severe the original injury, the more likely there will be permanent deficiencies.

These results should be compared to the natural history data available. Smith and coauthors published a study of 170 patients to assess the natural history of brachial plexopathy with regard to timing of biceps recovery.[161] Twenty-eight patients with absent biceps at 3 months of age were followed long term. Biceps contractions were observed in 20 patients (71%) by 6 months of age. Ultimately, 27 out of 28 had at least antigravity biceps muscle function. Patients who regained biceps between 3 and 6 months had better Mallet scores than patients who achieved biceps muscle function after 6 months of age. Twelve (55%) of the 22 patients who did not have brachial plexus surgery had class IV shoulder function. The authors concluded that the long-term function was favorable for the majority of C5-6 infants without nerve surgery.

Zancolli and Zancolli[194] found that 82% of affected infants monitored from birth had recovery of biceps function and that recovery in 75% began between months 4 and 5. Waters[179] addressed the same issue and found that of the 49 infants with no biceps recovery at 3 months, 42 recovered biceps function by 6 months. By assessing function at 2 years of age, infants with recovery of biceps function between 3 and 6 months had a progressive decrease in Mallet grades for abduction, external rotation, hand-to-mouth, and hand-to-neck activities stratified by month of biceps recovery.[179] In infants with biceps recovery between 3 and 6 months of age, recovery of function by Mallet grade was as follows: global abduction II (3%), III (52%), and IV (45%); global external rotation II (54%), III (31%), and IV (15%); hand-to-neck II (39%), III (33%), and IV (28%); and hand-to-mouth II (33%), III (24%), and IV (43%). These results are similar to Gilbert's published microsurgical results.

In addition, in both natural history and nerve surgery patients, secondary shoulder transfer and osteotomies improve function. For patients with recovery of biceps function between 3 and 6 months of life and later shoulder reconstruction, there will be an expected improvement to an average grade IV for all Mallet movements that involve external rotation and abduction. However, in both natural history and nerve surgery patients with incomplete recovery, there may be some deterioration in function with time.[132,165] A driving question is how different are patients who undergo nerve surgery at 3 months from those who recover biceps function between 3 and 6 months and undergo secondary reconstruction? This answer is critical to resolve the question as to whether unnecessary surgery is being performed or whether some centers are failing to perform nerve surgery at a young age. This controversy is presently unresolved because of lack of comparable data.[28,53,161]

The increasing use of nerve transfers further complicates the indications for nerve grafting. Nerve transfers utilize direct neurorrhaphy at a site closer to the target muscle. The more distal location of the neurorrhaphy allows a shorter regeneration time, faster recovery, and a longer window of time to await spontaneous recovery before fearing irreversible motor endplate demise. Therefore, surgeons may prolong the decision to intervene when viable nerve transfer options are available. Ladak et al reported results of 10 patients treated with three nerve transfers (i.e., spinal accessory to suprascapular, radial to axillary, and ulnar or median fascicle to musculocutaneous) at 10 to 18 months of age.[96] Recovery of function progressed between 6 and 24 months postoperatively, with ultimate function equivalent to published results of nerve grafting despite being performed at a later age.

Tse[168] demonstrated equivalent restoration of shoulder external rotation between patients treated with nerve grafting from C5 to the suprascapular nerve and those treated with a spinal accessory nerve to suprascapular nerve transfer; note that the latter patients had more severe brachial plexus injuries overall. Similar encouraging results of spinal accessory-to-suprascapular nerve transfer have been found by others, even in patients treated as late at 30 months of age.[150] Elbow flexion can also be restored by nerve transfer in properly selected patients. Little and colleagues, in a multicenter study, outlined the expected results and indications for ulnar and/or median fascicle transfer to restore elbow flexion and supination in neonatal brachial plexus palsies.[101] Elbow flexion could be reliably restored in children as old as 18 months of age, with supination recovery more dependent on age and with better supination following double-fascicle transfer (median and ulnar to both biceps and brachialis) over single-fascicle transfer to the biceps alone.

Ultimately, the decision between nerve grafting and nerve transfers should be individualized for each patient. Clearly, C5-6 avulsion injuries that cannot be treated with grafting are ideal candidates for nerve transfers. Similarly, dissociative recovery can occur, where only some of the muscles innervated by the upper trunk have recovered sufficient function, and the surgeon's goal is to restore innervation of the remaining paralyzed muscles without resecting the upper trunk and losing function of the muscles that have already recovered. In such cases, a la carte nerve transfers can be targeted to specific distal motor nerves. Nonetheless, precise indicators for nerve transfers remain unclear at the present time.

Surgical Technique: Nerve Grafting

The extent of surgical exposure depends on the level and severity of the injury. All microsurgical procedures in infants are performed under general anesthesia without the use of neuromuscular blocking agents. Both lower extremities are prepared for sural nerve graft harvest in cases of global palsies, although one sural nerve is generally sufficient for grafting isolated C5-6 injuries, so the other leg may be left undraped for venous access. Alternatives to nerve autograft, such as allograft and nerve conduits, have not yet been proven safe or effective in pediatric

CRITICAL POINTS

- The major determination for surgical intervention is the lack of recovery based on repeated physical examination.
- The role, timing, and technique of nerve surgery remain controversial issues.
- The spectrum of nerve surgery includes neurolysis, neuroma resection and nerve grafting, and nerve transfers. Direct repair is unlikely because of the etiology and extent of the lesion.
- Neurolysis has a limited role in brachial plexus birth palsy as long-term studies have not supported its efficacy.
- Neuroma resection with sural nerve grafting is the standard microsurgical care for extraforaminal ruptures, although nerve transfers have an evolving role. A combination of nerve grafting and nerve transfers is performed on infants with severe global lesions.

Expected Outcome With Nerve Surgery

- The outcome after microsurgery is difficult to decipher. Few studies have long-term follow-up or include patients who have undergone only microsurgery.
- Studies infer that successful nerve surgery performed between 5 and 8 months of age will have a better outcome compared to the natural history.
- Multicenter studies are necessary to truly elucidate the natural history and what will be the results of microsurgery.
- In contrast to adults, nerve grafting to the lower trunk can achieve hand function and should be a priority for children.

brachial plexus surgery. The shoulder girdle, chest, and neck are prepared for exposure of the brachial plexus and all possible planned nerve grafting and nerve transfer procedures (i.e., intercostals, spinal accessory, partial ulnar nerve, contralateral plexus).

The infant is placed supine, head tilted to the unaffected side, in a slight reverse Trendelenburg position to improve venous outflow from the head. For upper trunk ruptures, exposure can be performed through a transverse incision in the supraclavicular region. Dissection is carried out through the platysma and supraclavicular fascia to the plexus. The omohyoid muscle can be transected or retracted inferiorly. At times, the transverse cervical artery is transected (Figure 40.9). The phrenic nerve is identified, usually in a scarred position on the anterior scalene muscle or the anterior surface of the upper trunk neuroma (Figure 40.10), following the phrenic leads to the C5 root (Figure 40.11). The C5, C6, and C7 roots are sequentially exposed between the anterior and middle scalene muscles and labeled with Silastic loops. A decision is made regarding the integrity of each nerve root.

Electrophysiologic studies, inspection of the transected nerve under the microscope, and rapid histologic staining may all be factors in decision making. Generally, the upper roots are intact at the level of the foramina, and there is an

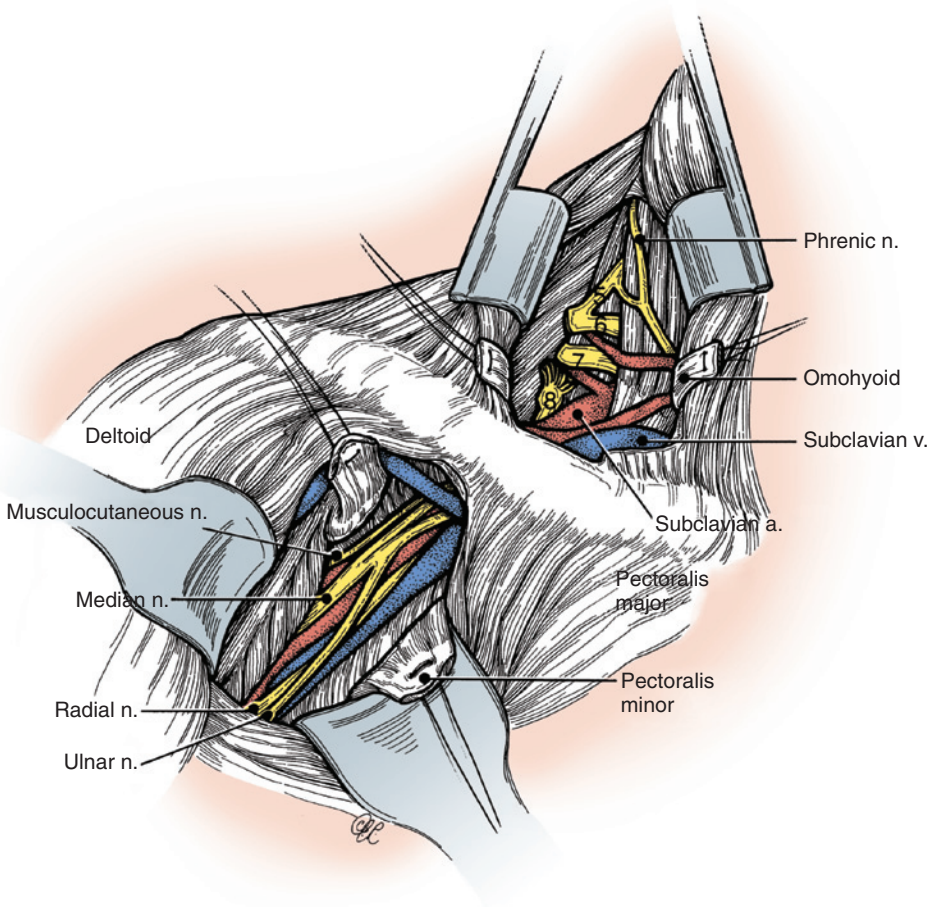

FIGURE 40.9 Key anatomic landmarks include the omohyoid muscle and the pectoralis minor muscle, which are divided between ligatures for later reapproximation. The C8 root is located just above and posterior to the subclavian artery, whereas the T1 root is almost directly posterior to the artery. With dissection of the deltopectoral groove, the lateral cord is the most superficial structure. In this example, the superior trunk and the C7 root are ruptured and the C8 root is avulsed (note the rootlets attached to the swollen dorsal root ganglion). (Copyright © Elizabeth Martin.)

extraforaminal neuroma at the junction where the C5 and C6 roots form the upper trunk (Erb's point). Distal dissection beneath the clavicle leads to identification of the divisions, cords, and major nerves. The axillary artery should also be identified and protected. In infants, the clavicle can often be left intact and mobilized with a Penrose drain or retractor for adequate exposure. If necessary, the clavicle can be transected obliquely and repaired with a suture through drill holes along with periosteal repair at the end of the operation.

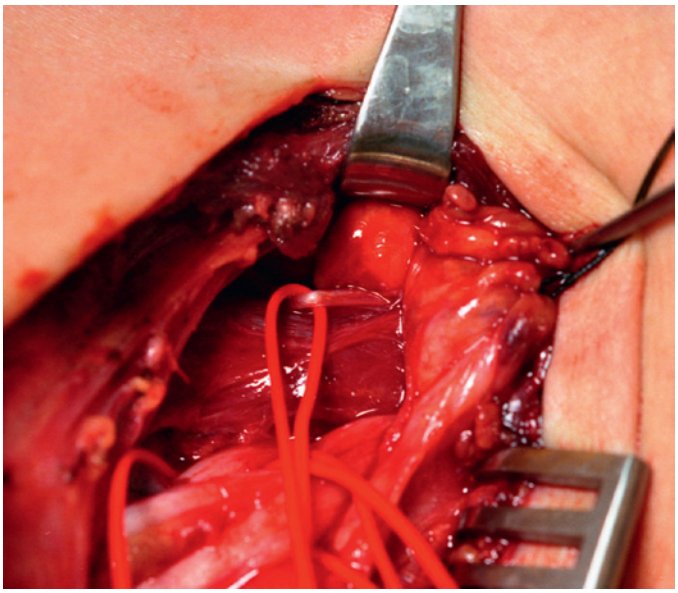

FIGURE 40.10 Phrenic nerve is isolated and protected. The nerve runs along anterior aspect of the anterior scalene. Patient is supine and head is to the right. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

Sequentially the major nerves are identified. The suprascapular nerve is exposed and labeled with a Silastic loop, usually as it exits the upper trunk neuroma and passes posterior toward the suprascapular notch. The musculocutaneous nerve is identified, labeled, and exposed from distal to proximal for the lateral cord to the anterior division of the upper trunk until the neuroma is encountered. Similarly, the radial and axillary nerves are exposed and dissected to the posterior cord and posterior divisions of the upper, middle, and lower trunks. The posterior division of the lower trunk is generally intact, but the posterior division of the upper trunk and at times the middle trunk are usually encased in the neuroma. Intraoperative evoked potentials and nerve conduction are performed to determine the integrity of the nerve roots proximally and the peripheral nerves distally.

Some centers still advocate neurolysis if at least 50% of a normal action potential is generated across the neuroma by electrical stimulation.[99] However, Gilbert, Meyer, Laurent, Clarke, and their colleagues have all reported suboptimal results with neurolysis.[36,61,99,114] Therefore, transection of the fibrous neuroma proximally and distally and reconstruction of the defect with sural nerve grafts in an end-to-end fashion is frequently performed (Figure 40.12). The graft can be secured to the proximal and distal nerve ends using epineural sutures, fibrin glue, or both. The use of fibrin glue alone can dramatically decrease operative time and has become standard practice for many authors. Fibrin glue is particularly useful for the proximal neurorrhaphy given the difficulty of suturing within or adjacent to the neural foramen. With either neurorrhaphy

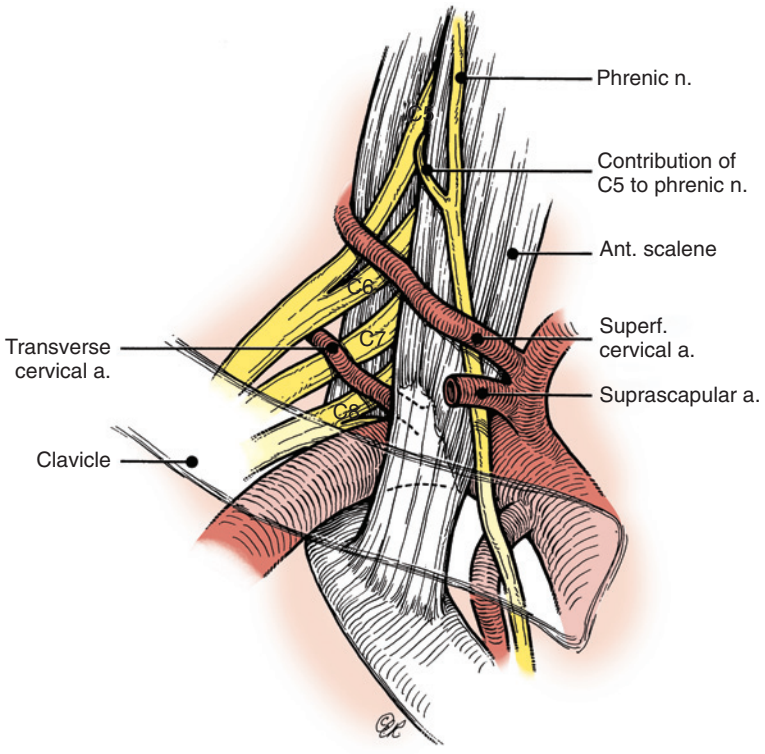

FIGURE 40.11 Additional landmarks helpful in identifying the various roots include the phrenic nerve contributions from the C5 root and the transverse cervical (scapular) artery, which frequently crosses over the C7 root. (Copyright © Elizabeth Martin.)

technique, however, it is important to cut the graft cables sufficiently long to avoid tension on the neurorrhaphy.

When avulsions are encountered, especially in the lower roots, more extensive exposure is necessary. This may include modifying the skin incision to a "Z" or using a second infraclavicular transverse incision to expose the infraclavicular area. Each nerve root is assessed closely to determine the viability of the root, which can be difficult because of partial avulsions. Electrophysiologic studies and histologic staining can augment direct microscopic observation. The C5 and C6 roots are usually intact with an extraforaminal rupture. The exception is an upper trunk lesion resulting from a breech delivery, in which case C5 and C6 are often avulsed. With severe lesions, C8 and T1 are usually avulsed and C7 is variable in integrity. Each case presents a unique intraoperative decision-making challenge. However, there are principles and general case scenarios with avulsions that can lead to the most optimal results.

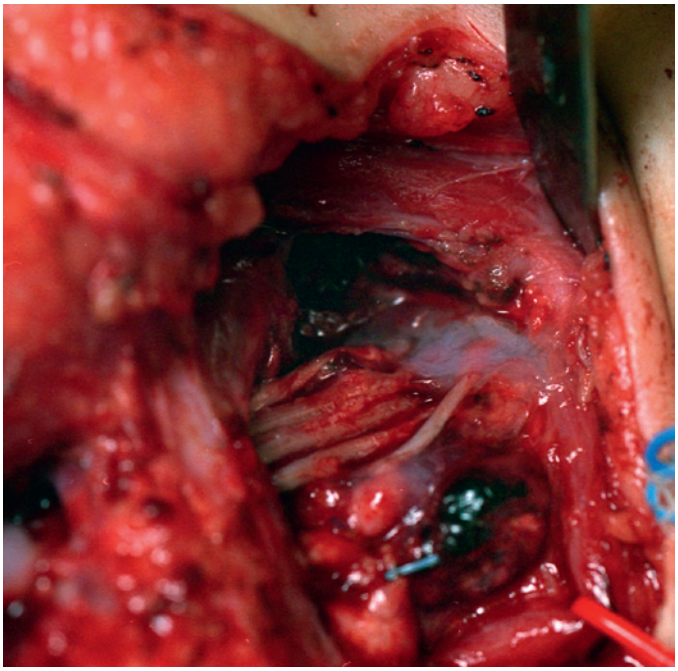

FIGURE 40.12 Six-month-old child with left brachial birth palsy. Supraclavicular exposure revealed ruptures at C5 and C6. Sural nerve grafts to upper trunk anterior division, upper trunk posterior division, and suprascapular nerve secured with fibrin glue. Child is supine and head is to the right. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

- The C5, C6, and C7 nerve roots have extraforaminal ruptures, and C8 and T1 are avulsed. With three nerve roots available for grafting, it is possible to reconstruct the entire injured plexus. In this situation, the C5 and C6 nerve roots are transected to viable nerve and coapted by sural nerve grafting to the most viable proximal aspects of the suprascapular nerve and the medial, lateral, and posterior cords (see Figures 40.5, *B*, and 40.12).
- The C5 and C6 nerve roots have extraforaminal ruptures and C7, C8, and T1 have avulsions (Figure 40.13, *A*). This scenario means there is less viable proximal nerve. The hand receives priority with grafting from C5 or C6 to the medial (ulnar and median nerves) and lateral cords (musculocutaneous and median nerves) (Figure 40.13, *B*). Suprascapular nerve reconstruction is achieved either by nerve grafting or more commonly by transfer of the spinal accessory nerve. Reconstruction of the posterior cord may need to be abandoned or performed by transferring intercostal nerves to the musculocutaneous nerve and nerve grafting to the posterior cord.
- C5 is the only viable nerve root. This is the most difficult situation and requires prioritizing an anatomic site. In infants, it is advised that the hand be given priority with grafts from C5. A combination of spinal accessory and intercostal nerve transfers to the suprascapular, musculocutaneous, and median nerves along with C5 grafts to the lower

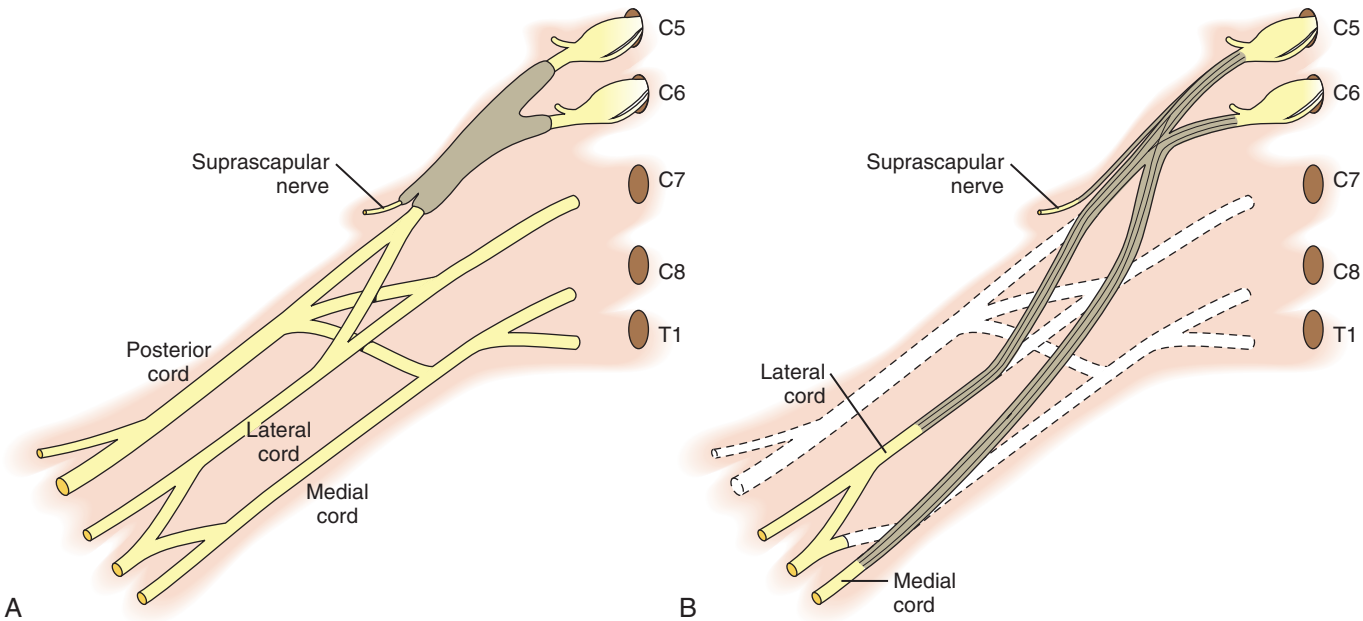

FIGURE 40.13 **A, B,** Combination grafting for a C5-7 rupture and C8-T1 avulsion.

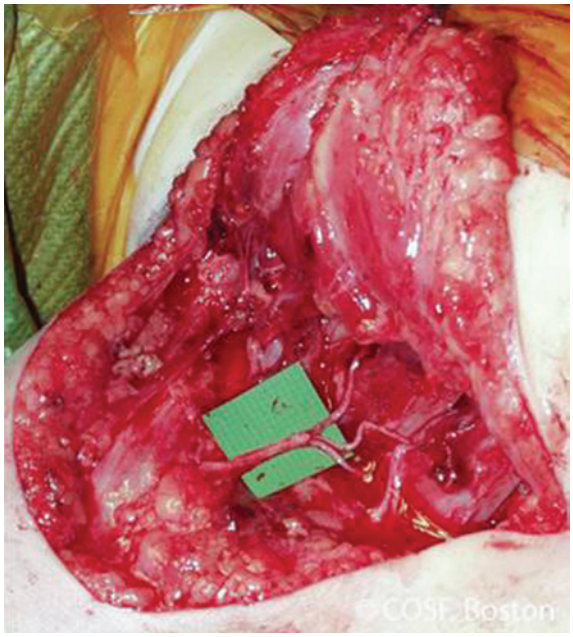

FIGURE 40.14 T2, T3, and T4 nerve transfers to the musculocutaneous motor branch for biceps reconstruction.

trunk is performed (Figure 40.14). The lower plexus is mobilized as much as possible to limit the length of the nerve grafts. Use of the contralateral C7 nerve may be necessary to maximally reconstruct the plexus, but published results are variable.[24] Reports of contralateral C7 transfer with short or no grafts through a retropharyngeal approach may prove promising in such cases,[191] although few centers are currently performing this technique.

Surgical Technique: Nerve Transfers

Nerve transfers can be performed as part of the reconstruction of an explored brachial plexus as described earlier or can be performed without formal exploration of the brachial plexus. The advantages of nerve transfers include a shorter axonal regeneration distance, no need for nerve grafts, and an operative field distant from the zone of injury and therefore no scarring. The techniques have been adequately described for transfers of the (1) spinal accessory to suprascapular nerve, (2) radial triceps branch to axillary nerve, and (3) median and/or ulnar fascicle to the musculocutaneous branches to the biceps and/or brachialis.

The spinal accessory to suprascapular nerve transfer can be performed through an anterior supraclavicular approach, although a posterior approach affords a more distal neurorrhaphy and the opportunity to free the suprascapular nerve from the suprascapular notch (see Figure 40.8).[24] The radial-to-axillary transfer is performed through an incision in the posterior arm, and the elbow flexion transfers are performed through a medial brachial approach. Therefore, performance of these three nerve transfers simultaneously requires exposure of the posterior shoulder and posterior and medial brachium. Such exposures can be accomplished with the patient in the lateral decubitus position. The dependent axilla is sufficiently protected with a lateral chest wall pad, and all bony prominences are well padded, paying careful attention to the lower extremities. The entire affected arm, chest wall, and scapular region is draped. Muscle relaxant is avoided to allow nerve stimulation.

For the spinal accessory to suprascapular nerve transfer, a transverse incision is made immediately superior to the spine of the scapula (Figure 40.15). The upper trapezius is elevated from the spine of the scapula and reflected superiorly to identify the supraspinatus muscle. The supraspinatus muscle is retracted inferiorly to expose the superior margin of the scapular body. The suprascapular notch is identified and its ligament is sectioned to expose the suprascapular nerve. The spinal accessory nerve is then identified on the anterior surface of the trapezius that is just medial to the scapular spine. The nerve is traced as distally as possible and then cut and rerouted superiorly and laterally, preserving as many proximal muscular branches as possible until it reaches the suprascapular nerve without tension. The suprascapular nerve is cut proximal to the notch and coapted to the spinal accessory nerve.

The radial-to-axillary transfer is performed through a transaxillary or posterior longitudinal midline incision in the arm, beginning at the inferior margin of the posterior deltoid and extending in a distal direction (Figure 40.16). The deltoid is retracted superiorly to identify the axillary nerve exiting the quadrangular space. The cutaneous branch of the axillary nerve is separated from the branches to the deltoid and teres minor muscles because transfer of the donor nerve into the cutaneous portion would dilute the axons available to the targeted muscles. The interval between the long and lateral heads of the triceps is then identified, and dissection is carried down to the teres major tendon.

The radial nerve is identified as it becomes posteriorly visible distal to the inferior margin of the teres major tendon. Branches to the long, medial, and lateral heads of the triceps are identified, and a suitable donor branch of sufficient caliber and function (determined by stimulation of the nerve branches producing strong contraction of the relevant portion of the triceps) is selected. The donor nerve is dissected into the triceps muscle belly and transected distally to produce enough length for coaptation to the axillary nerve. The triceps branch is then coapted to the deltoid branch of the axillary nerve after transecting the axillary nerve within the quadrangular space.

Transfer of ulnar and/or median nerve fascicles to the elbow flexors is accomplished through a longitudinal incision in the midbrachium (see Figure 40.16) (Video 40.2). The ulnar nerve is identified posterior to the intramuscular septum. The musculocutaneous nerve is usually identified by anterior retraction of the atrophic biceps muscle belly. The branch of the musculocutaneous nerve innervating the biceps is typically just deep the vascular pedicle to the muscle and runs more obliquely. The branch to the brachialis is located more distally. Donor fascicles from the ulnar and/or median nerves are selected through an epineurotomy and stimulation of individual fascicles to identify fascicles predominantly innervating the wrist flexors.

Because of the redundancy and interconnection of fascicles at this proximal level, no one fascicle will be strictly devoted to wrist flexion. Most fascicles produce some degree of finger flexion when stimulated, but a fascicle is chosen that does not innervate the intrinsic muscles of the hand. This redundancy avoids functional deficits in the median and ulnar nerves after these transfers. Once an appropriate fascicle is identified, it is dissected distal from the surrounding fascicles for 1 to 2 cm and

transected. The surgeon should cut the recipient musculocutaneous branch first and approximate it to the donor nerve before transecting the donor fascicle to ensure adequate length for coaptation. The donor and recipient nerves can then be coapted without tension.

Transfer of thoracic intercostal nerves (usually T2-4) are used when there are limited donor options and for more severe injuries (see Figure 40.6). A transverse chest wall or extended axillary incision can be used. The transverse chest incision is performed inferior to the nipple. The sensory branch of each intercostal nerve is isolated. Careful dissection under each rib is performed to isolate the segmental motor branch without injury to the adjacent blood vessels or underlying pleura. The rib is elevated with a double skin hook retractor. The motor branch

of each intercostal is followed distal toward the anterior chest until it trifurcates. The motor branch is also dissected to the posterior axial fold to maximize length. Each intercostal nerve is cut, and all three motor branches are combined into one direct transfer, usually to the motor branch of the biceps. Direct transfer has better outcomes than use of an intercalary graft.

❖ AUTHORS' PREFERRED TREATMENT: Nerve Surgery

There is limited information available for the clinician to make decisions regarding the timing of microsurgical intervention and the outcome when comparing those patients with and without surgery, especially with the addition of secondary tendon transfers. Within these limitations, we treat the infants in the following ways:

- Observation of all infants with brachial plexus birth palsy who demonstrate antigravity biceps muscle recovery in the first 3 months of life is necessary. Physical therapy is performed until complete recovery to maintain a full range of motion of all joints of the upper limb, especially shoulder abduction and external rotation.
- If there is Horner syndrome and failure of recovery of some antigravity biceps strength by 3 months, microsurgery is performed at that time. Nerve grafts are performed if there are any intact nerve roots. Nerve transfers are uniformly necessary because of the limited viable nerve roots and inflow axons. Transfer of a branch of the spinal accessory nerve, thoracic intercostal nerves, or anterior fascicles of the ulnar nerve (see Figures 40.14 through 40.17) is performed as appropriate; this requires an intact C8-T1 root. The hand/wrist, elbow, and shoulder are prioritized in that order.
- If there is progressive recovery of wrist and finger extension without Horner syndrome, we wait until 5 to 6 months to determine whether some antigravity biceps strength will return. If there is still no adequate return of function, surgery is performed at that time. Neuroma resection and nerve grafts or nerve transfers are performed based on the intraoperative findings.
- All nonoperative patients are observed closely for the first 9 months to be certain that their recovery is progressive. In the

rare instances of failure of biceps recovery to progress to sufficient antigravity strength by month 9 (i.e., a positive "cookie test"), nerve surgery is performed, usually a nerve transfer to restore biceps function.

Postoperative Management: Nerve Surgery

Postoperative immobilization is achieved with a well-padded stockinette, sling, and swathe that bind the arm to the side. If there is any concern that neck motion will cause undue tension on the neural repairs, the neck is included in the immobilization. Lower extremity bandages for the sural nerve graft donor sites are removed 2 weeks postoperatively. Arm immobilization is discontinued at 4 weeks. Shoulder and arm range of motion is reinitiated to prevent the development of contractures. On occasion, a botulinum toxin (Botox®) injection in the internal rotators can be used at the time of nerve surgery to facilitate stretching postoperatively. In these cases, the child is placed in a shoulder spica cast with the shoulder in external rotation. The parents and therapists are informed that improved function will not occur for 6 to 18 months. However, failure to observe progressive recovery of the biceps by 6 to 9 months is concerning. Reexploration and additional microsurgery (i.e., nerve transfers) may be indicated for failure of biceps recovery by 9 to 12 months postoperatively.

Complications secondary to infection, bleeding, chylothorax, or a worsening neural condition are rare. At times, a phrenic nerve palsy can result in an elevated hemidiaphragm with exploration of the upper trunk, as the phrenic nerve is often involved in the scarring of the neuroma. The clinical scenario is not true respiratory depression or desaturation; rather, the child will have difficulty with feeding or recurrent respiratory infections. A phrenic nerve palsy is usually the result of traction on the nerve and resolves with time. A feeding specialist consultation may be necessary until recovery. If the diaphragmatic paralysis persists and affects respiratory function, a late diaphragmatic plication may be necessary. Nonunion of a clavicular osteotomy leads to chronic pain and decreased function. Treatment requires internal fixation and possibly bone grafting.[90]

The major complication of microsurgery is failure to achieve the desired outcome. If there is no recovery at 6 to 12 months postoperatively, observation will not improve function.[154] Either reexploration and further nerve reconstruction, or secondary regional tendon or free muscle transfers,[45,175] are warranted to improve outcome. Prior to surgery, it is imperative for parents to understand that perfect range of motion, strength, posture, and function are not achievable with nerve surgery.[90] However, functional improvement compared to the natural history is possible. Recovery of hand function is variable, depending on the original injury and microsurgical reconstruction. The mean Raimondi score was 4.57 for C5-6, 4.26 for C5-7, and 2.16 for total plexus patients (Table 40.4).[37] Avulsion injuries correlated with poor hand recovery. In addition, even with a positive outcome of hand function and strength, the majority of these patients require secondary tendon transfers to further improve usage.

TABLE 40.4 Raimondi Grading System for Hand Function*

Raimondi Grading System for Hand Function	Hand Grade
Complete paralysis or slight finger flexion or no use; useless thumb with no pinch; no or some sensation	0
Limited active flexion of fingers; no extension of wrist or fingers; possible lateral pinch of thumb; supinated forearm	I
Active extension of wrist gives passive flexion of fingers (by tenodesis); passive lateral pinch of thumb; pronated forearm	II
Complete active flexion of wrist and fingers; mobile thumb with partial abduction and opposition; some intrinsic balance; no active supination; good sensation; good possibilities for secondary surgery	III
Complete active flexion of wrist and fingers; active wrist extension; weak or absent finger extension; good thumb opposition with active intrinsics; partial active pronation and supination	IV
Grade IV plus active finger extension and near complete pronation and supination	V

*The grading system incorporates movement and sensation. Grades III, IV, and V are considered "good outcomes" after surgical intervention.

SECONDARY MUSCULOSKELETAL PROBLEMS

Neurologic injury during the neonatal period disturbs normal postnatal growth and development of the musculoskeletal system. Unless the nerve injury recovers within the first few weeks of life, such disturbances cause permanent and progressive secondary musculoskeletal problems. The two main manifestations of such disturbed development include joint contractures and bony deformity. The contractures substantially impair function and quality of life[17,18,78] and are the most common reason for surgery following a birth palsy. Contracture development is especially troublesome at the shoulder, where residual paralysis of muscles innervated by the upper trunk leads to restriction of passive glenohumeral motion and resulting glenohumeral dysplasia. The most conspicuous restriction of passive glenohumeral motion is the internal rotation contracture, which has been recognized and treated for more than a century.[52] One theory for the development of the shoulder internal rotation contracture is muscle imbalance between functioning internal rotators and paralyzed external rotators, leading to static internal rotation joint posturing and ultimate joint contracture.[135,180,184]

However, more recent investigations suggest that denervated rather than functioning muscles are responsible for contracture development. MRI studies have demonstrated the degree of the internal rotation contracture correlates with atrophy of the subscapularis, an internal rotator.[76,145] Furthermore, simple muscle imbalance cannot explain paradoxical contractures, where the joint becomes tight in the direction of the paralyzed muscles. The most notably paradoxical contracture is the elbow flexion contracture one that occurs in the setting of initial elbow flexor paralysis.[21,70,144] In fact, the elbow flexion contracture has been shown to correlate on MRI only with atrophy of the brachialis.[143] At the shoulder, one such paradoxical contracture is glenohumeral abduction that occurs following paralysis of the shoulder abductors.[48a,64,186] Because patients with this contracture cannot fully adduct the glenohumeral joint, adducting the arm to the side requires rotation of the scapula on the chest wall.[182] The resulting superior protrusion of the superior-medial angle of the scapula has been termed the Putti sign, after its initial description in 1932.[146] This abduction contracture exists in the setting of abductor muscle atrophy,[48a] again consistent with tightness of denervated muscle being responsible for the contracture. Furthermore, physical assessment[150a] and motion analysis[151] studies have demonstrated external rotation contractures as well as a greater than normal contribution of scapulothoracic motion to global shoulder motion, suggesting a functional ankylosis of the glenohumeral joint in all directions, consistent with contractures of all the denervated rotator cuff muscles.

Uncertainty regarding the precise etiology of glenohumeral contracture and dysplasia has led to attempts to investigate the pathophysiology in animal models of neonatal brachial plexus injury. Upper trunk neurotomy in rats and mice leads to glenohumeral dysplasia that closely resembles that in humans,[88,100,101] and the use of animal models for studying the effects of neonatal denervation on musculoskeletal growth and development has been established by several authors.[88,100,101,128] Using one such model, impaired growth of neonatally denervated muscle has been found to contribute to contracture pathogenesis.[126,128,187] Without normal neonatal innervation, muscles fail to grow sufficiently to keep up with skeletal growth, leading to relative muscle shortening and loss of passive joint range of motion. Early reinnervation prevents this impaired muscle growth and contractures but delayed reinnervation does not, suggesting a critical window of postnatal muscle development in which innervation is required for muscle growth. These findings have recently been replicated in similar animal models in different laboratories.[38a,107a]

Furthermore, impaired growth of denervated muscles can account for both the restriction of passive motion at the shoulder and elbow, as well as the axial plane deformity of glenohumeral dysplasia. Computer modeling of the human glenohumeral joint[32a,39] has demonstrated that the growth impairment identified in animal models is sufficient to both restrict the passive range of motion and increase the contact pressure on the posterior glenoid, consistent with glenoid retroversion and posterior glenohumeral subluxation. This effect may be exacerbated by muscle activity imbalance, whereby the shoulder is positioned in internal rotation by the functioning pectoralis major muscle and other internal rotators, worsening the eccentric posterior load on the glenoid. The interplay between denervation, muscle atrophy, and musculoskeletal growth is complex, and we are far from understanding the biological mechanisms of contracture development. Nonetheless, the shoulder contracture is more complex than a unidirectional internal rotation contracture, and the pathogenesis is more complex than a simple lack of mechanical stretch of the muscles or joint capsule. It is likely that a combination of contractures from impaired muscle growth and forces from muscle imbalance contribute to the pathoanatomy of glenohumeral dysplasia, as supported by a recent computational model.[39]

Glenohumeral deformity following a birth palsy was described in the early 20th century,[52,152] but more recent studies have defined risk factors and progressive deformities in more

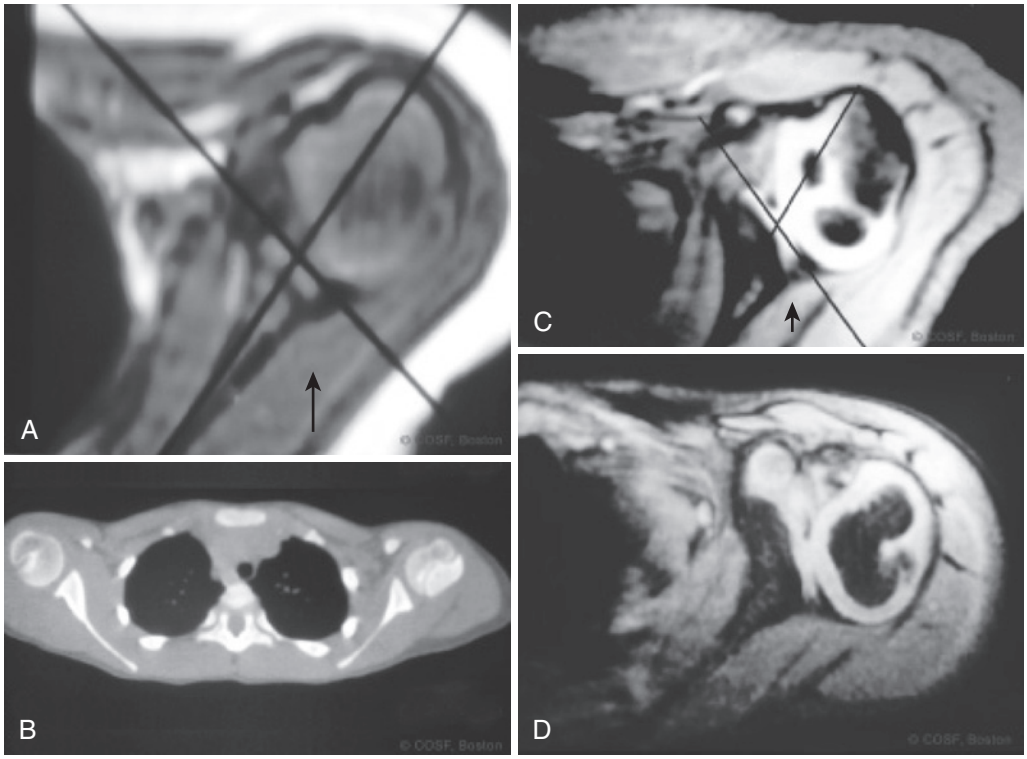

FIGURE 40.18 Radiographic types as determined with use of computed tomography (CT) or magnetic resonance imaging (MRI). **A,** MRI of a type I (normal) glenohumeral joint (<5-degree difference in glenoid version in comparison to that on the normal, contralateral side). The *bisecting line* extending from the spine of the scapula through the humeral head is outlined. The angle in the posterior medial quadrant is indicated by the *arrow*. Ninety degrees is subtracted from this measurement to determine glenoid version. **B,** CT scan of a glenohumeral joint with a type II deformity of the left shoulder. The deformity is minimal (>5-degree difference in glenoid version in comparison to that on the normal, contralateral side and no evidence of posterior subluxation of the humeral head). **C,** MRI of a glenohumeral joint with a type II deformity. There is moderate deformity of the glenoid with posterior subluxation of the humeral head (<35% of the head is anterior to the scapular line). The *scapular line* and the *tangential line* indicating the anterior and posterior cartilaginous margins of the glenoid are shown. The angle in the posterior medial quadrant is indicated by the *arrow*. **D,** MRI of a glenohumeral joint with a type IV deformity. There is progressive deformity (a false glenoid) and subluxation. detail using arthrography,[138,189] CT, and MRI (Figure 40.18).[184,186] The glenohumeral deformity is progressive with age and appears very early in infancy as evidenced by ultrasound, MRI,[93] and clinical data.[73,136,180,194] Adapting Severin's classification of hip dysplasia, Waters and colleagues described various grades of deformity (Figure 40.5).[186] The deformity evolves sequentially by grade from normal (I) to increased glenoid retroversion (II), posterior glenohumeral subluxation with posterior glenoid dysplasia (III), development of a false glenoid (IV), to flattening of the humeral head and glenoid (V). In addition, on occasion a true infantile glenohumeral deformity (VI) occurs. Pearl and colleagues' arthrographic classification is similar.[138] The deformity is progressive without treatment.[186]

The infantile treatment options of physical therapy, splinting, Botox injections, and surgical interventions are all designed to reverse this process. Early intervention is advocated because this dysplasia occurs much sooner than previously thought, with nearly 10% of infants progressing to glenohumeral dislocation in the first year, even as early as 3 months.[41,119] Thus, there can be a subluxated or dislocated shoulder that needs to be addressed with "secondary" procedures even before the child is old enough to determine whether "primary" nerve surgery is necessary. Recognition of the early development of glenohumeral dysplasia is critical in the management of the shoulder following a birth palsy because early treatment of the glenohumeral joint deformity can reverse the process and preserve shoulder alignment.

Several studies have demonstrated remodeling of the glenohumeral dysplasia following release of the internal rotation contracture with or without muscle transfers to augment external rotation strength.[49,94,137,183] Even humeral head deformity has been shown to remodel following restoration of appropriate glenohumeral alignment.[147] However, it is still unknown beyond what age remodeling is no longer possible, or the severity of glenohumeral deformity that can be remodeled. Nonetheless, the possibility of restoring normal skeletal structure with early intervention underscores the importance of timely detection and management of glenohumeral dysplasia.

Preoperative Evaluation: Shoulder

Recovery of active muscle strength in infants is graded by the MRC system, the Mallet classification, AMS scores, or any combination of these systems. Assessing infants for shoulder function involves observation of spontaneous activity, neonatal reflex activity (i.e., Moro, asymmetric tonic neck, symmetric tonic neck), and stimulated activity with and without the assistance of gravity. Passive glenohumeral motion is assessed with stabilization of the scapula (Figure 40.19). Internal and external

FIGURE 40.19 Firm stabilization of the scapulothoracic joint to determine amount of glenohumeral joint external rotation. One hand is used to stabilize the scapular body and the other external hand rotates the shoulder. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

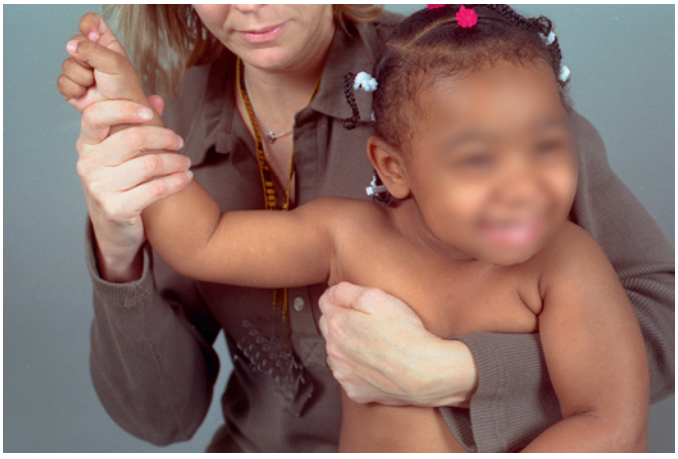

FIGURE 40.20 External rotation 90 degrees of abduction while stabilizing the scapula against the thorax. (Courtesy of Shriners Hospitals for Children, Philadelphia).

rotation is performed both in adduction and in 90 degrees of abduction while stabilizing the scapula against the thorax (Figure 40.20). The degree of scapular winging posteriorly with internal rotation, superiorly with full adduction (Putti sign), and into the axilla with full abduction and forward flexion is assessed. It is important to palpate for posterior glenohumeral joint dislocation in the posterior soft spot because it is critical to not miss infantile dislocation. Dynamic instability is assessed by palpation posteriorly while measuring passive and active range of motion, especially with adduction and internal rotation. Tightness of the subscapularis is evaluated by measuring passive external rotation in adduction, again with scapular stabilization. Pectoralis major, latissimus dorsi, and teres major tightness is assessed by palpation with the shoulder abducted and externally rotated.

Infantile treatment of the shoulder focuses on maintaining full passive range of motion. Previous clinical recommendations for nerve protection by immobilization to prevent recurrent stretching during the first 4 to 6 weeks of life are no longer

FIGURE 40.21 Clinical photograph of a child with limited right shoulder external rotation and abduction. (Courtesy of Shriners Hospitals for Children, Philadelphia).

followed. Early motion is important to prevent contracture. Initially, a gentle home program is begun, followed by a formal physical therapy program with home supervision of infants who do not recover rapidly in the first month of life. Children with clavicle fractures are immobilized only until early healing, usually at 10 to 14 days old. Full passive glenohumeral range with scapular stabilization is the goal. Abduction and external rotation splints have been used in some centers to improve or maintain range of motion.

Compliance can be variable and Zancolli and Zancolli have expressed concern about the risk for injury to the physis and developing joint.[194] Botox injections have been used to decrease the force of contracting muscles. It has also been shown to allow closed reduction of dislocated shoulders in infancy, in some cases obviating the need for surgical reduction.[51] After Botox, a variety of modalities have been recommended including splints, spica casts, electrical stimulation, and intensified therapy. However, Botox injection does not address the underlying neuromuscular pathophysiology, and its effects on function may be short-lived unless the underlying muscle denervation is addressed.[15] Nonetheless, it is clear that the failure to maintain full passive range of motion of the joint leads to the development of glenohumeral deformity.[93,186,194]

If the child fails to recover external rotation strength, there are considerable functional consequences. External rotation of the shoulder in abduction is necessary to achieve above-horizontal shoulder activity (i.e., reaching the hand to the occiput or forehead) (Figure 40.21). Scapulothoracic winging can compensate for limited glenohumeral motion in all planes except external rotation. In this circumstance, the scapula abuts the posterior portion of the thorax. This leads to marked

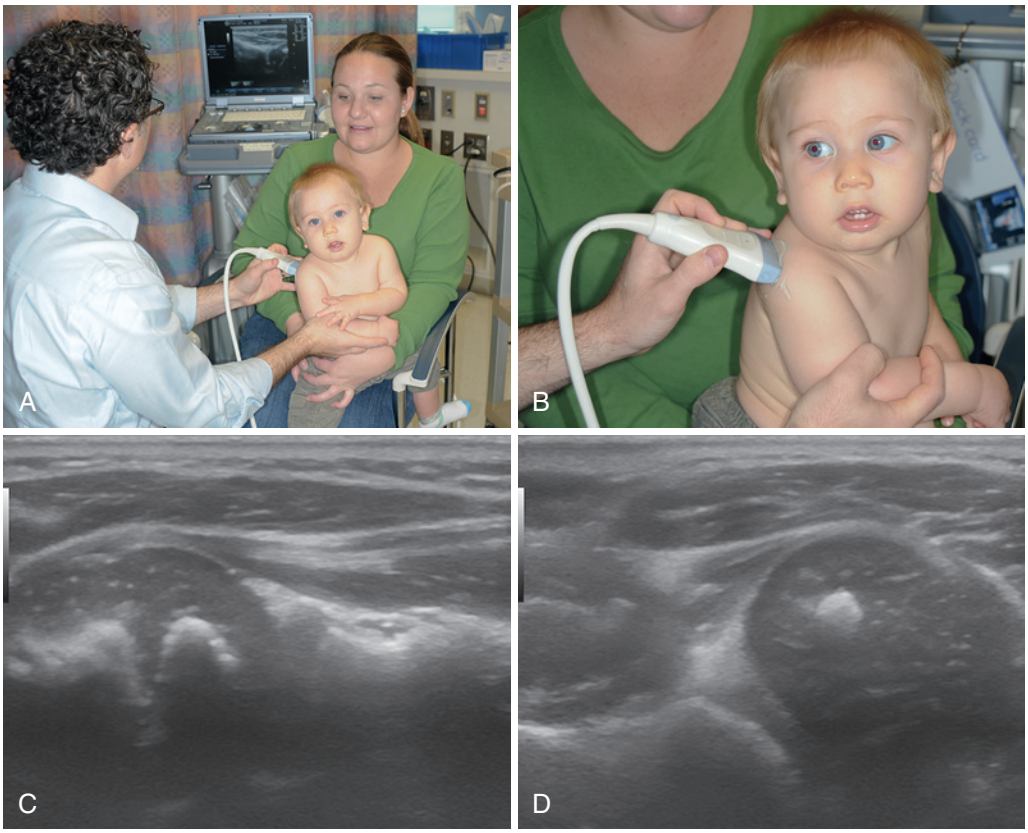

FIGURE 40.22 The posterior portal is the most useful in infants with brachial plexus birth palsy. **A,** Child seated on mom's lap and ultrasound positioned on posterior aspect of shoulder. **B,** Ultrasound probe placed along scapular spine and shoulder rotated into external and internal rotation for dynamic imaging. **C,** Normal shoulder with the hypoechoic cartilage surrounding the ossification centers that is located within anterior to the axis of the posterior scapular margin within the glenoid. **D,** Dysplastic shoulder with humeral head far posterior to the scapular margin. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

limitation of function because of an inability to appropriately place the hand in space for many activities. More important, ligamentously lax children can compensate better by sliding the scapula across the thorax, which accounts for some of the differences in function in children with similar neurologic injuries and glenohumeral joint deformity. In addition, weakness about the shoulder limits hand use away from the body. These children have difficulty placing and maintaining the hand at a desired location in space.

Ultrasound can be used in infancy to evaluate the glenohumeral joint and proximal part of the humerus. Rare proximal humeral physeal fractures and glenohumeral joint dislocations can be detected by ultrasound. Similar to the hip, the joint can be assessed for congruency and dynamic stability by ultrasound (Figure 40.22).[119,144,186] Such a study can be done without sedation. Plain radiographs are not helpful to assess the glenohumeral joint during infancy because the secondary centers of ossification are absent until 6 months of age. Arthrograms provide a clearer picture of the joint and bone development than do radiographs in infants and children.[136]

An arthrographic classification of the glenohumeral joint deformity can be used.[92] However, most institutions use an MRI to assess the cartilaginous surfaces of the glenohumeral joint in young children.[20,138,139,186] In infants and young children, MRIs require sedation. The glenohumeral deformity progresses from posterior glenoid deformity (II), to humeral head subluxation and further glenoid dysplasia (III), to the development of a false glenoid (IV), and finally to flattening of both the glenoid and humeral head (V) (see Figure 40.18).

The degree of joint deformity can guide the surgeon in selection of the appropriate procedure. It is clear that with minimal joint deformity (grades I and II), releases or lengthening of contracted muscles and tendon transfers for improved external rotation and abduction have a favorable clinical outcome.[32] With more severe deformity of the joint (grade V and advanced grade IV), humeral derotational osteotomy improves function considerably but does little to correct joint deformity.[91,184] Arthroscopic releases (Figure 40.23) and joint reduction and open reduction (Figure 40.24; Video 40.3) of the glenohumeral joint in young children have both led to glenoid remodeling in patients with grades II, III, and IV deformity.[137,139,182] In selected cases with severe glenoid deformity, glenoid osteotomy can correct the retroversion by way of a posterior opening wedge osteotomy, although its place in the treatment armamentarium for glenohumeral dysplasia remains unclear.[44]

Historical Review: Shoulder

In 1888, Stimson[164a] described a posterior dislocation of the shoulder in a child with a brachial plexus birth palsy. Later, Whitman[189a] (1905) distinguished between a congenital dislocation and an acquired dislocation associated with a brachial plexopathy. Fairbanks (1913) performed operative reduction of a dislocation by anterior capsulotomy and subscapularis release.[52] L'Episcopo[52a] described the results of tendon

rebalancing procedures about the shoulder for obstetric paralysis in the 1930s, initially with the teres major alone and subsequently with the teres major and the latissimus dorsi muscles. Wickstrom[189b] defined a high incidence of permanent deficits about the shoulder with joint deformity.

Roper and later Hoffer, Wickenden, and Roper[75] described transferring the latissimus dorsi and teres major into the greater tuberosity region to improve not only external rotation but also abduction. Many authors since then have reported favorable results with tendon transfers about the shoulder in patients with residual brachial plexus birth palsies.[32,72,93,132,138,185,186] There is evidence that these transfers improve not only range of motion in abduction and external rotation but also outcome function as measured by aggregate Mallet and Pediatrics Outcomes Data Collection Instrument (PODCI)[16,43] scores.

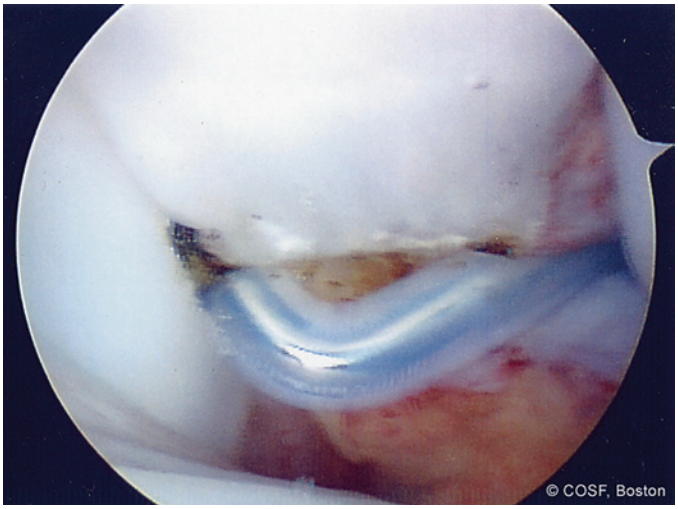

FIGURE 40.23 Arthroscopic release of a thickened anterior capsule and partial subscapularis release for treating an internal rotation and adduction contracture in a 14-month-old child.

CRITICAL POINTS

- Secondary musculoskeletal deformities are common in children with residual brachial plexus birth palsy.
- Impaired muscle growth from neonatal denervation leads to contractures, which together with muscle functional imbalance at the shoulder, lead to glenohumeral dysplasia.
- Glenohumeral dysplasia begins in infancy and progressively gets worse.
- Maintenance of passive motion through nonsurgical and surgical means can prevent contractures and dysplasia.
- Restoration of muscle functional imbalance can lead to remodeling of glenohumeral dysplasia.
- Imaging studies to evaluate the glenohumeral joint include ultrasounds and cartilage-sensitive MRIs.

Operations: Shoulder

Indications for surgical intervention about the shoulder include (1) infantile dislocation, (2) persistent internal rotation–adduction contracture despite extensive nonoperative management, (3) limitation of abduction and external rotation with plateauing of neural recovery, and (4) progressive glenohumeral

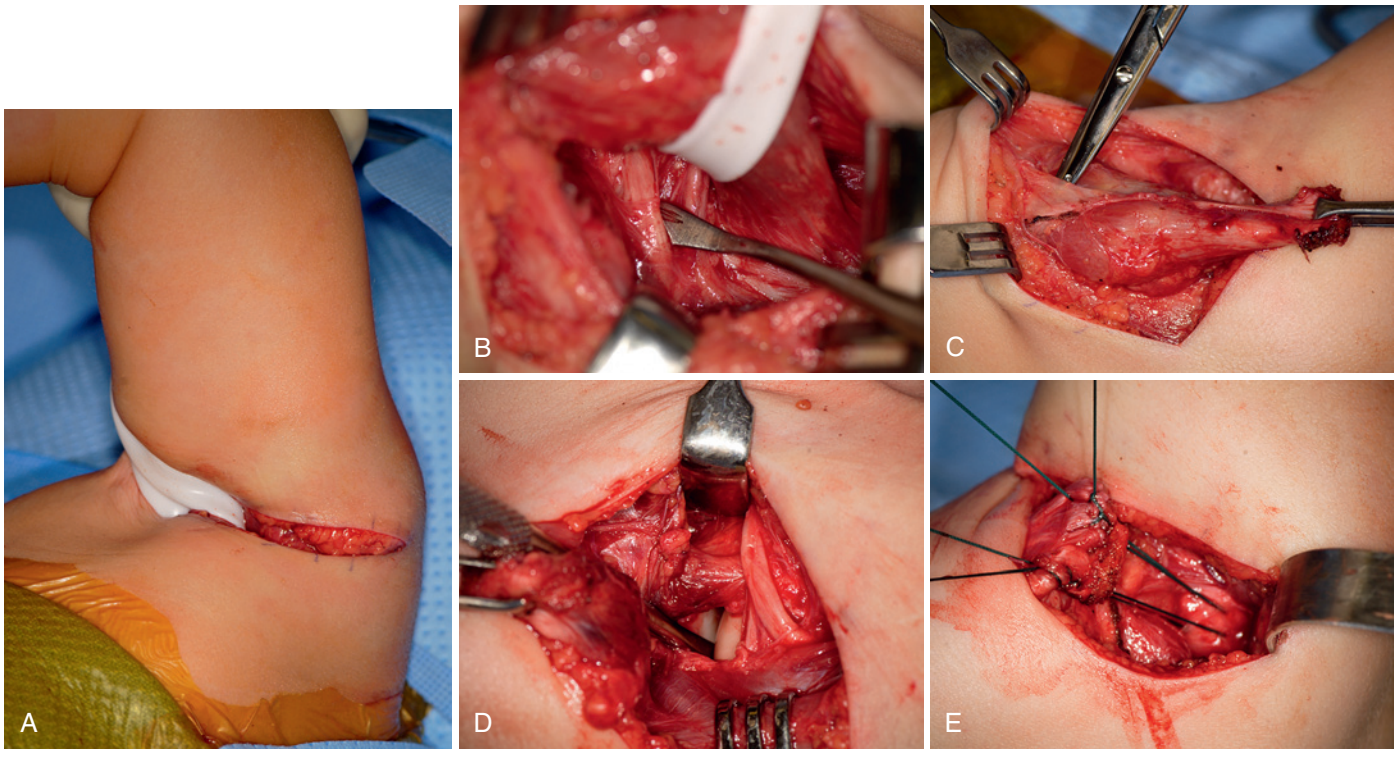

FIGURE 40.24 Technique for open joint reduction and tendon transfer. **A,** Axillary incision with penrose around latissimus dorsi and teres major. **B,** Identification of axillary nerve deep to latissimus dorsi and teres major. **C,** Mobilization of musculotendinous latissimus dorsi and teres major. **D,** Open joint reduction with protection of axillary nerve. **E,** Transfers of latissimus dorsi and teres major tendons using transosseous sutures. deformity. The age at intervention depends on the problem and its severity.

Infantile dislocation is treated as early as it is recognized before the glenoid deficiency becomes unreconstructable. Ideally, this is within the first 3 to 12 months of life. Surgery can be performed arthroscopically or by open reduction. Arthroscopic reduction is performed in the lateral decubitus position. At this point, there is no infantile arm holder for distraction of the joint. A surgical assistant is required for distraction and appropriate positioning of the arm for arthroscopic examination and surgical release. Standard portals are used.

A hooked bipolar cautery or up-biting arthroscopic cutter is used for anterior-inferior release of the capsule and glenohumeral ligaments (see Figure 40.23). Partial release of the subscapularis tendon is preferred to complete release because of the risk for loss of internal rotation power and development of an external rotation contracture.[94,139,171] Often, release of the intraarticular portion of the subscapularis alone yields sufficient release to improve passive external rotation without capsular release. If a capsular release is performed, however, the axillary nerve needs to be protected. Rotation can be achieved, usually in the range of 30 to 70 degrees, with the arm adducted. Reduction is palpable following release with a clunk as the humerus is externally rotated. Reduction can be confirmed with intraoperative ultrasonography.

Open reduction can be performed with a transaxillary incision (see Figure 40.24; Video 40.3). Partial musculotendinous lengthening of the subscapularis and pectoralis major muscles is often required. Similar to arthroscopic reductions, in some cases joint reduction can be achieved by partial release of the subscapularis alone. If stable joint reduction and sufficient passive external rotation correction cannot be performed, then an open reduction is also performed. Partial anterior release of the thickened capsule and middle and inferior glenohumeral ligaments enables reduction of the humeral head.

Similar to arthroscopic reduction, overlengthening of the subscapularis must be avoided because it will lead to an external rotation contracture and loss of midline function. In some situations, there is a marked contracture of the deltoid and other shoulder girdle musculature, consistent with the shortening of neonatally denervated muscles, that may require similar lengthening to achieve reduction. A posterior capsulorrhaphy can be performed if necessary for joint stabilization after reduction. Overtightening of the joint capsule, however, needs to be avoided because it will limit postoperative glenohumeral motion; surgeons rarely tighten the posterior capsule.

For children younger than 12 to 24 months, it is unclear whether simultaneous transfer of the latissimus dorsi and teres major tendons to the greater tuberosity of the humerus should be performed because there is still the possibility of external rotation recovery with time. A transfer will provide immediate posterior joint support and prevent redislocation. In addition, staging tendon transfers after joint reduction can make the subsequent transfer more difficult. Postoperative immobilization in the reduced position is achieved with a shoulder spica splint or cast for 4 to 6 weeks.

In children with a progressive internal rotation–adduction contracture, the risk for progressive glenohumeral deformity increases. If therapy fails to maintain a nearly full passive arc of glenohumeral motion, intervention is recommended before marked deformity develops. Imaging of the shoulder by ultrasound or MRI is helpful in timing and planning appropriate interventions. Choices for correcting a progressive contracture include (1) Botox injections in the subscapularis pectoralis major and latissimus dorsi/teres major complex, followed by immobilization and subsequent therapy; (2) isolated subscapularis slide; (3) arthroscopic or open releases alone with or without concomitant tendon transfers.

Comparative data are unavailable to guide optimum treatment selection. Gilbert, Brockman, and Carlioz advised subscapularis lengthening for infants who fail to regain passive external rotation by 6 to 12 months of life despite extensive physical therapy.[59] The subscapularis can be lengthened by anterior "Z"-lengthening of the tendon, musculotendinous lengthening with a posterior axillary incision, or elevation of the subscapularis off the anterior portion of the scapula as a muscle slide. All techniques improve passive external rotation. Complications are rare, and improved shoulder motion and function are expected.[95,126,137,182]

As mentioned previously, arthroscopic or open release of the joint can be used to correct the contracture. Arthroscopic release alone in children younger than 3 or in combination with tendon transfers in older children are similar to open reduction alone or with tendon transfers; both lead to improved function, motion, and glenoid remodeling.[136-138] Overlengthening will result in an external rotation contracture and loss of internal rotation power (Figure 40.25). This limits important activities of daily living such as zippering and buttoning in the midline.

Children who fail to attain active abduction and external rotation are candidates for tendon transfers. Most commonly, this involves transfer of the latissimus dorsi and teres major to the insertion of the rotator cuff on the greater tuberosity

FIGURE 40.25 Overlengthening of the external rotators can result in loss of internal rotation. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

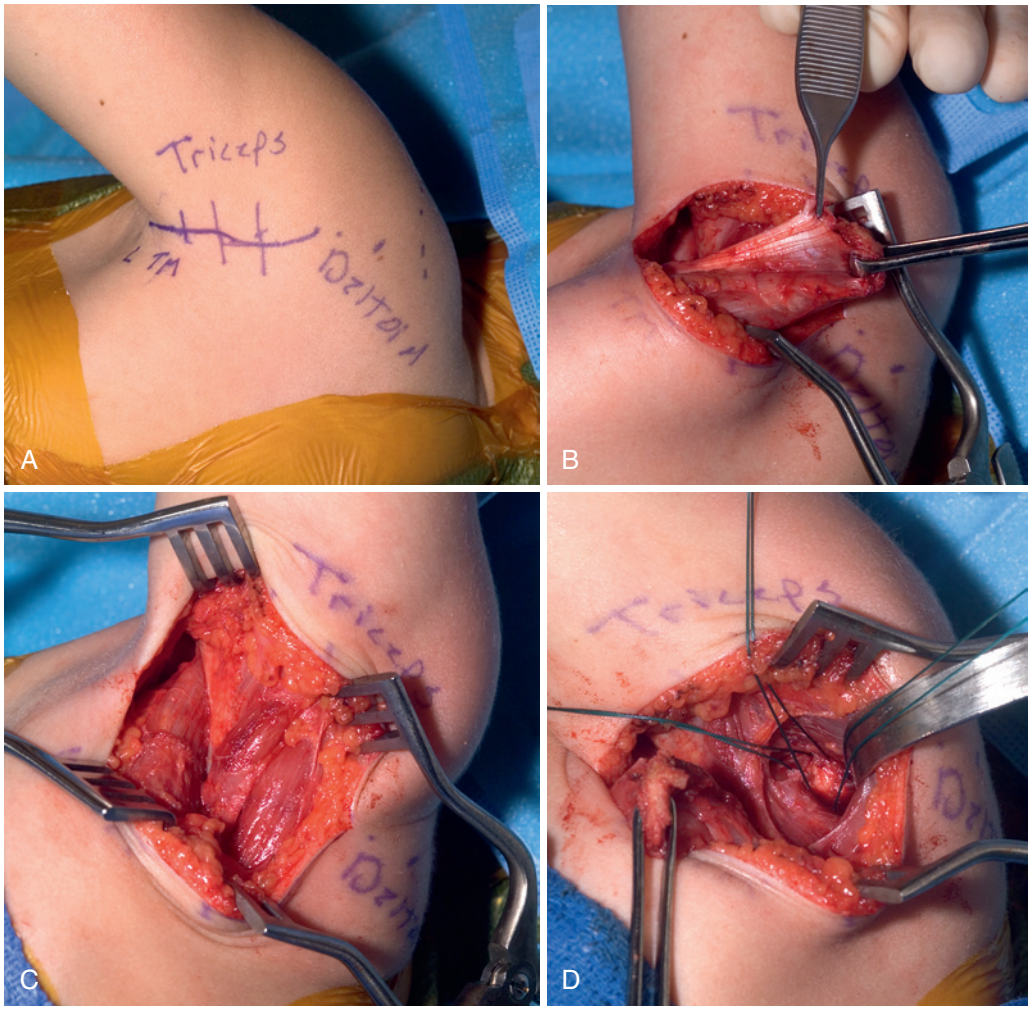

FIGURE 40.26 Technique for transfer of the latissimus dorsi and teres major to the insertion of the rotator cuff on the greater tuberosity. **A,** Posterior axillary incision from the tendon of the latissimus dorsi muscle to the posterior acromion. **B,** Latissimus dorsi and teres major tendons are traced to their humeral insertion and released with a strip of periosteum. **C,** The interval between the posterior deltoid and triceps is isolated. **D,** Sutures are placed into the interval between the infraspinatous and supraspinatous insertions. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

(Figure 40.26). For children with an associated internal rotation contracture, joint release and reduction may be indicated as described in the preceding. Examination of passive range of motion in the operating room will complete the diagnosis regarding contractures of the pectoralis major, subscapularis, triceps, teres major, latissimus dorsi, and coracoid musculature. Surgery is performed in the lateral decubitus position. If the pectoralis major is contracted with external rotation of 90 degrees of abduction, a small 2- to 3-cm anterior axillary incision is used to perform musculotendinous lengthening.

Through the same incision, the origin of the coracobrachialis, short head of the biceps, and pectoralis minor can undergo musculotendinous lengthening while protecting the musculocutaneous nerve if there is a mild elbow flexion contracture. A second, small posterior axillary incision is made from the edge of the latissimus dorsi anteriorly to the inferior edge of the deltoid posterosuperiorly. In obese children or those requiring joint reduction, these two incisions can be joined to improve exposure (see Figure 40.24). The conjoint insertion of the latissimus dorsi and teres major often is isolated and released from the humerus. These muscles can be confused with the more posterior long head of the triceps. The muscles are mobilized for maximum excursion while identifying and protecting the neurovascular pedicle.

The interval between the triceps and deltoid is exposed. There are often crossing fascial connections between the triceps, latissimus, and axillary skin that need to be released to improve excursion and line of pull. The greater tuberosity and infraspinatus and supraspinatus tendons are identified. The axillary nerve and circumflex vessels are also identified and protected. The subacromial space is decompressed by removing any bursae. The glenoid and posterior humeral head should be easily palpable. If the joint is unstable or subluxed, joint reduction is performed with appropriate anterior–inferior capsular releases and muscle lengthenings. This usually involves lengthening of subscapularis as previously described; however, at times this also includes triceps musculotendinous lengthening when there is a tight scapulohumeral angle on the table. Finally, the latissimus dorsi and teres major tendons are inserted into the greater tuberosity at the supraspinatus–infraspinatus point.

Periosteal, tendinous, or transosseous sutures are appropriate for the young. Osseous suture anchors are rarely necessary in older children or adolescents. When placing bone anchors, however, care must be taken to avoid injury to the proximal humerus physis. The choice of tendon transfer insertion site depends on the desired function to be achieved by it. Superior insertion into the greater tuberosity restores abduction and external rotation in abduction, but does little to improve external rotation in adduction. Conversely, insertion of the transferred tendons inferior to the physis will improve external rotation more in adduction but less in abduction; this will not improve active abduction as the tendons pass inferior to the axis of shoulder abduction–adduction. Always check the passive range of motion before closure including testing for a Putti sign. Postoperative immobilization in appropriate mild abduction (30-40 degrees) and external rotation (>40 degrees) is maintained for 4 to 6 weeks.

If the glenohumeral joint is markedly deformed, a derotational humeral osteotomy is indicated for patients with functional limitations of abduction and external rotation. However, humeral head flattening alone does not preclude successful improvement in function from tendon transfers, since release of the contracture restores articulation between the glenoid and the still-rounded posterior portion of the humeral head. In cases with more severe deformity, a humeral osteotomy can reliably improve active abduction and external rotation motion and function as shown by aggregate Mallet and PODCI scores.[16,170,182] Under anesthesia, a final assessment of passive range of motion of the joint is performed. Frequently, these children have limited glenohumeral motion because of their deformity. It is critical that one understands the range of motion available because this will ultimately determine the degree of correction of humeral external rotation. A minimum of 90 degrees, and ideally greater than 120 degrees of passive motion, is required for successful reorientation of the humerus.

The goal is to have the hand reach the mouth, forehead, and occiput without losing the ability to reach the genitalia, abdomen, chest, or contralateral hand. Surgery is performed with the patient in a limited beach-chair position. The entire shoulder girdle region, including the scapula, is left exposed during preparation and draping. The proximal end of the humerus is exposed in an extended deltopectoral or medial arm incision. A curvilinear deltopectoral incision that takes into account the expected external rotation of the skin with correction will lessen the risk for unsightly hypertrophied scars (Figure 40.27). Subperiosteal exposure of the humerus is performed. If a deltopectoral approach is used, the osteotomy is performed just proximal to the deltoid insertion. If a medial approach is used, the osteotomy is performed distal to the deltoid insertion.

In the distal osteotomy site, the ulnar and radial nerves need to be protected. In the proximal osteotomy, the radial nerve needs to be protected. Securing the proximal screws of the plate before the osteotomy controls the humerus and facilitates correction. The proximal and distal aspects of the humerus are marked for the desired rotational correction, usually 40 to 90 degrees. It is important to protect the radial nerve during the osteotomy because it lies posterior to the humerus at this level. With derotation, the plate is temporarily fixed to be certain that the hand can reach the mouth, occiput, chest, abdomen, and genitalia. Definitive internal fixation is then performed (Figure 40.28). Postoperative immobilization depends on the age of the child and the strength of the internal fixation. Improvement in shoulder motion (average improvement of 64 degrees in external rotation) and function (improvement in average aggregate

Mallet score from 13 to 18 out of 25) is to be expected.[5,182] A combination of varus and external rotation osteotomy[182] can improve associated severe abduction contractures both functionally and cosmetically (Figure 40.29).

❖ AUTHORS' PREFERRED TREATMENT

Infants with brachial plexus birth palsy are followed closely for subluxation/dislocation or contractures about the shoulder joint. Clinical signs of dislocation (i.e., rapid loss of passive external rotation, apparently shortened humeral segment, asymmetric axillary skin folds, posteriorly palpable humeral head) warrant an ultrasound. If the glenohumeral joint is reduced but subluxatable, physical therapy is continued with renewed efforts to improve passive external rotation in both adduction and abduction. If the joint is subluxated/dislocated but reducible, consideration is given to a Botox injection and shoulder spica casting in external rotation to maintain a reduced position. Subsequently, therapy is restarted while awaiting further external rotator reinnervation. If the joint is dislocated and irreducible in external rotation, an MRI is performed to establish a baseline evaluation of the glenohumeral deformity. The joint is surgically reduced using techniques described previously. If surgical release is required for reduction of an infantile dislocation, we have found tendon transfers are usually necessary to prevent redislocation.

Even in the absence of an infantile subluxation or dislocation, an internal rotation and adduction contracture about the shoulder is common in infants and children with a residual brachial plexus birth palsy. Ideally, physical therapy for passive range of motion with scapular stabilization is begun in the first few weeks of life in an attempt to prevent contractures and joint deformity. If a contracture develops in the first 1 to 2 years that does not resolve within 3 months of supervised therapy, MRI is performed to assess the glenohumeral joint. If the joint is reduced, more intense therapy with or without Botox, splinting, and/or casting is continued. At times, an isolated scapularis lengthening or partial release is performed to allow functional external rotation.[59]

Unfortunately, joint deformity often occurs early in life. For children with mild deformity (type II), release of joint contracture and tendon (i.e., latissimus dorsi and teres major) transfers are performed. If the joint deformity is more severe (type III or IV), formal joint reduction is performed in conjunction with tendon transfers. A variety of techniques have been shown to be equally capable of improving function and allowing remodeling of the glenohumeral dysplasia, provided they restore passive range of motion, realign the humeral head with the center of the glenoid, and rebalance muscle forces acting across the glenohumeral joint. The glenoid will remodel most of the time but the limits and quality of glenoid remodeling over time in all scenarios is still unknown. If the joint deformity is too severe at any age (advanced type IV, type V), a humeral external rotation osteotomy is preferred.[5,181,182]

This procedure is done when it is determined that the joint is not reconstructible or the child is too old to remodel (Figure 40.30). This is common in adolescent patients with an internal rotation contracture, limited external rotation, and advanced deformity. The author has performed a posterior, opening wedge glenoid osteotomy with bone graft to provide posterior bony stabilization in children with reconstructible type IV deformities. However, the indication for and outcome from this procedure are still under investigation.

Postoperative Management

Infants and young children who have undergone open reduction or tendon transfers (or both) are immobilized in a shoulder spica cast or brace for 4 to 6 weeks. Generally, the position of immobilization is in mild abduction and external rotation with a scapular mold to maintain correction of contractures, to preserve joint reduction, and to protect the soft tissue repairs. Active and passive motion is initiated after immobilization. Improved active motion of forward flexion, abduction (improvement of >60 degrees), and external rotation (improvement of >45 degrees) is expected after tendon transfers. Global improved function is also expected as shown by aggregate Mallet scores, with average preoperative scores of 13, improving

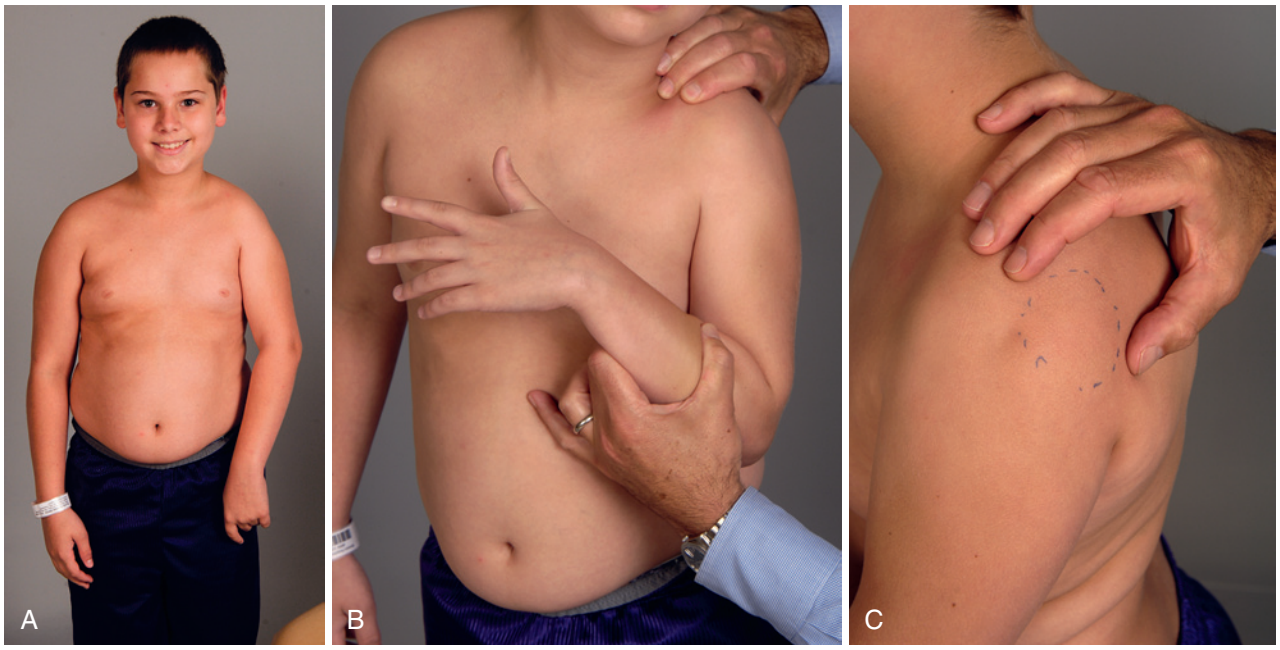

FIGURE 40.30 Nine-year-old with left residual BPP and frank shoulder subluxation prior to humeral osteotomy. **A,** Apparent shortening of the humeral segment. **B,** Lack of passive external rotation. **C,** Palpable fullness of the shoulder posterior to the glenoid. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

to 18 out of 25 postoperatively.[180] In addition, improved hand use occurs because it can be better positioned in space.

Humeral osteotomies, with rigid internal fixation, are typically performed in children old enough to be immobilized with a sling and swathe for 4 weeks. Rehabilitation is initiated once bony healing has occurred. Outcomes with osteotomy are similar to those with tendon transfers. Equivalent increased function is expected, despite no net increase in overall range of motion.[180]

Complications are rare following these operations. Even in situations of marked weakness of the affected arm, the latissimus dorsi and teres major muscles provide a positive outcome after transfer, potentially by way of passive tenodesis.[180] The status of the glenohumeral joint determines the selection of specific surgical intervention. If the joint remains deformed, there may be continued restriction of motion after tendon transfer. Motion is the most limited in external rotation and adduction after transfer in the presence of joint deformity. Although there is increased scapulothoracic motion, it cannot compensate for all the limitations of glenohumeral motion. A secondary, humeral osteotomy with varus and external rotation may be necessary to remedy the marked trumpet posture and inability to externally rotate the arm from an adducted position. This situation could be viewed as failure to select the appropriate surgical technique.

Loss of internal rotation power and an external rotation contracture can occur with excessive soft tissue release or overcorrection with an osteotomy. If physical therapy fails to resolve the situation, an internal rotation osteotomy may be required to rebalance shoulder function. If an internal rotation osteotomy is to be performed, a segment of the humeral shaft may need to be removed to prevent tension on the radial nerve that gets pulled taut as the humeral shaft is internally rotated. Persistent joint deformity may occur. The risk for long-term pain and disability from a deformed joint is unknown, although the incidence appears to be much less compared to a dysplastic hip.

There may be some loss of function with time and growth in children after extraarticular tendon transfers. Long-term loss of active external rotation and recurrence of adduction–internal rotation contractures have been described.[91,132] The progressive loss of function reported in early studies may be due to underappreciation of the importance of glenohumeral alignment, or because of the persistent neuromuscular abnormalities affecting the growth of the muscles about the glenohumeral joint. Further investigation is required to design optimal interventions to restore and preserve muscle growth and development throughout skeletal growth.

EXPECTED OUTCOME

- Early diagnosis of glenohumeral joint deformity offers the possibility of arthroscopic or open reduction. Reduction is associated with glenohumeral joint remodeling over time.
- Tendon transfers about the shoulder improve overall range of motion, especially abduction and external rotation. However, tendon transfers alone do not result in joint remodeling.
- Derotational humeral osteotomy is indicated for older children with limited external rotation. Published results after osteotomy are positive.

ELBOW

Early in infancy, the major issue is failure of return of biceps function for elbow flexion. As mentioned in the preceding sections, this is one of the major indicators for nerve surgery intervention in the first 3 to 9 months of life. Fortunately, in the long term it is uncommon to have persistent lack of antigravity elbow flexion. Sometimes the perceived failure of elbow flexion

function results from aberrant reinnervation of the elbow flexors producing flexor–extensor cocontraction. This problem can be ameliorated by Botox injection into the triceps to temporarily prevent triceps recruitment. The child is then able to learn how to functionally recruit the innervation pathways to the elbow flexors, improving elbow flexion function well beyond the efficacy of the Botox injection.[69,148]

True failure to recover antigravity biceps strength is a disappointing end result to both natural history observation and nerve reconstruction. As described previously, however, elbow flexion can be improved with later nerve transfer, provided appropriate donor nerves are available. Other options available for failure of biceps recovery include regional tendon transfers and vascularized muscle transfers. Regional tendon transfers include the pectoralis major, latissimus dorsi, triceps, or forearm flexor–pronator muscle origin (Steindler flexorplasty). The donor muscles must be nearly normal in strength for successful transfer, and the loss of donor function cannot lead to worsening impairment. All three muscle groups have been used successfully. The latissimus dorsi and pectoralis major muscles need to be mobilized on their neurovascular pedicles without undue tension (Figure 40.31). Both are aligned from the proximal coracoid or acromion to the distal native biceps tendon, radial tuberosity, or coronoid.

In performing a Steindler flexorplasty, the medial epicondyle and origin of the forearm flexor–pronator mass is detached and secured to the central aspect of the distal humerus with a compression screw and washer. The ulnar nerve needs to be decompressed and protected. Doi has popularized the use of free gracilis vascularized muscle transfers.[45] For elbow flexion the gracilis is similarly secured proximally at the coracoid or acromion and distally at the native biceps tendon, radial tuberosity, or coronoid for elbow flexion alone; or it is extended down to the wrist or finger extensors for combined function. Nerve connection is via the intercostals, spinal accessory, or contralateral C7.[67,175] Results have been described as encouraging, with improved function and active motion (average of 125 degrees).

The development of an elbow flexion contracture is common in children with residual plexopathy affecting 62 to 89% of children following unresolved birth palsy.[21,193] These elbow contractures range from mild (10-30 degrees)[21, 167] to moderate (30-60 degrees) to severe (60-90 degrees),[7,71,176] limiting the functional range of elbow motion[118] and exacerbating the aesthetic deformity of an already short, malpositioned upper extremity.[7] The severity of elbow flexion contracture does not differ between upper and global plexus injuries, and in most cases the elbow flexor strength is less than elbow extensor strength; therefore it is unlikely that the contracture is caused by elbow flexors overpowering a weak triceps.[21,70,143,144,155]

Many authors have proposed numerous conflicting theories for etiology of the elbow flexion contracture, although recent work with an animal model demonstrates the contracture to occur from impaired growth of the denervated elbow flexor muscles.[126,128,187] Initial treatment of the elbow flexion contracture is physical therapy with stretching of the biceps, brachialis, and anterior elbow capsule. Nighttime splinting, including dynamic devices, may be helpful, although there is limited information to determine its cost effectiveness. Fortunately, most of these contractures are mild and less than 30 degrees; this mild degree of contracture does not limit activities of daily living. More substantial contractures (>60 degrees) may need to be addressed surgically.

Recommendations for surgical treatment vary widely, with proponents of no treatment,[74] serial casting,[71] surgical release,[65,193] external fixator distraction,[176] flexor-to-extensor muscle transfers,[33] and humeral osteotomy.[7] Anterior lengthening of the biceps and brachialis has a short-term positive benefit in our hands. However, postoperative rehabilitation is extensive, and with the persistence of impaired muscle growth, recurrence is high. Thus, the preference is perform surgery later in

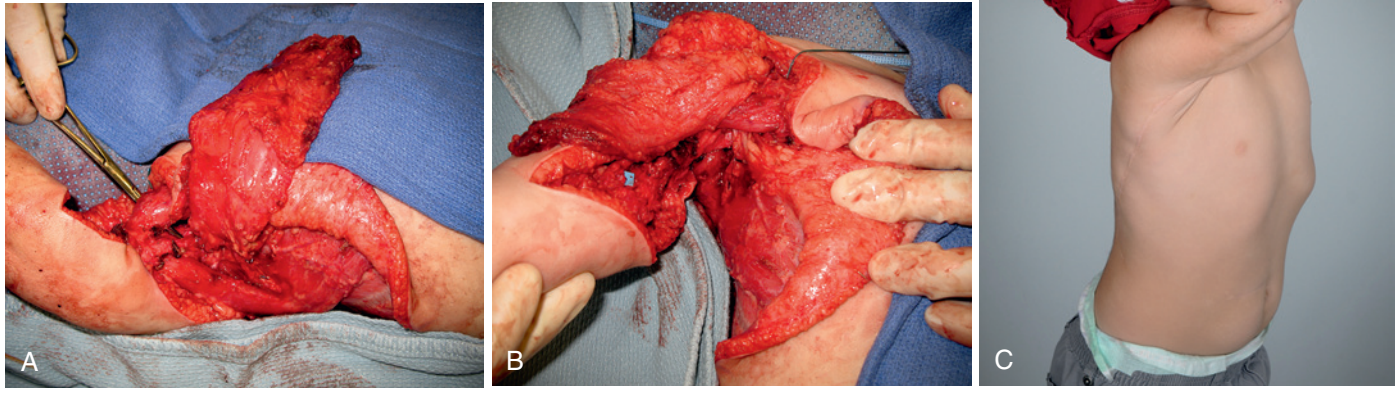

FIGURE 40.31 An 18-month-old with infraclavicular brachial plexus injury, absent elbow flexion, and insufficient soft tissue along the anterior arm. **A,** Latissimus dorsi muscle harvested on the thoracodorsal neurovascular pedicle prior to transfer beneath the pectoralis major muscle. **B,** Latissimus dorsi muscle passed under pectoralis major and into arm for restoration of elbow flexion. **C,** Postoperative right elbow flexion against gravity with well-healed posterior axillary incision. adolescence to decrease the possibility of recurrence. Once again, methods to restore muscle growth must be elucidated to prevent the occurrence and progression of this contracture.

FOREARM

Limitation of active and passive forearm rotation occurs commonly in children with incomplete recovery. Limitation of active pronation, and supination, correlates with worsening Mallet scores and Narakas group IV patients.[157] Loss of active pronation was more common than loss of supination in one study series.[157] When combined with an internal rotation contracture and external rotation weakness of the shoulder, the rotational deficiency becomes more obvious. Early in life these children have posture in pronation, and they raise their hands toward their mouths with marked abduction, internal rotation, and a neutral or pronated forearm (trumpet sign). Correction of the shoulder problem will improve forearm posturing because shoulder adduction, shoulder external rotation, and forearm supination are complementary motions. In the absence of full biceps strength, however, there will often be some unresolved supination weakness. Therapy, splints, and electrical stimulation often resolve this problem. Surgery is rarely indicated for the supination loss alone because the degree of functional limitation is minimal.

Conversely, children with global brachial plexus palsies posture into elbow flexion and forearm supination, often with a marked contracture of both joints. There may be active wrist extension and potentially some limited finger flexion. The wrist is frequently contracted into extension because of the lack of antigravity flexor strength. These children use only their forearm for an assistive function such as lifting. They avoid active use of their hand, often far beyond what one would expect.[194] Frequently, they are bothered by their unsightly posture. Surgery is indicated to improve elbow extension, forearm pronation, and hand function. Factors that determine the type of operation include (1) triceps function, (2) passive range of pronation, (3) status of the proximal radioulnar joint, (4) wrist extension strength, and (5) available donor muscles.

The elbow flexion contracture is addressed with a brachialis musculotendinous lengthening procedure, biceps musculotendinous or "Z"-lengthening, and sometimes with anterior elbow capsular release. The lack of active pronation is most often addressed by rerouting the biceps tendon, as long as passive pronation is maintained. The biceps tendon is rerouted around the radial neck while protecting the posterior interosseous nerve so that the line of pull of the biceps provides forearm pronation. It is repaired in a "Z"-lengthened position to improve passive extension of the elbow. The brachioradialis can similarly be rerouted by passage of its tendon around the radius.[131] Fixed supination contracture can be addressed by interosseous membrane release, forearm osteotomy or osteotomies, or radioulnar fusion. Zancolli and Zancolli advocate an interosseous membrane release.[194]

Gilbert et al perform a radial osteotomy distally along with biceps rerouting.[62] With severe contractures, osteotomy of both the radius and ulna may be necessary and is usually performed at the metaphyseal–diaphyseal junction proximally in the ulna and distally in the radius with internal fixation (Figure 40.32). Forearm pronation osteotomy can be performed even in the setting of radial head dislocation at the elbow, much like a humeral osteotomy can improve arm position despite a dislocated glenohumeral joint. However, in the presence of distal radioulnar joint dislocation, creation of a single-bone forearm is the best solution. The forearm is positioned in neutral-to-mild pronation (20 degrees) in all these procedures to avoid overcorrection.

Antigravity wrist extension strength must be present for the hand to function in a pronated position, although the strength of this function can be difficult to assess when the forearm is constantly in the supinated position. Therefore, if weakness in wrist extension is seen once the forearm is pronated, a tendon transfer (i.e., flexor carpi ulnaris to extensor carpi radialis brevis) can be performed as long as active flexor carpi ulnaris function is seen preoperatively. Following correction of the supination deformity, patients are often pleased with the function and the aesthetic result because of more natural posturing of the arm and hand in social settings. Nonetheless, as with other contractures, fixed ones tend to get worse with time, thus recurrence can occur following osteotomy in early childhood.

WRIST AND HAND

Fortunately, the majority of children with a brachial plexus birth palsy have an upper trunk lesion with near-normal wrist and hand function. C7 functional recovery may be incomplete with some limitation of wrist and finger extension, but frequently there is sufficient compensatory function by redundant innervation or tenodesis to avoid surgery. With considerable finger extension weakness, a tendon transfer, usually the flexor carpi ulnaris to the digital extensors, is performed to improve extension.

There are individuals who have permanent, devastating limitations in their affected hand. The dilemma is that there are few options for improving hand function in these children later in life. Therefore, strategies during primary nerve surgery should aim to innervate the lower trunk. A retrospective review of 25 patients who underwent primary brachial plexus exploration and nerve grafting/transfers highlights this point.[104] Patients operated before 1995 had no attempt to reconstruct the lower trunk and had good hand function according to the Raimondi scale in only 3 of 8 patients. In patients operated on after 1995, priority was placed on reconstruction of the lower trunk, and results tended to improve with good to very good function in 8 of 14 patients.

In a similar study, useful hand function (grade 3 or higher on the Raimondi scale) was restored in 9 of 13 patients in whom the lower trunk was reconstructed but only 1 of 3 in whom the lower trunk was not reconstructed.[140] Thus, prioritizing the hand in nerve surgery with more severe brachial plexus birth palsies is necessary, as there are limited donor muscles for active transfer; generally, the muscles available are weak. Wrist stabilization may be necessary for functional transfers to work. This can be achieved by wrist (1) capsulodesis, (2) fusion of the radial epiphysis to the carpus in a skeletally immature patient, or (3) arthrodesis in a skeletally mature person. The results of these procedures show improvement, although rarely to the level of an independently functioning hand. Double free gracilis muscle transfers for prehension with complete avulsion of the

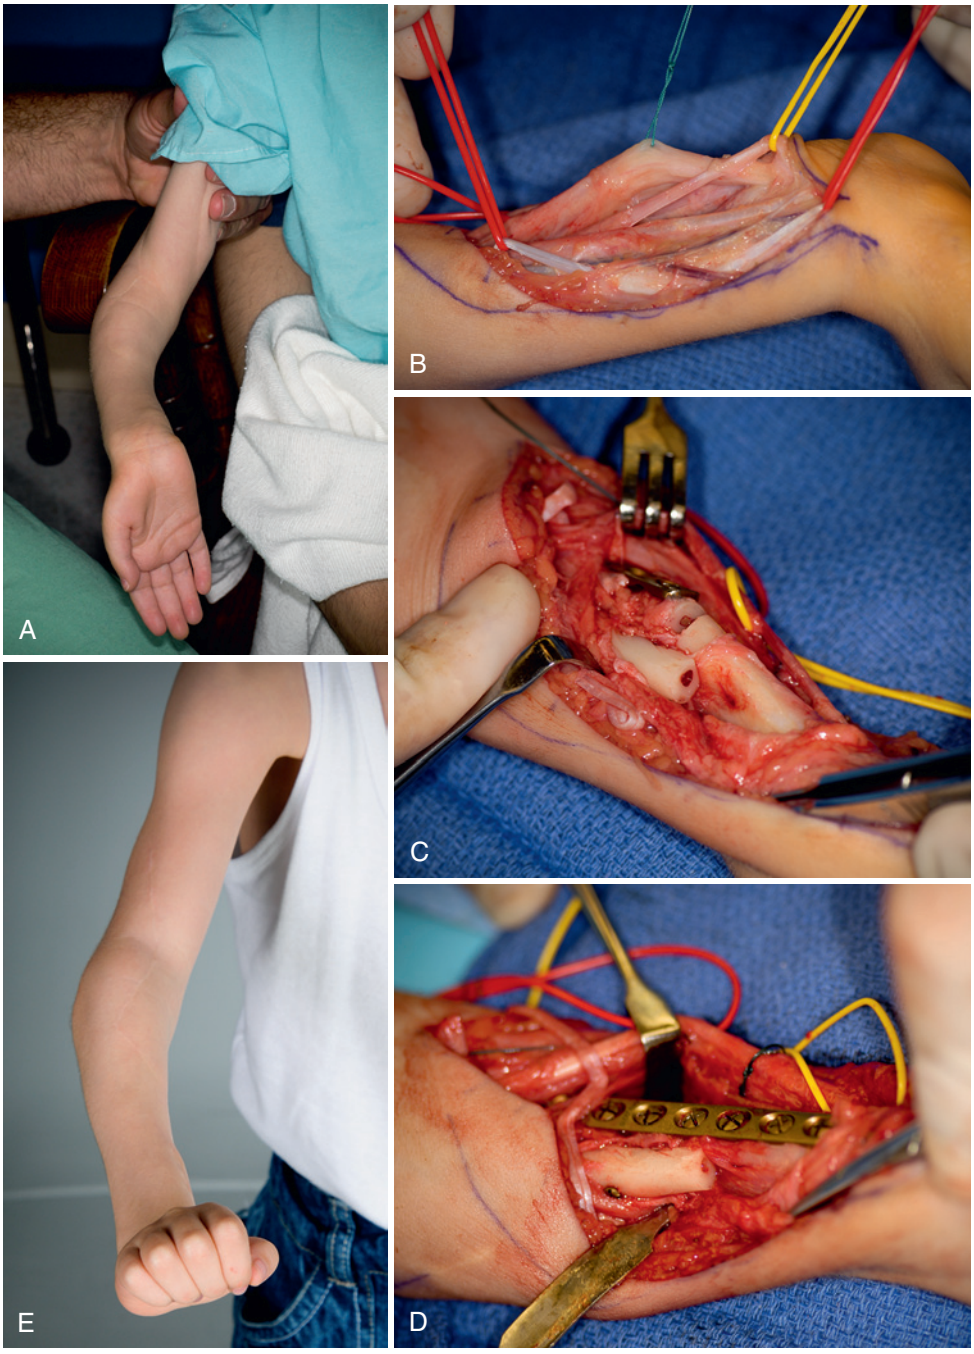

FIGURE 40.32 Eight-year-old male with residual right global brachial plexus birth palsy and fixed forearm supination deformity. **A,** Clinical deformity. **B,** Curvilinear incision and identification of the entire contents of the volar forearm. **C,** The radius is cut distal to the ulna and manually mobilized toward the proximal ulna. **D,** The forearm is rotated into the desired position and the ulna secured to the distal radius using dynamic compression. **E,** Final position of right forearm after osteotomy site. (Courtesy of Shriners Hospitals for Children, Philadelphia.)

brachial plexus have been performed with positive results even in the very young.[67]

Ulnar deviation deformity of the wrist is common in children with incomplete recovery of hand and wrist function. The deforming force is an unbalanced extensor carpi ulnaris or flexor carpi ulnaris (or both). Transfer of the deforming force to a more central location, usually to the extensor carpi radialis brevis, is recommended. This is usually performed at the same time as elbow and/or forearm procedures. There is often improvement in both function and appearance; however, the improvement is unlikely to achieve the desired independence and hand function.

Sensation is critical for function in the hand although it is difficult to assess in young children. A recent study tested hand sensation by Semmes-Weinstein monofilaments in 95 children over 6 years of age with brachial plexus birth palsies.[133] Impaired sensation was detected in 7 of 64 C5-6 patients, in 5 of 19 C5-7 patients, and in 4 of 12 C5-T1 patients. These findings

are consistent with another series of 105 patients in whom sensation correlated with number of nerve roots involved, with normal sensation in only 69% of C5-6 patients.[90] Even more difficult to assess is afferent innervation of the muscles, which allows joint proprioception. Elbow joint position sense has recently been found to be impaired following a brachial plexus birth palsy,[29] although the impact of this finding on hand and upper limb function remains to be determined.

HAND FRACTURES

Children are not small adults. Although many similar treatment principles and techniques are used in all age groups, a number of special considerations are required in the treatment of hand fractures in skeletally immature patients. Examination of the injured hand can be challenging, particularly in an anxious or a nonverbal child. An accurate diagnosis is dependent on the clinical history, careful observation, and skilled physical examination. These challenges are compounded by the smaller size of the affected musculoskeletal structures and the abundant surrounding subcutaneous fat and soft tissue. In addition, the smaller size of the underlying skeletal structures necessitates the use of smaller implants placed with precision during surgical procedures. Although the robust healing potential of skeletal injuries in children reduces the risk of delayed union and nonunion compared with their adult counterparts, it also narrows the window of opportunity to correct deformities using closed means. Much of this robust healing potential arises from the thick and biologically active periosteum, which contributes to appositional bone growth, promotes remodeling, and provides a smooth gliding surface for overlying tendons.

The presence of the physis leads to a unique set of treatment considerations. In many situations, an initial bony deformity will remodel with continued skeletal growth. This remodeling potential is dependent on a number of factors, including the magnitude and pattern of bony deformity, proximity of the injury to the adjacent physis, and amount of remaining skeletal growth. In general, the greatest remodeling potential is seen with displacement in the plane of adjacent joint motion, in close proximity to the physis, and in young children with many years of remaining growth.[19,156] Rotational deformity has little remodeling potential and will persist if not addressed acutely. Similarly, remodeling of radioulnar angulation is limited and is dependent on the amount of adjacent radioulnar joint motion. Efforts to preserve physeal growth may also influence the choice of surgical techniques for operative injuries.

Because children demonstrate varying degrees of compliance following injury or postoperative care, more restrictive immobilization is required to maximize long-term outcomes. Fortunately, the use of longer and more restrictive immobilization following hand fractures in children is not associated with the stiffness seen in adults. Indeed, children are often their own best therapists and quickly resolve issues of stiffness and strength through daily activities of play and sports.

In addition to these considerations, a number of hand injuries are characteristically found in children. Awareness of these injuries and their treatment options is essential for the practicing hand surgeon.

The purpose of this section is to review the epidemiology, pertinent anatomy, and treatment principles for fractures of the child's hand, with particular emphasis on pediatric injuries requiring surgical care.

Epidemiology

Hand fractures are common in children and adolescents. In their analysis of the 1998 National Hospital Ambulatory Medical Care Survey (NHAMCS), Chung and Spilson reported on the epidemiologic findings of hand and forearm fractures in the United States.[39] Based on their four-stage probability model and subsequent extrapolation of the NHAMCS data, an estimated 1,465,874 patients with hand or forearm fractures present to U.S. emergency departments annually. Phalangeal and metacarpal fractures represented 23% and 18% of these cases, respectively. Interestingly, 15% of all metacarpal fractures and 33% of all phalangeal fractures occurred in patients between 0 and 14 years of age. Furthermore, the highest rate of multiple hand fractures was seen in patients between 0 and 4 years of age (29.8%). The calculated incidence of phalangeal fractures in patients 0 to 4 years old was 207.2 per 100,000. The incidence of metacarpal and phalangeal fractures in patients 5 to 14 years old was 100.0 and 184.9 per 100,000, respectively. Although this analysis was limited by the study design and the nature of the NHAMCS database, the results clearly highlight the frequency with which hand fractures occur in the pediatric population.

Feehan and Sheps performed a population-based study evaluating the epidemiology of hand fractures in British Columbia, Canada, from 1996 to 2001.[55] During the 5-year study period, 72,481 fractures were identified, for an overall annual incidence of 3.63 per 1000 across all age groups. The peak incidence for hand fractures was between 10 and 14 years of age (8.69 per

1000). When divided according to gender, the highest incidence was seen in males between 15 and 19 years of age (12.3 per 1000) and females between 10 and 14 years of age (5.3 per 1000). The authors attributed this peak incidence during adolescence to a combination of accelerated skeletal growth and participation in higher risk sporting and recreational activities.[48,49,55]

Over a 6-month period in 2000 at the Pulvertaft Hand Center in Derby, England, 360 children younger than 16 years were seen for hand injuries.[189] Skeletal injuries accounted for 66% of cases, for an annual incidence of 418 per 100,000 children. The peak incidence was in patients between 10 and 16 years of age. Although crushing injuries were the most common mechanism overall, sports-related fractures occurred most commonly in patients older than 10 years. The small finger was most commonly fractured (52%), followed by the thumb (23%). The proximal phalanx was the most frequently injured phalanx (67%). Metacarpal fractures were most commonly diaphyseal, whereas phalangeal fractures typically involved the proximal metaphysis or physis.

Shah and colleagues more recently reported their retrospective analysis of the National Electronic Injury Surveillance System of patients less than 18 years of age treated at U.S. emergency departments from 1990 to 2009.[167] They estimated an incidence of hand injuries at 11.6 per 1000. Approximately one-quarter of all hand injuries consisted of fractures, most commonly affecting patients between 10 and 14 years of age and resulting from recreational and sporting activities.

In addition to the wealth of information on the frequency of hand fractures in children and adolescents, a number of published reports have provided insights into the mechanisms and patterns of injury. Taking these and previous epidemiologic studies together, it is clear that there is a biphasic distribution of hand injuries, with the peak incidences in young toddlers and older adolescents. Bhende and coworkers analyzed 464 children with 477 hand injuries presenting to a level I pediatric emergency department during a 6-month period in 1989.[21] Fractures accounted for 19.3% of all hand injuries, and a bimodal distribution of injuries was seen. Toddlers and younger children presented with lacerations, burns, and fingertip injuries, such as distal phalangeal fractures, as they explored the world around them. Conversely, adolescents tended to present with hand fractures sustained during sporting activities, fights, and self-inflicted trauma.[49] These findings are supported by Liu and associates and Young and colleagues in their separate analyses of children presenting to plastic surgery emergency clinics.[109,212]

Rajesh and associates similarly attempted to characterize the pattern and nature of pediatric hand fractures in their radiographic review of 280 children treated at the Leicester Royal Infirmary in the United Kingdom.[154] Isolated distal phalangeal tuft fractures were most common in the 0- to 4-year-old age group. Distal phalangeal tuft and shaft fractures were most common in 5- to 8-year-old children. Small finger proximal phalangeal fractures were most common in patients 9 to 12 years of age, and small finger metacarpal neck fractures were seen most often in 13- to 16-year-old adolescents (Figure 41.1). Other published reports have also documented a higher frequency of injury to the border digits and to the small finger in particular.[19,77]

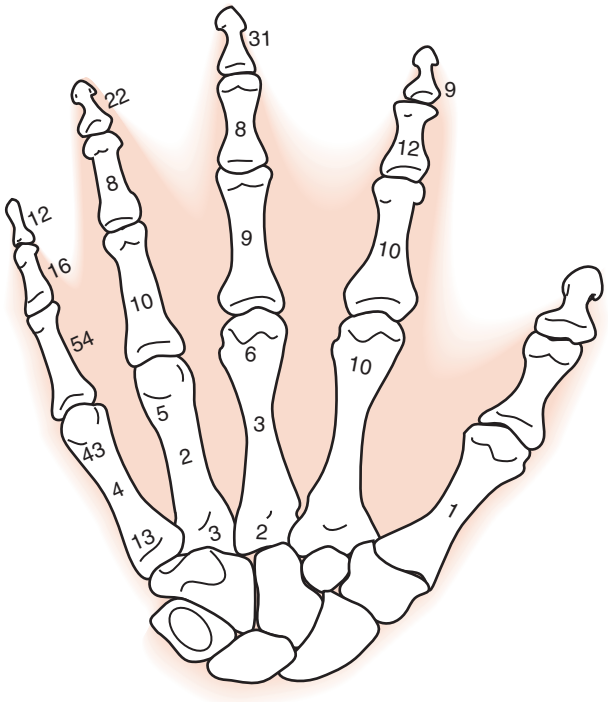

FIGURE 41.1 Schematic diagram depicting the distribution of hand fractures in 280 children younger than 16 years. (From Rajesh A, Basu AK, Vaidhyanath R, et al: Hand fractures: a study of their site and type in childhood. *Clin Radiol* 56:667–669, 2001.)

Approximately one-third of all fractures of the hand propagate through the phalangeal or metacarpal physis.[9,10,77,212] Salter-Harris type II fracture patterns predominate, most commonly of the proximal phalanx.[77,154,161,209,210] Despite the relative frequency with which physeal fractures occur, posttraumatic physeal arrest is an uncommon sequela in isolated closed injuries.

Preoperative Evaluation

Physical examination of a child's injured hand can be challenging, particularly in an anxious, noncompliant, or nonverbal patient. Observation and gentle maneuvers are mandatory to obtain the information needed for an accurate and timely diagnosis. The presence of swelling, ecchymosis, guarded active motion, or soft tissue injury can guide the examiner to the region of the pathologic condition.

The *tenodesis effect*, or gentle pressure applied to the more proximal muscle bellies of the forearm (away from the site of injury), aids in the assessment of both tendon integrity and angular or rotational deformity (Figure 41.2). Assessment of rotational deformity is critical because the deformity exhibits little remodeling and may result in compromised hand function owing to digital overlap or underlap. Malrotation can also be assessed by careful examination of the nail beds of adjacent digits in extension; rotation of greater than 10 degrees out of the plane of adjacent nail plates should alert the examiner to rotational malalignment, although these differences are often subtle and difficult to quantify. Rotational deformity can be better assessed by evaluating digital alignment with attempted finger flexion. In general, the index through small fingers point

FIGURE 41.4 Schematic diagram of the Salter-Harris classification of physeal fractures. (McElfresh EC, Dobyns JH: Intra-articular metacarpal head fractures. *J Hand Surg [Am]* 8:383–393, 1983.)

to the scaphoid tubercle in flexion, roughly in parallel alignment; often, patients normally exhibit some degree of digital underlap, such as small finger beneath ring finger. Comparison to the uninjured contralateral hand is valuable in these situations to determine baseline alignment. In young, anxious, or nonverbal patients who are unable to actively flex their digits during physical examination, the tenodesis effect can be used; gentle passive extension of the wrist also allows obligate digital flexion to assess for rotational alignment. Only after all pertinent information has been derived from observation and indirect examination techniques should direct palpation or stress testing be performed.

Sensibility is difficult to elicit in young patients, and threshold testing or two-point discrimination is generally unreliable until children are older than 8 years. In rare situations in which there is concern about an associated digital nerve injury, warm water immersion can be used. The presence of skin wrinkling after several minutes of water immersion implies innervation.

Thorough and directed radiographic evaluation is imperative in the evaluation of a child's injured hand. In general, dedicated anteroposterior (AP), lateral, and oblique radiographs of the injured digit are preferred over hand radiographs, in which overlying structures, projection artifacts, and lack of bony magnification can lead to errors in diagnosis. As part of the systematic evaluation of hand radiographs, the phalangeal line test has been proposed as a means of identifying joint malalignment or bony angulation in younger children whose skeletal structures are not yet ossified (Figure 41.3).[31] When expedited or comprehensive radiographic assessment is needed, fluoroscopy or mini-imaging units may assist in obtaining appropriate views of the injured digit, comparison views of the contralateral hand, or dynamic assessment of bony and articular stability. As ultrasonography becomes increasingly ubiquitous, ultrasound imaging may similarly be used to detect subtle or radiographically occult fractures.[134] The normal sequence of skeletal ossification, as well as common normal radiographic variants (discussed later), should be kept in mind to avoid mistaking these for traumatic injuries.[72,177] Indeed, Chew and Chong previously reported on 204 children referred to a tertiary care center for hand fractures; injuries were misdiagnosed in 16 cases (8%), of which the leading cause was mistaking the epiphyses for fractures.[37]

Among the many proposed classification systems, that of Salter and Harris is most widely used owing to its simplicity and its ability to guide fracture management and prognosticate outcome (Figure 41.4).[161]

PERTINENT ANATOMY

In the skeletally immature hand, the physes of the phalanges lie perpendicular to the long axis of the bones proximally. The metacarpal physes are distal, with the exception of the thumb metacarpal, which is proximal.

The secondary centers of ossification in the epiphyses appear in a timely and orderly fashion. Although there is variation among individuals, the proximal phalangeal epiphyses become radiographically apparent between 10 and 24 months of age, in females before males.[72,177] The epiphyses of the middle and distal phalanges ossify approximately 6 to 8 months later. Conversely, physeal closure proceeds in a distal to proximal direction, typically between the ages of 14 and 16 years. The index through small finger metacarpal epiphyses ossify at 12 to 27 months of age and fuse between 14 and 16 years of age. The thumb metacarpal epiphysis, however, does not typically ossify until 24 to 36 months of age.

Common normal radiographic variants include the appearance of a pseudoepiphysis of the distal thumb metacarpal and the proximal index metacarpal.[75] The pseudoepiphyses become radiographically apparent at an early age, do not contribute to the longitudinal growth of the metacarpal, and typically fuse to the metacarpal diaphysis by the seventh year of life.[75] Other anatomic variants include the double epiphysis, most commonly appearing in the index finger and thumb metacarpals. These physeal variants can be misinterpreted as fractures.

As in other long tubular bones that develop via enchondral ossification, the physis of the phalanges and metacarpals is divided into a number of histologic zones. Proceeding from the epiphysis to the metaphysis, the physis contains a resting zone, proliferative zone, zone of hypertrophy, and zone of provisional calcification. Because most physeal fractures propagate through the zone of hypertrophy without disrupting the resting or proliferative zone, posttraumatic growth disturbance is an uncommon sequela of pediatric hand fractures. In the less common circumstance in which the plane of cleavage traverses the zone of proliferation or the resting zone (e.g., Salter-Harris type III, IV, and V fractures), physeal arrest may occur.[161] As the physis becomes more irregular and calcified as patients approach skeletal maturity, Salter-Harris type III and IV injuries are more likely to occur, mimicking more adult fracture patterns (e.g., Bennett fracture at the base of the thumb metacarpal).

Knowledge of the soft tissue anatomy is critical in understanding common fracture patterns and guiding nonoperative as well as surgical treatment. In the interphalangeal joints, the collateral ligaments arise from the collateral recesses of the phalangeal neck proximally and insert to the epiphysis and metaphysis of the adjacent phalangeal base distally. Conversely, at the metacarpophalangeal (MP) joint, the radial collateral ligament arises from the metacarpal epiphysis proximally and inserts on the proximal phalangeal epiphysis distally; the ulnar collateral ligament originates from both the metacarpal epiphysis and metaphysis and inserts on the proximal phalangeal epiphysis.[23] For these reasons, Salter-Harris III fractures are common about the MP joint but rarely involve interphalangeal joints because the epiphysis is "protected" by the collateral ligaments. Conversely, diaphyseal or Salter-Harris II fractures of the distal phalanx or fractures of the proximal phalangeal head or neck more commonly arise from laterally directed forces on the interphalangeal joints.

Understanding of the tendinous insertions in the hand also helps elucidate fracture patterns and guide treatment. The terminal tendon of the long digital extensor inserts onto the dorsal phalangeal epiphysis, and the flexor digitorum profundus insertion to the index through small fingers spans both the volar epiphysis and metaphysis. This anatomic relationship is particularly relevant in the treatment of distal phalangeal physeal fractures, as described later. In the thumb, the extensor pollicis longus inserts onto the dorsal epiphysis of the distal phalanx, the extensor pollicis brevis inserts onto the epiphysis of the proximal phalanx, and the abductor pollicis longus inserts broadly on both the epiphysis and metaphysis of the thumb metacarpal. As in the digits, the flexor pollicis longus inserts on the metadiaphysis of the distal phalanx.[23]

Historical Review

Most hand fractures in children can be managed nonoperatively on an outpatient basis.[31,59,77,212] Indeed, it has been estimated that only 10% to 20% of pediatric hand fractures require surgical care, and these statistics have been corroborated by contemporary published series.[21]

Hastings and Simmons published a retrospective analysis of 354 hand fractures in skeletally immature patients.[77] Border digits were most commonly fractured, and the metacarpal and proximal phalanx were most commonly affected. Although they found a higher prevalence of physeal fractures than had been reported in previous studies, there were only two cases of growth disturbance, seen in patients with severe crush injuries or infection. Overall results were excellent in most cases, but a number of risk factors were associated with fracture malunion and poor results, including failure to obtain adequate radiographs at the time of injury, false assumptions regarding the remodeling potential of phalangeal fractures, and failure to evaluate clinical deformity (i.e., malrotation). Displaced articular fractures, physeal fractures of the distal phalanx, phalangeal neck fractures, and open fractures were identified as carrying a high risk for suboptimal outcomes in the pediatric population (Box 41.1). Given this information, treatment of these fractures is emphasized in the following sections.

Types of Operations

Distal Phalangeal Fractures

Most distal phalangeal fractures are successfully treated without surgery. Recognition of open fractures and subsequent operative treatment lead to a successful result.

Shaft and Tuft Fractures. Fractures of the distal phalanx typically result from crush injuries in younger patients.[191] In general, patterns of these extraphyseal injuries include transverse, longitudinal split, and comminuted fractures.[99] As expected, these bony injuries are often accompanied by soft tissue avulsions or nail bed lacerations. Treatment is predicated on stabilization of the skeletal injury and appropriate soft tissue injury care, including wound irrigation and débridement, nail plate removal, and nail bed repair.[221,222] Although the majority of

BOX 41.1 High-Risk Pediatric Hand Fractures

- Distal phalangeal physeal fractures (Seymour fractures)
- Phalangeal neck fractures
- Open fractures

distal phalangeal fractures can be treated effectively with splint or cast immobilization following gentle fracture repositioning, surgical stabilization is occasionally needed for widely displaced injuries.[31] In these situations, a single Kirschner wire placed through the digital tip and across the fracture site will suffice. Some have proposed using a hypodermic needle placed under local anesthesia for fracture stabilization.[126]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

The majority of extraphyseal distal phalangeal fractures are treated with simple splint or cast immobilization for 4 weeks, with excellent healing and outcomes. Rarely, if complete displacement or translation occurs in transverse fracture patterns, Kirschner wire fixation is used to maintain reduction. A single Kirschner wire is passed in a retrograde fashion through the fingertip, across the fracture, and across the distal interphalangeal (DIP) joint, engaging the head of the middle phalanx. The wire is bent and cut outside the skin and is removed in the office after 4 weeks, followed by range-of-motion exercises and a return to activities as symptoms abate.

Physeal Fractures. Salter-Harris I fractures result in the so-called pseudomallet finger because the distal diaphyseal fragment is volarly displaced, with apex dorsal angulation, by the action of the flexor digitorum profundus.[65] Treatment usually requires extension splinting of the distal phalanx and DIP joint for 4 to 6 weeks.

Seymour fractures are characteristic pediatric injuries of the distal phalangeal physis that merit special attention.[3,166] Typically resulting from crush injuries to the distal phalanx and DIP joint, these are displaced physeal fractures of the distal phalanx accompanied by an overlying nail bed laceration (Figure 41.5). Often there is interposed soft tissue (i.e., germinal matrix) within the displaced physeal fracture. Technically, this is an open physeal fracture; therefore, treatment should consist of nail plate removal, irrigation, and débridement; liberation of any interposed soft tissue; open reduction of the physeal fracture; and meticulous nail bed repair (see Figure 41.5). Dorsal skin incisions from both corners of the dorsal nail fold back toward the DIP joint extension crease elevate the dorsal skin and provide exposure of the germinal matrix and nail bed laceration. The terminal tendon attachment to the dorsal epiphysis must be preserved. Replacement of the trephinated nail plate beneath the dorsal nail fold after nail bed repair often results in sufficient bony stabilization. In cases of excessive instability, transarticular longitudinal pinning of the distal phalanx and DIP joint is used. Krusche-Mandl and colleagues reported results of 24 children treated for Seymour fractures with a mean follow-up of 10 years.[100] With adherence to the above-stated treatment principles, 23 of 24 patients regained full motion, and no infectious complications were noted. Although appropriate and timely treatment results in excellent functional outcomes, failure to attend to these treatment principles and technical steps may lead to late osteomyelitis, physeal arrest, and nail plate deformity (Figure 41.6).[3,65,100]

Salter-Harris III fractures of the dorsal base of the distal phalanx represent the pediatric equivalent of the adult mallet finger (Figure 41.7). Fracture displacement is caused by the proximal pull of the terminal tendon on the epiphyseal fracture fragment. Although minimally displaced or nondisplaced fractures can be treated successfully with extension splinting for 4 to 6 weeks, markedly displaced injuries resulting in volar subluxation of the distal phalanx or articular incongruity unamenable to closed reduction merit surgical consideration. Treatment options include formal open reduction and internal fixation via a dorsal approach (with care taken to preserve terminal tendon attachments to the epiphyseal fragment) or closed reduction and transarticular or extension block pinning.[81]

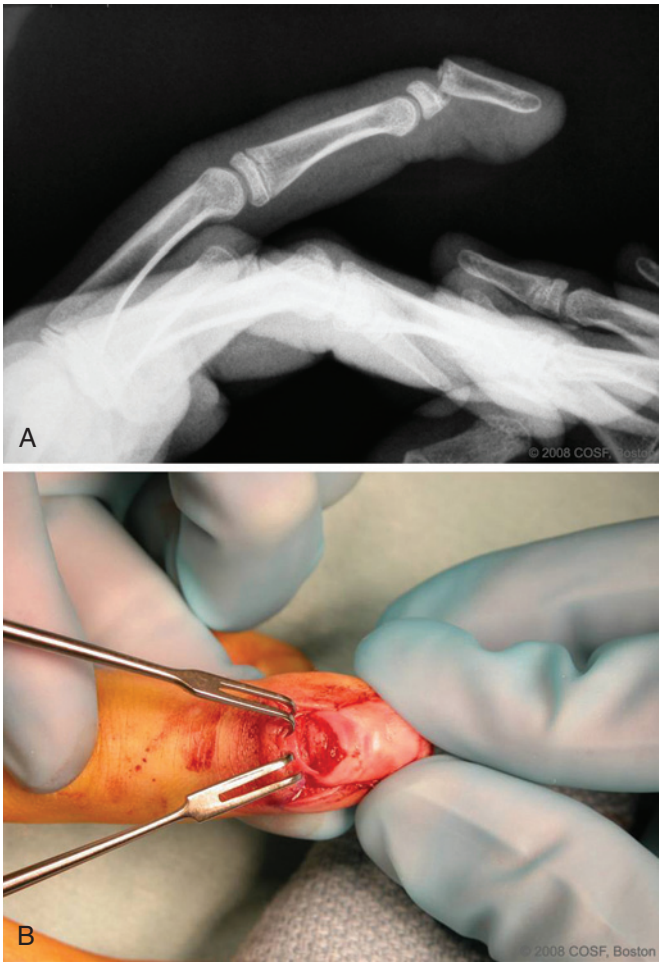

FIGURE 41.5 **A,** Lateral radiograph depicting a displaced physeal fracture of the distal phalanx with an associated nail bed laceration, the so-called Seymour fracture. **B,** Intraoperative photograph following nail plate removal and elevation of the dorsal nail fold. The fracture has been reduced after extrication of interposed germinal matrix, and the cartilaginous physis is visualized. The transverse nail bed laceration can also be seen. (Courtesy of the Children's Orthopaedic Surgery Foundation. See also McQuinn AG, Jaarsma RL: Risk factors for redisplacement of pediatric distal forearm and distal radius fractures. *J Pediatr Orthop* 32:687–692, 2012.)

Rarely, injury to the distal phalangeal physis may result in extrusion of the epiphysis, the so-called epiphyseal dislocation (Figure 41.8).[127] In young children in whom the epiphysis is not yet or incompletely ossified, radiographic findings may be very subtle. For this reason, careful correlation between radiographs and clinical examination is necessary. A heightened suspicion for underlying epiphyseal injury is appropriate when there is a "flake," "crescent," or poorly defined opacity with irregularity or incongruity of the DIP joint. Because the epiphysis typically displaces dorsally, a true lateral radiograph of the digit is needed for diagnosis.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Physeal fractures resulting in pseudomallet deformity are treated with closed reduction and immobilization for 4 to 6 weeks. Variations of mallet splinting are viable options in older patients; however, cast immobilization is often needed in the very young to ensure compliance and protection of the injured digit. If an apex dorsal physeal fracture is seen in association with a subungual hematoma, the potential of a Seymour fracture is raised. If there is any question, the nail plate is removed, and appropriate soft tissue repair and bony stabilization are

performed, as described earlier. This is particularly true if a persistent widening of the dorsal phalangeal physis is noted after reduction, suggesting soft tissue interposition. Surgical treatment for dorsal Salter-Harris III fractures of the distal phalanx is reserved for patients with greater than 40% articular surface disruption and volar subluxation of the DIP joint, similar to adult bony mallet injuries. Percutaneous pinning techniques are used when adequate closed reduction can be achieved. Otherwise, an open technique to achieve fracture reduction is necessary.

CRITICAL POINTS *Distal Phalangeal Fractures*

- Most distal phalangeal fractures can be treated nonoperatively with appropriate immobilization and care of associated soft tissue injuries.
- A high index of suspicion is required for Seymour fractures, which should be treated with nail plate removal, fracture débridement and reduction, and nail bed repair.
- Dorsal Salter-Harris III fractures represent the pediatric equivalent of adult bony mallet fractures, with similar treatment principles.

Middle and Proximal Phalangeal Fractures

Fractures of the middle and proximal phalanx are categorized according to their location, pattern, and displacement. Fractures tend to occur at the distal articular surface, diaphysis, physis, or epiphysis. Each has its own set of anatomic and treatment considerations and is discussed separately.

Recognition of and surgery for displaced phalangeal neck and intraarticular fractures reliably result in union and restoration of motion. A delayed presentation complicates surgical management and diminishes outcome.

Articular Fractures of the Phalangeal Head. Articular fractures of the head of the proximal and middle phalanges include unicondylar, bicondylar, and comminuted fracture patterns.[154] As with adult injuries, treatment is predicated on articular congruity and angular or rotational deformity. Nondisplaced injuries can be treated with cast immobilization. In these situations, however, weekly radiographic examinations should be considered to confirm maintenance of reduction and articular congruity.[168,206] In fractures with greater than 5 to 10 degrees of angulation or 1 to 2 mm of articular incongruity, surgical intervention is recommended. Closed or open reduction with smooth Kirschner wire or interfragmentary screw fixation is recommended (Video 41.1). Although closed reduction is desirable, it is imperative to achieve an anatomic reduction to restore articular congruity. In cases in which closed reduction is not feasible, open reduction is performed via a dorsal approach, allowing visualization of the articular surfaces while carefully preserving the collateral ligament and other soft tissue attachments to the condylar fracture fragments to preserve their vascularity. With careful surgical technique, restoration of motion and preservation of joint stability and articular congruity can be expected.[168] Patients and families should be counseled, however, regarding the potential for long-term stiffness and arthrosis, particularly with severely displaced injuries requiring open treatment.[20]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

For displaced fractures of the phalangeal head, open reduction and internal fixation using smooth pins (or, less commonly, screws) are performed (Figure 41.9). A dorsal curvilinear incision is centered over the affected interphalangeal joint, with the convexity directed to the side of the fracture. Soft tissue flaps are elevated, preserving the dorsal veins and subcutaneous nerves. An incision between the extensor tendon and lateral bands is made, and the overlying extensor apparatus is carefully retracted. The joint capsule is incised to allow visualization of the fracture line and articular surface. Care is taken to preserve soft tissue attachments to the displaced fracture fragments to maintain vascularity and ligamentous stability. Under direct visualization, the fracture is reduced, and restoration of articular congruity is confirmed. Fixation can then be performed with interfragmentary screws or smooth Kirschner wires or a combination thereof. Two screws or pins are used to provide rotational stability and prevent loss of reduction.[206] Intraoperative fluoroscopy confirms reduction, and the pins are left in a percutaneous location to facilitate subsequent removal. The joint capsule, extensor apparatus, and skin are closed in layers, and the patient is placed in a splint or short-arm hand-based cast. Pins are removed after 3 to 4 weeks, after which time range-of-motion exercises are initiated.

Phalangeal Neck Fractures. Phalangeal neck fractures are characteristic injuries of childhood. They are usually the result of "doorjamb" injuries in which a digit is crushed or trapped in a door and forcefully withdrawn, imparting both extension and rotational forces on the affected digit. Border digits are most commonly affected, and the middle phalanx is injured more frequently than the proximal phalanx. The fracture occurs at the level of the phalangeal neck, and typically the more distal articular segment is displaced into extension, with varying degrees of rotation. Patients present with swelling, tenderness, ecchymosis, and limited interphalangeal joint motion, although the last is often difficult to appreciate in an acutely injured child. A slight angular deformity may be seen.

Careful radiographic evaluation is critical for a timely diagnosis and appropriate treatment.[77] Because the distal fragment typically displaces dorsally, with apex volar angulation, standard AP views of the affected digit often appear benign. A true lateral radiograph of the injured digit is necessary. In addition, in very young patients the phalangeal head remains predominantly cartilaginous, so subtle or seemingly innocuous "bony flecks" should raise the suspicion of a displaced cartilaginous cap or osteochondral fracture. Although the radiographs may appear innocuous, displaced phalangeal neck fractures result in both abnormal digital alignment (in the sagittal plane) and disruption of the normally concave subcondylar fossa. Obliteration of the subcondylar fossa results in a bony block to interphalangeal joint flexion, because the adjacent phalangeal base abuts the bony prominence at the distal end of the proximal fracture fragment.

Al-Qattan's classification of extraarticular phalangeal neck fractures is clinically useful because it can indicate prognosis and guide treatment.[6] Type I fractures are nondisplaced; type II fractures are partially displaced, with some bony or cortical contact; and type III fractures are completely displaced, without bony apposition. Cast immobilization is sufficient in cases of nondisplaced injuries, although serial radiographs are required to confirm maintenance of reduction. Closed reduction and splinting or cast immobilization are often insufficient for type II and III fractures; therefore, surgical treatment in the form of

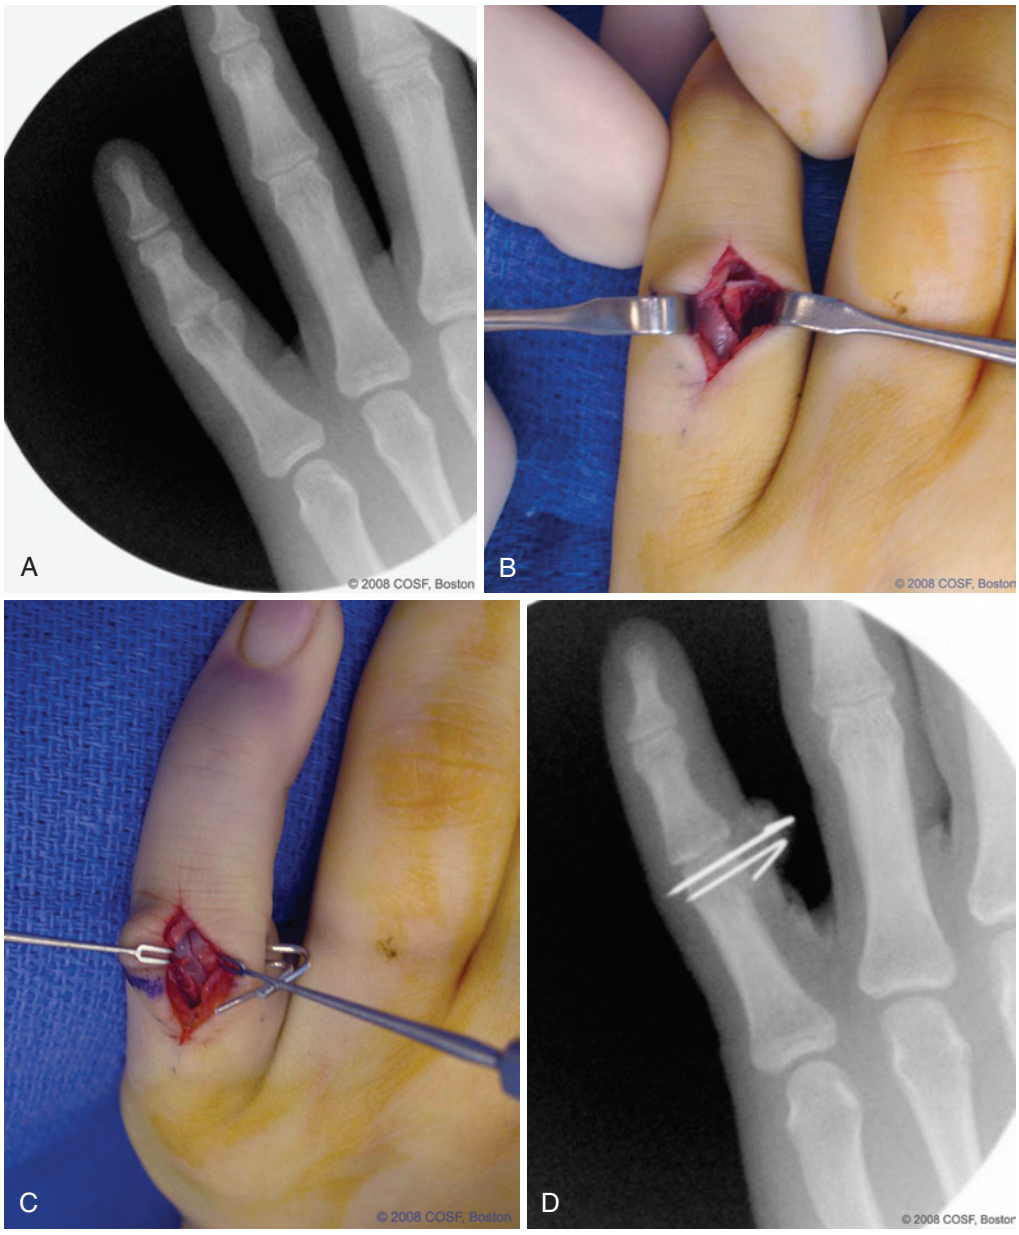

FIGURE 41.9 **A,** Anteroposterior radiograph of the small finger showing a displaced unicondylar fracture in a 14-year-old girl. **B,** Intraoperative photograph depicting the dorsal curvilinear incision, retraction of the extensor apparatus, and exposure of the fracture. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

closed reduction and percutaneous pin fixation is recommended (Figure 41.10). In Al-Qattan's series of 66 patients with 67 phalangeal neck fractures, 13 fractures were nondisplaced and went on to good to excellent results with nonoperative care.[6] Type II fractures accounted for the majority of injuries, and results were highly dependent on treatment. Patients treated with closed or open reduction and Kirschner wire fixation went on to successful bony healing and good to excellent results. Type II injuries treated with closed reduction without surgical stabilization achieved fair to poor results in 66% of cases. Among the seven type III injuries, failure to perform surgical reduction and Kirschner wire fixation uniformly led to fracture nonunion and poor results. Matzon and Cornwall have proposed a treatment algorithm for the care of acute type II phalangeal neck fractures, beginning with minimally invasive interventions and advancing to more involved techniques as needed.[119] In their series of 61 consecutive children, 49 patients were successfully treated with closed manipulation and percutaneous pin fixation, and 12 underwent percutaneous pin-assisted reduction; no children with acute injuries required open reduction. Overall, the vast majority of patients achieved good to excellent results with low complication rates.

Given the fact that these injuries occur in the phalangeal neck and that the physis is located at the proximal phalangeal metaphysis, remodeling potential is limited. There have been only a handful of reported cases of complete skeletal remodeling of phalangeal neck malunions.[40,79,130,149,179] Puckett and associates have previously published a retrospective case series of

FIGURE 41.10 Anteroposterior (AP) **(A)** and lateral **(B)** radiographs of a displaced proximal phalangeal neck fracture of the small finger in a 9-year-old boy. The radiographic findings are subtle on the AP projection, but dorsal displacement is clearly seen on the lateral. **C** and **D,** Postoperative radiographs following closed reduction and percutaneous pin fixation. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

eight children with displaced phalangeal neck fracture malunions followed for a mean of 5 years after injury.[153] In this small series of selected, nonconsecutive patients, sagittal plane angulation improved from 31 to 0 degrees, whereas coronal plane alignment changed from 11 to 4 degrees. Although no patients reported functionally limiting loss of motion, two complained of a persistent aesthetic difference in the coronal plane. Although the authors still support surgical reduction and stabilization for acute displaced phalangeal neck fractures, they believe that children may have some remodeling potential of these injuries.

Review of these case reports leads to a number of observations. First, phalangeal neck remodeling may be expected only in very young patients with a considerable amount of growth remaining. Second, sagittal plane deformity has the greatest remodeling potential; coronal plane angulation or bony malrotation will not improve to the same extent. In addition, although radiographic remodeling may be seen and interphalangeal joint motion improved, in some cases interphalangeal joint flexion is only restored to 80 or 90 degrees. Finally, many reported cases involved the middle phalanx, in which more deformity is tolerated due to the relatively smaller amount of DIP joint flexion needed for composite digital flexion and fist formation. Based on these published reports, observation of displaced phalangeal neck fractures should be considered only if there is no rotational or radioulnar deformity, the adjacent interphalangeal joint is congruently reduced, substantial skeletal growth remains, the resultant loss of interphalangeal joint flexion is tolerable without undue functional compromise, and the patient or family is willing to wait months to years for gradual remodeling.[40,153]

In cases of displaced phalangeal neck fractures with incipient malunion that present late, percutaneous pin osteoclasis has been advocated as a way to restore bony alignment, improve interphalangeal joint flexion potential, and minimize the risk of osteonecrosis.[205] The most appropriate patients for percutaneous pin osteoclasis are those with persistent tenderness at the fracture site, a fracture line that is still radiographically apparent, and corresponding interphalangeal joint flexion of less than 90 degrees.

In cases of phalangeal neck malunions, there is a great temptation to perform a corrective osteotomy procedure to restore bony alignment and interphalangeal joint motion. Formal open corrective osteotomy carries the risk of osteonecrosis of the phalangeal head in young patients and is not recommended. In cases of long-standing phalangeal neck fracture malunions, subcondylar fossa reconstruction may be considered.[170,179] Indications include persistent bony malalignment associated with restricted interphalangeal joint motion and functional compromise.[79]

Phalangeal neck fracture nonunions are rare.[4,5,7] Patients will present with complaints of instability, deformity, or stiffness. In the absence of osteonecrosis of the small articular fragment, bone grafting and longitudinal Kirschner wire fixation will allow for healing, though often some residual stiffness remains.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Nondisplaced phalangeal neck fractures can be treated with cast immobilization, but weekly radiographs are required to rule out delayed displacement. In type II or III injuries, closed reduction and percutaneous pinning via cross pins are performed. Patients are casted for 3 to 4 weeks, after which pins are removed and motion is initiated. In the rare situation in which an adequate reduction cannot be obtained with closed techniques, open reduction can be performed via a mid-axial approach, with care taken to preserve the collateral ligament and soft tissue attachments to the articular segment.[6] In fractures with nascent malunion that present late, percutaneous pin osteoclasis is considered if the fracture is still radiographically visible and tenderness to palpation is felt at the fracture site (Figure 41.11).[203] In cases presenting late in which active or passive interphalangeal joint flexion to 90 degrees or more is documented on examination and fluoroscopy, observation is recommended. In established malunions with functionally limiting restrictions in interphalangeal joint flexion, subcondylar fossa reconstruction via a volar or midlateral approach is performed. Rongeurs or burs can be used to remove the bone obliterating the subcondylar fossa. Care must be taken to avoid overzealous resection because the dorsal bony bridge can become quite narrow in cases with considerable dorsal displacement of the articular fragment. Intraoperatively, adequate bony resection is confirmed by passive interphalangeal joint flexion to 90 degrees or more. Early active and passive motion is initiated to maximize the outcome.

Phalangeal Shaft Fractures. Diaphyseal fractures of the phalanges represent approximately two-thirds of phalangeal injuries.[59,77] The most common mechanism is combined bending and torsional forces sustained during falls or sporting activities. Proximal phalangeal shaft fractures usually exhibit apex volar angulation owing to the combined forces of the extensor mechanism on the distal fragment and intrinsic musculature on the proximal fragment. Conversely, fractures of the middle phalanx exhibit either apex palmar or dorsal angulation, depending on the location of the fracture in relationship to the flexor digitorum superficialis insertion. Fractures distal to the flexor digitorum superficialis insertion typically angulate in an apex volar manner, with the extensor mechanism pulling the distal fragment dorsally. Although up to 10 degrees of angulation is acceptable, closed reduction is recommended for greater amounts of angulation or any malrotation resulting in digital overlap or underlap (see Figure 41.2). Al-Qattan and coworkers previously reported on 92 children studied prospectively with proximal phalangeal base fractures.[8] The authors noted excellent outcomes in patients treated with closed reduction with or without percutaneous pinning for cases with greater than 10 degrees of angulation, whereas remodeling was seen in patients with less than 10 degrees of radiographic angulation.

Following closed reduction and cast immobilization, serial clinical and radiographic evaluations are necessary to ensure maintenance of adequate alignment. In patients with irreducible or unstable fractures, surgical treatment via closed or open reduction and smooth pin fixation are recommended. In cases of long oblique fractures, two or more smooth Kirschner wires placed orthogonally to the fracture plane provide both axial and rotational stability. In transverse fractures, oblique cross-pinning may be used, although care should be taken to avoid crossing pins at the fracture site because this results in suboptimal fixation. The end of the pins are bent and trimmed external to the skin and removed after 4 weeks, followed by motion exercises. Boyer and colleagues previously reported a series of 105 patients

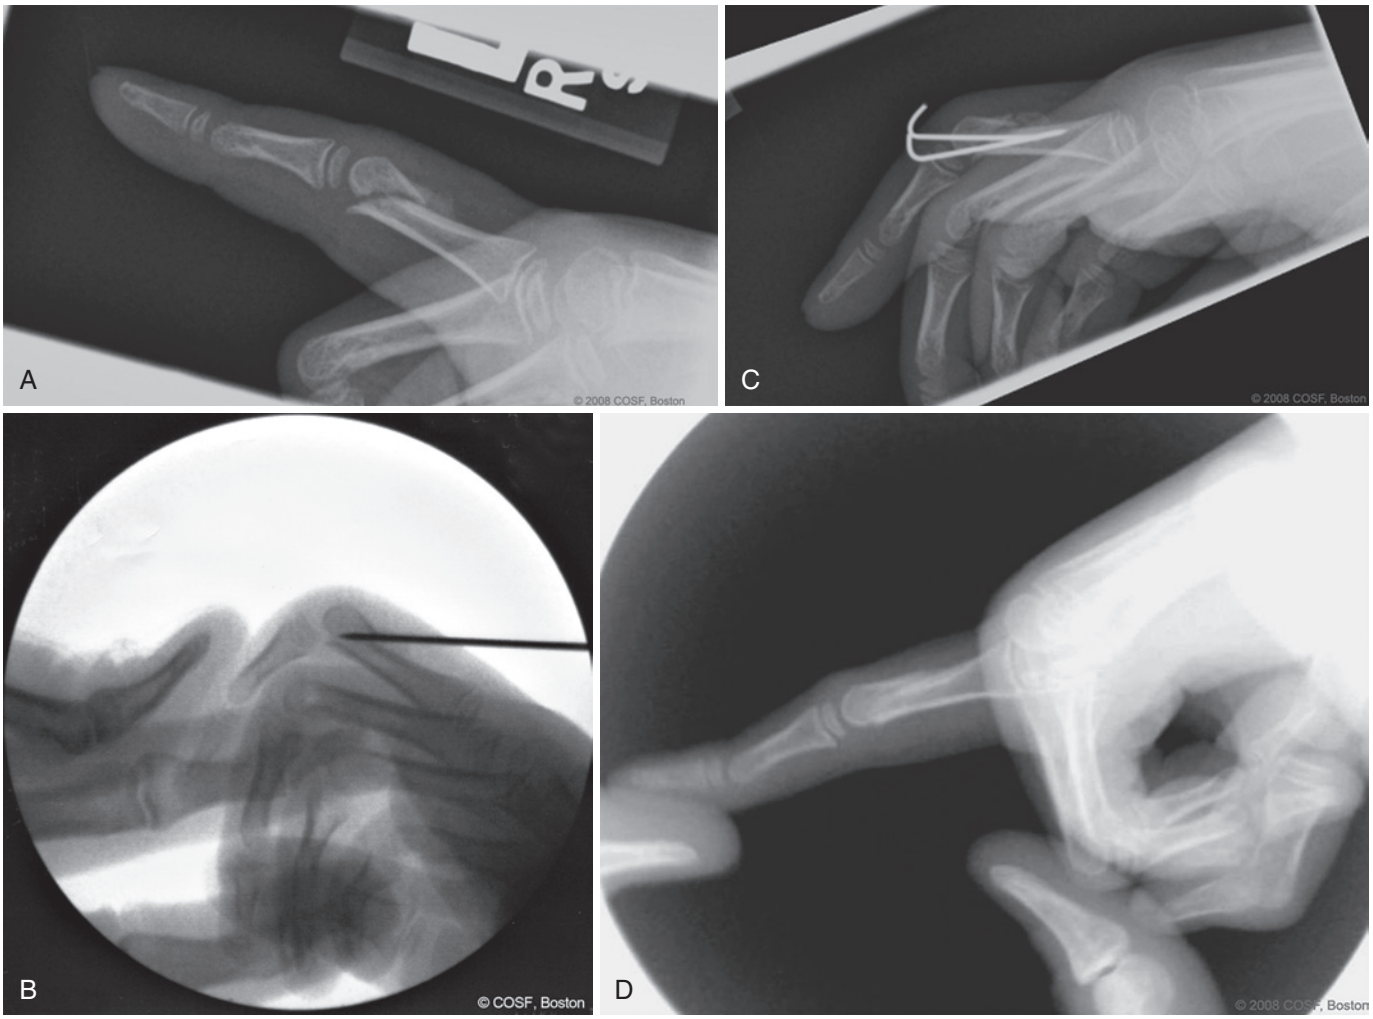

FIGURE 41.11 **A,** Lateral radiograph showing an incipient proximal phalangeal neck malunion, presenting 4 weeks after injury in a 6-year-old patient. Note the formation of fracture callus dorsally, although the fracture line can still be seen. **B,** Intraoperative radiograph depicting percutaneous placement of a smooth pin for osteoclasis and reduction. **C,** Postoperative radiograph following reduction and pin fixation. **D,** Follow-up lateral radiograph demonstrating improved bony alignment, with no evidence of osteonecrosis of the phalangeal head. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

treated with percutaneous pinning for displaced proximal phalanx fractures.[27] In this retrospective cohort, 36 had postoperative stiffness and 31 ultimately underwent therapy to restore motion. Despite this high proportion of patients with stiffness in the initial postoperative period, patients with follow-up for longer than 12 months regained full motion and excellent function.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Closed reduction and cast immobilization are recommended for phalangeal shaft fractures with malrotation or angulation of greater than 10 degrees. Serial radiographs are necessary to confirm maintenance of reduction. Immobilization is discontinued after 3 to 4 weeks, with a gradual return to activity. In cases of fracture instability or inadequate alignment, closed reduction and percutaneous pin fixation are performed (Figure 41.12). Pins are removed at 3 to 4 weeks, followed by range-of-motion exercises. Irreducible fractures require open reduction and pin fixation.

Physeal Fractures. Physeal fractures of the phalanges are common injuries, secondary to combined bending and rotational moments sustained during falls and sporting activities. Patients and families may express anxiety upon learning of the occurrence of a growth plate fracture; however, multiple studies have demonstrated that one-third of all bony injuries of the growing hand involve the physis, and physeal arrest is uncommon.[59,77,145] The proximal phalanx of the small finger is most commonly affected, resulting in the so-called extraoctave fracture (Figure 41.13).[156] The thumb is injured in roughly one-fifth of cases.[145] Physeal fractures of the middle phalanx are considerably less common than those involving the proximal phalanx. Salter-Harris type II patterns predominate owing to the anatomic features of the collateral ligaments described previously.

Closed reduction is recommended for fractures with greater than 10 degrees of angulation and any malrotation, owing to the limited remodeling potential of radioulnar or rotational deformity. During closed reduction maneuvers, flexion of the MP joint assists in stabilizing the proximal fracture fragment by tensioning of the collateral ligaments, and a pen or pencil can be placed in the adjacent web space at the apex of the deformity to serve as a fulcrum during angular correction. Following

closed reduction, both careful assessment of rotational alignment and radiographic confirmation of desired correction are essential for a successful outcome.[77] Cast immobilization in the intrinsic-plus position is required for 3 to 4 weeks, followed by a gradual return to activity. Although splint immobilization and earlier motion have been advocated by some, the risks of noncompliance with removable splint immobilization and the late loss of fracture reduction generally outweigh the benefits of early motion, particularly in young patients in whom posttraumatic stiffness is less common.

FIGURE 41.12 Anteroposterior radiograph of a displaced phalangeal diaphyseal fracture following closed reduction and percutaneous pin fixation. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

In rare cases, these fractures may be unstable. Such fractures tend to be high-energy injuries that disrupt the stabilizing soft tissue envelope. In these cases, closed reduction followed by pin fixation is performed, and the pins are left percutaneous to facilitate removal after 3 to 4 weeks. Smaller wires (ranging from 0.028 to 0.035 inch) and fewer wires are used than in adults.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Closed reduction and cast immobilization are recommended for patients with greater than 10 degrees of angulation or malrotation. Stable fracture reduction is achieved in the majority of cases. Cast immobilization is discontinued after 4 weeks, followed by range-of-motion exercises. Percutaneous pinning is reserved for unstable or irreducible injuries with malrotation or greater than 10 to 15 degrees of angulation. Cast immobilization is discontinued and pins are removed at 3 to 4 weeks, followed by range-of-motion exercises.

Articular Fractures of the Phalangeal Base and Epiphyseal Fractures. Fractures of the phalangeal base with intraarticular extension represent Salter-Harris type III and IV injuries. In cases of articular incongruity, joint instability, or greater than 1 to 2 mm of displacement, closed or open reduction and smooth pin fixation are recommended to restore articular congruity, physeal integrity, and bony alignment. These injuries should be distinguished from volar plate avulsion fractures of the epiphysis. As in adults, small volar plate avulsions can be safely and effectively treated with simple Coban wrapping and "buddy

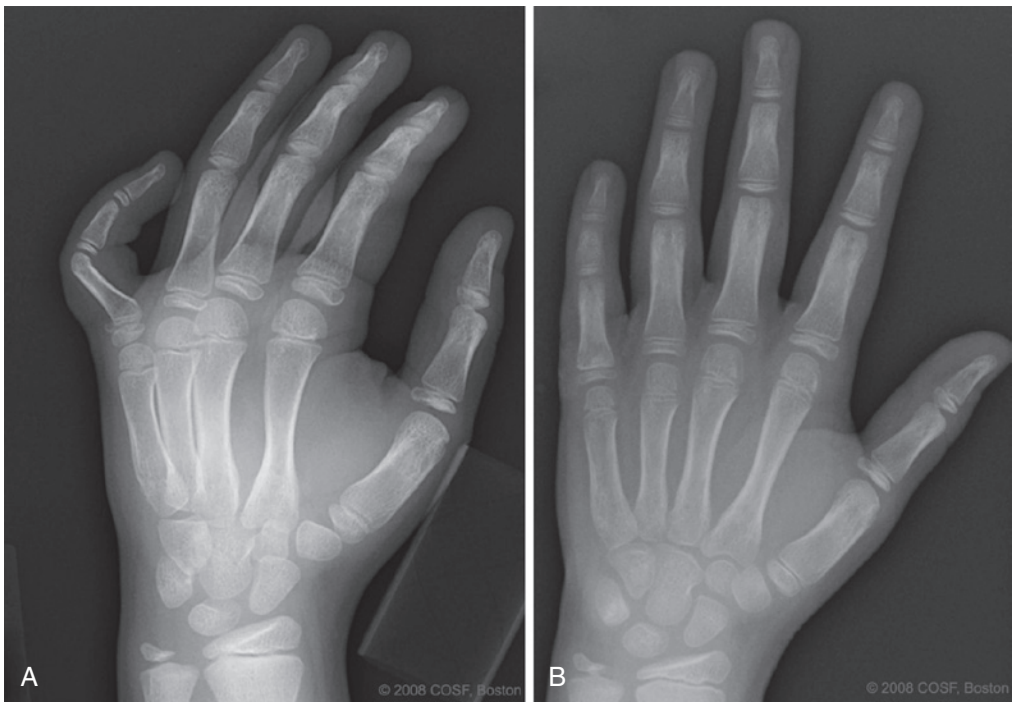

FIGURE 41.13 **A,** Anteroposterior radiograph of an "extraoctave" fracture in a 9-year-old girl. **B,** Radiograph after closed reduction and cast immobilization. Clinical alignment and rotation were restored to normal, with an excellent final outcome. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

taping" with early initiation of motion to avoid stiffness, provided the interphalangeal joint is stable and congruently reduced. In a prior study of 121 proximal interphalangeal joint hyperextension injuries randomized to either buddy taping or aluminum splinting, buddy taping was just as effective as splinting; in general, children had better outcomes than adults.[142]

Comminuted, unstable proximal interphalangeal fracture-dislocations are rare in children. When they do occur, treatment principles are similar to those in adults. Open reduction and internal fixation are recommended to restore joint stability and reconstitute the articular surface. The volar base of the middle phalanx is approached via a volar zigzag incision. The A3-C1 pulleys are elevated in either a radial or an ulnar direction, and flexor tendons are retracted to allow visualization of the joint surface and displaced fracture fragments. Anatomic reduction and restoration of joint congruity are performed, followed by stabilization with size-appropriate smooth pins or screws. Bone grafting may be required to fill any impacted metaphyseal defect. Although early motion is desired, 3 weeks of cast or splint immobilization is often necessary owing to the tenuous fixation achieved and compliance issues in young patients.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Closed or open reduction and internal fixation of displaced Salter-Harris III or IV fractures are performed for cases of articular incongruity, joint instability, or diastasis of greater than 2 mm. Whereas radial and ulnar base fractures may be approached via a dorsal curvilinear incision, proximal interphalangeal fracture-dislocations with volar phalangeal base fractures require a more extensive volar approach to access fracture fragments and restore joint stability. Smooth pin fixation is used, supplemented by cast immobilization. Pins are removed in 4 weeks, followed by range-of-motion exercises.

CRITICAL POINTS *Middle and Proximal Phalangeal Fractures*

- Surgical treatment is recommended for all displaced articular fractures, with care taken to preserve soft tissue attachments and vascularity to the displaced fracture fragment.
- Displaced phalangeal neck fractures are treated with closed reduction and percutaneous pin fixation to avoid posttraumatic interphalangeal joint stiffness.
- Percutaneous pin-assisted osteoclasis is effective in phalangeal neck fractures with persistent tenderness and radiographically visible fracture lines that present late; subcondylar fossa reconstruction may be considered in established malunions with functionally limiting loss of motion.
- Surgical reduction and fixation are recommended for displaced Salter-Harris III and IV fractures to restore articular congruity and joint stability.

Metacarpal Fractures

Treatment principles for metacarpal fractures in children are similar to those in adults. Metacarpal fractures arise from bending forces or axial loads sustained during falls, sporting injuries, or direct blows with a clenched fist. These fractures result in apex dorsal angulation secondary to the intrinsic musculature. Mild to moderate apex dorsal angulation results in little to no compromise of hand function; excessive angulation results in both aesthetic consequences and difficulties with digital extension (i.e., pseudo–claw deformity) or discomfort with forceful grasp. Closed reduction and pin fixation or open reduction of multiple metacarpal fractures results in union and return of function. Open reduction and internal fixation of intraarticular metacarpal head fractures can achieve articular restoration, but stiffness is common.

There is great variation in what is deemed "acceptable" angulation in metacarpal neck and shaft fractures, and each patient merits individualized decision making. Most authorities agree that up to 30 degrees of sagittal plane deformity is acceptable in physeal fractures, particularly in young patients with growth remaining and remodeling potential. Twenty to 45 degrees of apex dorsal angulation is acceptable in metacarpal neck fractures, with greater deformity allowable in the more ulnar digits. Shaft fractures tolerate less angular deformity, so 10 to 15 degrees of angulation is acceptable in the index and long fingers and 30 to 40 degrees in the ring and small fingers. Even mild rotational deformity (>10 degrees) results in digital overlap and functional problems. Malrotation is often undetectable on radiographic evaluation, and the importance of a thorough physical examination cannot be overstated.

In general, metacarpal fractures can be considered according to their anatomic location: epiphyseal, diaphyseal, neck, physeal, and articular fractures.

Epiphyseal Fractures. Fractures of the metacarpal epiphysis are rare and are usually Salter-Harris III or IV fractures.[59,152] These injuries result from axial loads during falls or closed fist injuries. Although nondisplaced injuries may heal satisfactorily with cast immobilization, open reduction and internal fixation are recommended for displaced fractures resulting in articular incongruity.[152] Internal fixation using countersunk interfragmentary screws can be used in older adolescents, as in adults; smooth Kirschner wire fixation is typically used in younger children. This method of fixation provides adequate fracture stability and minimizes the risk of iatrogenic physeal injury. In rare situations, extensive comminution of primarily cartilaginous fragments occurs, and bioabsorbable pin or suture fixation is used. Osteonecrosis has been reported following these severe injuries, and soft tissue attachments to displaced fracture fragments must be preserved during open reduction.[120] Torre has proposed that increased intracapsular pressure secondary to fracture hematoma may play a causative role, but there is little evidence to support this assertion.[184]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Open reduction is performed via a curvilinear dorsal incision. The interval between the extensor tendon and ulnar sagittal band is developed, leaving a cuff of tissue for later sagittal band repair. After dorsal capsulotomy, the fracture hematoma is evacuated, and reduction is performed. Any soft tissue attachments are preserved to maintain vascularity to the displaced fracture fragments. Internal fixation can be performed with smooth pins, screws, or even sutures, depending on the size and integrity of the articular fragments. After adequate stabilization is achieved, the dorsal capsule, sagittal band, and skin are closed. Cast immobilization is instituted for 4 weeks, followed by range-of-motion exercises.

Metacarpal Neck Fractures. Metacarpal neck fractures account for 56 to 70% of all metacarpal fractures in the pediatric and adolescent population.[154] These fractures often result from

closed fist injuries but may also occur after falls and sporting injuries, particularly if the affected hand is stepped on. The small finger is most commonly affected, and the characteristic deformity is apex dorsal angulation with varying degrees of rotation. These fractures usually occur through the distal metaphysis, although physeal involvement is fairly common.[59,77]

Relatively large degrees of apex dorsal angulation are acceptable in ring and small finger metacarpal neck fractures, resulting in minimal impairment owing to the compensatory MP and carpometacarpal (CMC) joint motion. In young children, because the metacarpal physis is distal, remodeling of angular deformity may occur with growth. In general, angulation that is 10 to 30 degrees more than the corresponding range of CMC motion is well tolerated in skeletally immature patients.[99]

Nondisplaced or minimally displaced fractures are effectively treated with cast immobilization for 3 to 4 weeks. Displaced injuries with malrotation or excessive angulation are treated with closed reduction and cast immobilization. Reduction maneuvers are performed under digital or wrist block using local anesthesia or conscious sedation in young patients. Reduction consists of longitudinal traction and correction of the apex dorsal angulation using three-point bending. The *Jahss maneuver* (i.e., flexing the MP joint to 90 degrees and applying a dorsally directed force on the metacarpal head through the flexed digit) is commonly used.[86] The Jahss maneuver also facilitates the correction of rotational malalignment because the MP collateral ligaments are taut in flexion, and torque applied to the flexed digit is imparted to the malrotated distal fracture fragment. Adequate rotational correction is confirmed by restoration of the normal digital cascade.

Traditionally, a cast was used to immobilize the hand in the intrinsic-plus position to avoid extension contractures of the MP joint. Extension of the MP joint often results in loss of reduction, particularly in more displaced injuries. Studies have established, however, that cast immobilization for 4 weeks with the MP joints in extension (the so-called pancake cast) is safe and is not associated with long-term stiffness or MP extension contractures in young adults or children.[181] Indeed, cast application with a three-point bending mold to maintain the desired fracture alignment is easier with the MP joints in extension.

In displaced fractures in which alignment cannot be maintained with closed reduction and cast immobilization, percutaneous pin fixation via either cross-pinning or transmetacarpal pinning techniques is performed. Intramedullary fixation, or "bouquet pinning," has been successful in adults, but these techniques are not commonly used in children owing to the small size of the metacarpal intramedullary canals and the presence of the intervening physis.[61] The Jahss maneuver is particularly helpful for closed reduction and pinning because it allows correction of both the apex dorsal angulation and the rotational alignment and permits pin placement within the collateral recesses without violating the collateral ligament complex. Care to minimize iatrogenic trauma to the metacarpal physis during surgical stabilization is necessary.

Metacarpal neck fractures that present late are common in the pediatric population. Because there is a large amount of compensable angular deformity via MP and CMC motion, usually no intervention is required. Excessive angulation or malrotation, particularly in the index and long finger rays, requires percutaneous pin osteoclasis or formal open reduction and internal fixation. In subacute situations (i.e., <4 weeks from injury, fracture line still visible on radiographs, tenderness still elicited at the fracture site), percutaneous pin osteoclasis can liberate the displaced fracture fragment and allow closed reduction and pin fixation. When percutaneous pin osteoclasis is not possible, open reduction or late corrective osteotomy is considered. As with other displaced physeal fractures with remodeling potential that present late, repeated forceful manipulations are avoided to prevent iatrogenic physeal arrest.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Closed reduction and cast immobilization are used for displaced injuries with excessive angulation or malrotation. In general, 10, 20, 30, and 40 degrees of angulation are acceptable in index, long, ring, and small finger metacarpals, respectively. Casting with the MP joints extended for 3 to 4 weeks is well tolerated and can be used without reservation, given the greater ability to maintain reduction and the infrequency with which long-standing stiffness occurs in young children. In unstable fractures that fail reduction and casting, closed reduction and percutaneous cross-pinning are used. Pins are removed in 3 to 4 weeks, and range-of-motion exercises are then begun.

Metacarpal Shaft Fractures. Metacarpal shaft fractures usually result from torsional or bending mechanisms, yielding spiral or transverse fracture patterns. As in adults, isolated diaphyseal fractures, particularly of the central rays, do not displace considerably owing to the stabilizing forces of the intermetacarpal ligaments and central CMC articulations. Conversely, fractures of the border rays or multiple metacarpal fractures are inherently more unstable and display greater displacement and angulation. Nondisplaced fractures are treated with 3 to 4 weeks of cast immobilization, followed by range-of-motion exercises. Displaced injuries are treated with closed reduction and well-molded cast immobilization in the majority of cases. Serial radiographs during the period of cast immobilization are required to ensure maintenance of reduction as the soft tissue swelling subsides. Four weeks of cast immobilization is sufficient, followed by range-of-motion exercises.

Surgical indications in children are similar to those in adults and include open fractures, multiple fractures, irreducible fractures, and unstable fractures. Additional indications include fractures with extensive soft tissue injury or neurovascular injury that precludes cast immobilization. A host of surgical stabilization options is available for the treatment of metacarpal shaft fractures, including percutaneous pinning, transmetacarpal pinning, interfragmentary screw fixation, plate and screw fixation, intramedullary fixation, and external fixation.[107] Choice of the surgical stabilization technique depends on the fracture pattern and associated soft tissue injury, as well as surgeon preference. In general, the least invasive technique that achieves the desired goals is the best choice. Surgical techniques are similar to those in adults (see Chapter 16), although the presence of the metacarpal physis must be considered during the decision-making process.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Isolated metacarpal shaft fractures are usually stable and are treated with cast immobilization. In cases of unstable fractures or persistent malrotation, closed reduction and percutaneous

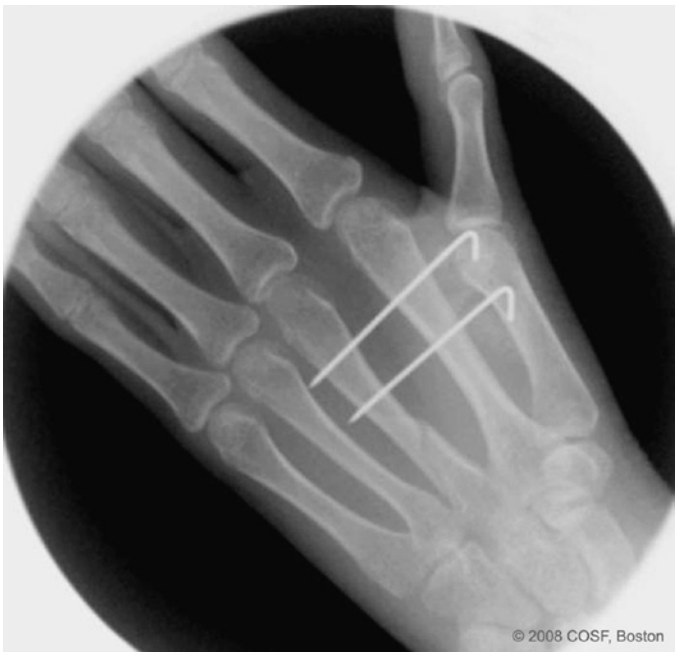

FIGURE 41.14 Postoperative radiograph depicting transmetacarpal pinning of a rotated diaphyseal fracture of the long finger. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

pin fixation via transmetacarpal or cross-pinning techniques are performed (Figure 41.14). Pins are removed at 4 weeks, followed by range-of-motion exercises. In cases of multiple metacarpal fractures, open reduction and internal fixation with interfragmentary compression screws (long oblique fractures) or size-appropriate compression plates (transverse, short oblique, comminuted fractures) are performed via a dorsal approach.

Metacarpal Base Fractures. Metacarpal base fractures account for approximately 13 to 20% of metacarpal fractures in children.[154] The vast majority involve the small finger ray. Rarely, intraarticular extension is possible, with subsequent CMC subluxation or dislocation of the metacarpal shaft (the reverse Bennett fracture equivalent). Clinical evaluation includes a careful assessment of digital rotation, flexion, and extension, as well as the associated soft tissue and neurovascular status. In crush injuries or high-energy trauma, compartment syndrome can occur, and emergent decompression is required. Radiographic evaluation includes AP and lateral radiographs of the affected hand, as well as oblique views to better visualize the border metacarpals.

Nondisplaced or minimally displaced injuries are treated with 3 to 4 weeks of cast immobilization. In displaced injuries, closed reduction is performed under local anesthesia or conscious sedation, with longitudinal traction and volarly directed pressure over the typically dorsal apex of the deformity. Malrotation can be corrected simultaneously by flexing the MP joint of the affected ray and restoring rotational alignment. After cast immobilization, radiographs are necessary to confirm reduction; treatment can then continue as described earlier. In unstable reductions or CMC fracture-dislocations, surgical stabilization is required. If reduction is achieved with closed manipulation, percutaneous pin fixation using transmetacarpal pinning techniques or oblique pins into the proximal fracture fragment or carpus usually suffice. When the fracture is irreducible, formal open reduction is performed via a longitudinal incision, followed by pin fixation. Pins are removed at 4 weeks, and range-of-motion exercises are initiated.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Closed manipulation and casting are mainstays in the treatment of most metacarpal base fractures. Surgical stabilization via percutaneous pinning is used for malrotated, widely displaced, or multiple adjacent metacarpal base fractures. Transmetacarpal pinning or transarticular pinning into the adjacent carpus can be used with little morbidity or concern for long-term arthrosis.

CRITICAL POINTS *Metacarpal Fractures*

- Open reduction and internal fixation are recommended for displaced intraarticular metacarpal head fractures.
- Closed reduction and pin fixation are recommended for unstable or rotationally malaligned metacarpal neck and shaft fractures.
- Given the remodeling potential and compensatory CMC joint motion, as much as 30 degrees of angulation may be acceptable in extraarticular metacarpal fractures.

Thumb Fractures

Phalangeal Fractures. Salter-Harris type III fractures of the thumb proximal phalanx are common injuries in children and represent the pediatric equivalent of "gamekeeper's thumb" in adults. The anatomy of the thumb MP collateral ligament complex explains the pattern of injury encountered. The collateral ligaments insert almost exclusively onto the proximal phalanx epiphysis, and a valgus force results in an avulsion fracture of the ulnar epiphysis rather than a pure ligamentous disruption. In cases of displaced Salter-Harris III fractures of the proximal phalanx of the thumb, surgical treatment is recommended to restore articular congruity and ligamentous MP joint stability.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Surgery is performed under general anesthesia and tourniquet control (Figure 41.15). A dorsal curvilinear incision is made over the thumb MP joint. Subcutaneous dissection is performed in line with the skin incision, identifying and protecting terminal branches of the radial sensory nerve. The adductor aponeurosis is incised along its insertion on the extensor tendon. Because the ulnar collateral ligament is usually intact, the MP joint is exposed through the fracture site, and the collateral ligament is protected. If better visualization of the articular surface is necessary, the dorsal capsule is incised. The fracture is reduced under direct visualization, restoring congruity of the articular surface. Two parallel Kirschner wires are placed into the reduced epiphyseal fragment, across the fracture site, and into the opposite radial cortex. In very young children or in cases of small, predominantly cartilaginous fracture fragments, fixation with only one wire may be feasible. Intraoperative fluoroscopy is used to confirm anatomic reduction and appropriate placement of the wires. Additional sutures can be placed between the ulnar collateral ligament and the underlying periosteum. Wires are bent and cut outside of the skin. Closure is performed in layers,

(Courtesy of the Children's Orthopaedic Surgery Foundation.)

with careful reapproximation of the adductor aponeurosis. A thumb spica cast is applied for 4 to 6 weeks, followed by range-of-motion exercises. Formal physical and occupational therapy is usually not required.

Metacarpal Diaphyseal Fractures. Metacarpal diaphyseal fractures of the thumb are treated according to principles similar to those used for fractures of the index through small finger rays.

Base of Thumb Metacarpal Fractures. Base of thumb metacarpal fractures are quite common, typically resulting from falls or sporting injuries. The fracture may be metaphyseal, physeal, epiphyseal, or intraarticular; recent investigations suggest that physeal fractures are most common.[10] Owing to the proximity to the proximal thumb metacarpal physis, these injuries demonstrate tremendous remodeling potential in young children. Impairment of hand function following displaced base of thumb metacarpal injuries is further mitigated by the nearly universal motion of the CMC joint. As a result, as much as 30 degrees of angular deformity is well tolerated, with minimal aesthetic or functional compromise[99] (Figure 41.16). In these situations, thumb spica cast immobilization for 3 to 4 weeks may suffice.

Kozin and Waters have classified base of thumb metacarpal fractures into four types.[98,99] Type A fractures are those in which the fracture line passes between the physis and the junction of the proximal and middle diaphysis. These fractures are transverse or oblique and often amenable to closed reduction and cast immobilization, with excellent functional outcomes.

Type B fractures are Salter-Harris II fractures with an ulnar Thurston-Holland metaphyseal fragment and apex radial angulation. The metacarpal diaphysis is adducted by the pull of the adductor pollicis and displaced proximally by the abductor pollicis longus, thereby effectively narrowing the first web space. Excessive displacement or angulation requires closed reduction

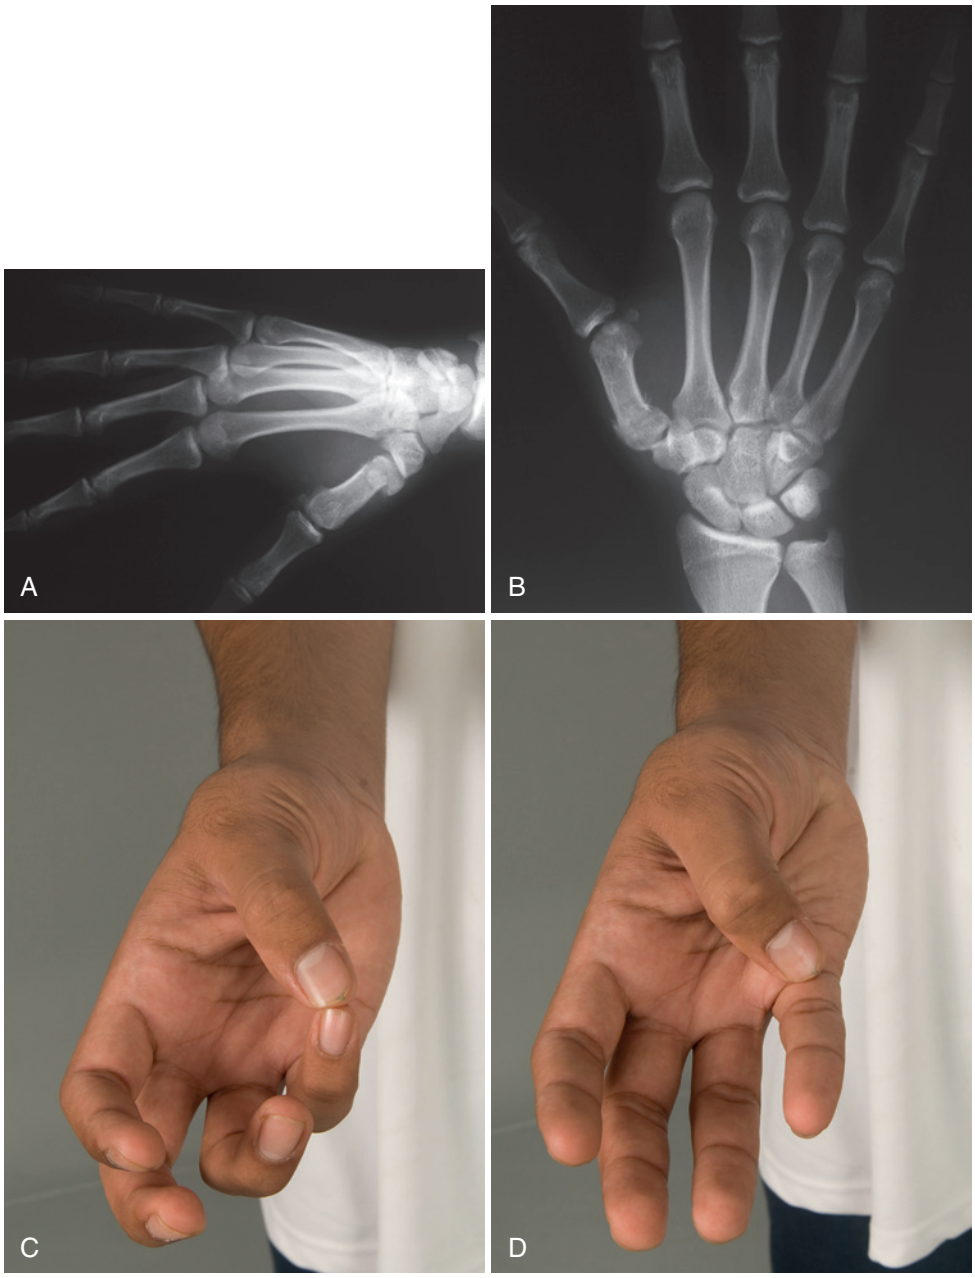

FIGURE 41.16 A 14-year-old boy presents 3 weeks after injury with mild pain and deformity of the base of the right thumb. **A,** Anteroposterior radiograph shows moderately displaced fracture of base of the thumb metacarpal. **B,** Lateral radiograph shows mild angulation. **C,** After splint immobilization of the fracture for an additional 2 weeks, home therapy was instituted. Follow-up thumb motion demonstrates excellent opposition. **D,** Thumb can touch base of small finger. (Courtesy of Shriners Hospital for Children, Philadelphia.)

and cast immobilization to restore bony and physeal alignment. If the reduction is unstable, percutaneous pin fixation into the intact epiphysis or adjacent trapezium is performed.[71] Rarely, open reduction is required when severe soft tissue injury and swelling preclude the ability to manipulate and maintain reduction of the fracture fragments.

Type C fractures are Salter-Harris II injuries with a radial Thurston-Holland fragment and apex ulnar angulation. Severe displacement or angulation requires closed reduction and pinning; however, comminution or soft tissue interposition may prevent bony realignment, necessitating open reduction and pin fixation.

Type D fractures are Salter-Harris III or IV fractures with intraarticular extension. This fracture pattern is the pediatric equivalent of the adult Bennett fracture, and similar treatment principles apply. Closed or open reduction with pin fixation is recommended to restore articular congruity and maintain bony reduction. As in adults, the reduction maneuver consists of longitudinal traction, pronation, and direct pressure applied to the thumb metacarpal base to adduct the thumb ray.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Base of thumb metacarpal fractures are usually treated with closed reduction and short-arm thumb spica casting. Excellent

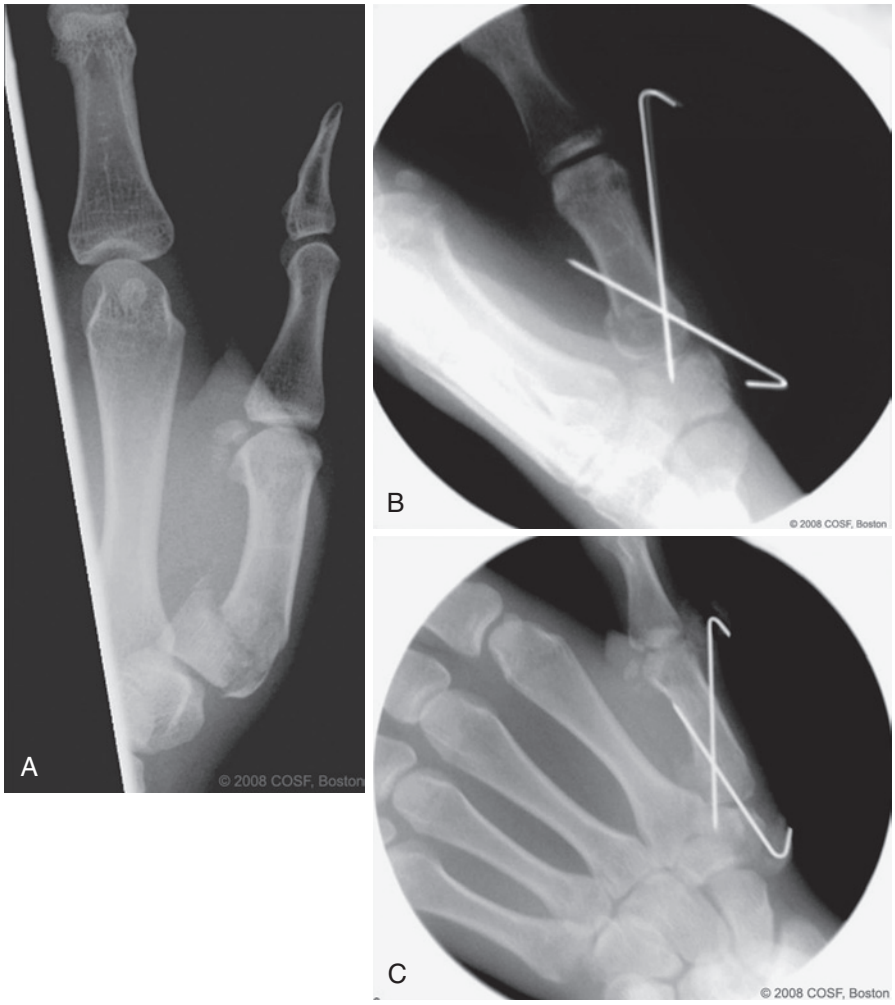

FIGURE 41.17 **A,** Lateral radiograph of a displaced base of thumb metacarpal fracture in a 16-year-old boy sustained in a high-energy motor vehicle collision. Given the fracture displacement and soft tissue swelling, closed reduction and percutaneous pinning were performed. Anteroposterior **(B)** and lateral **(C)** images following reduction and pinning. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

functional outcomes can be anticipated with up to 30 degrees of angulation in skeletally immature patients. In instances of fracture instability or excessive displacement not amenable to closed manipulation, closed or open reduction followed by percutaneous pin fixation is recommended (Figure 41.17). When needed, open reduction is performed via a radial skin incision at the junction of the glabrous and nonglabrous skin, centered at the thumb CMC joint. Subperiosteal dissection allows retraction of the thenar muscles in a volar direction, facilitating fracture exposure. Subsequently, fracture reduction is achieved, and percutaneous pin fixation is performed. An oblique crossed-pin configuration is typically used. I avoid pinning the thumb ray to the index metacarpal across the first web space unless this is necessary to achieve adequate stability.

WRIST FRACTURES

Epidemiology

Although relatively infrequent, scaphoid fractures are the most common carpal bone fractures in children as well as adults, with a peak incidence in the preadolescent and adolescent age group.[132,190,193] The lower incidence of scaphoid fractures in children may be due to the relatively thick cartilaginous cover of the developing ossification center, which protects the scaphoid.[43] Furthermore, the anatomy and ossification pattern affect which regions of the scaphoid are susceptible to injury. The scaphoid ossifies from distal to proximal; this explains the greater frequency of distal pole fractures in young children. Previous studies demonstrated that distal pole scaphoid fractures are most common in children, followed by distal third fractures and waist fractures.[2,43,190] The patterns of scaphoid fractures are changing, however, owing to the greater athletic and functional demands of children, resulting in an increasing frequency of scaphoid waist fractures.[67] In their retrospective analysis of 351 scaphoid fractures in children and adolescents treated from 1995 to 2010, Gholson and colleagues noted that 71% of fractures occurred at the scaphoid waist.[67] Distal and proximal pole fractures accounted for 23% and 6%, respectively, of that cohort. The authors concluded that with changes in activity patterns and patient characteristics, pediatric scaphoid injury patterns are now more similar to those of adults.

Unlike carpal injuries, distal radial fractures are among the most common fractures in children and adolescents, constituting approximately 20% to 35% of pediatric fractures.[16,35,102,209]

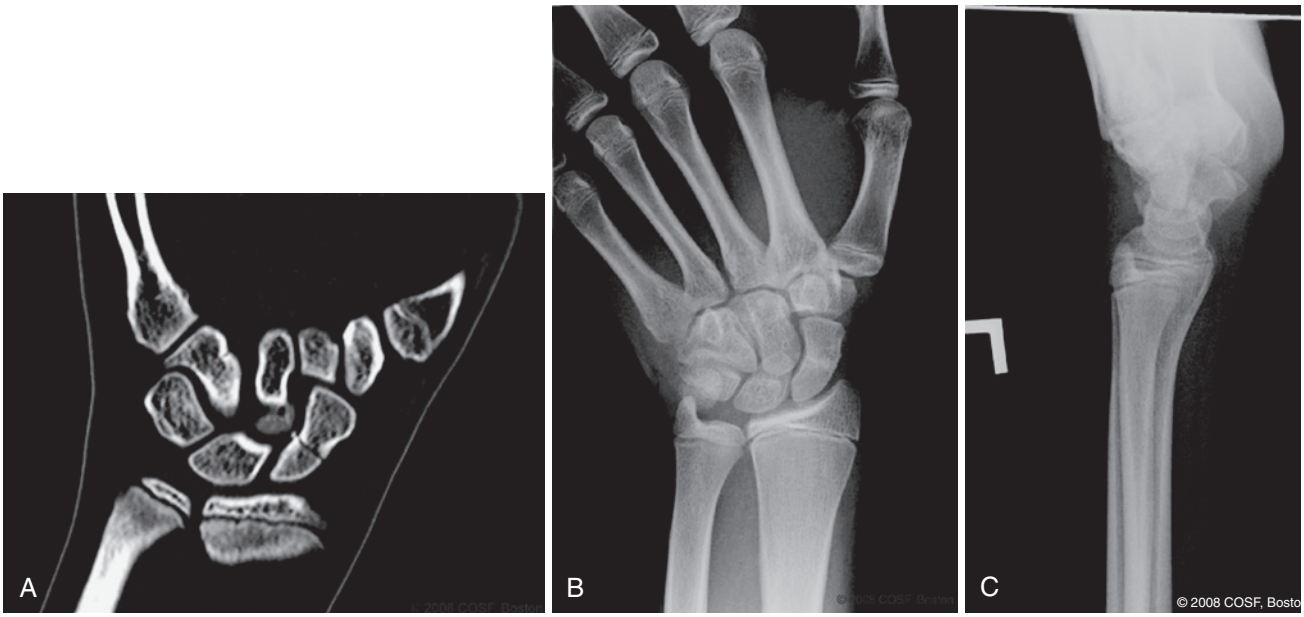

FIGURE 41.18 **A,** Computed tomographic scan of a nondisplaced scaphoid waist fracture in a 14-year-old boy that was not visualized on initial wrist radiographs. **B** and **C,** Follow-up radiographs demonstrating a healed scaphoid fracture after 8 weeks of cast immobilization. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

Similarly, distal radial physeal fractures account for approximately one-third of all physeal fractures, second in frequency only to physeal fractures of the phalanges.[145] These fractures occur most often in patients between the ages of 10 and 14 years, in part due to the increased porosity of the distal radial metaphysis during accelerated skeletal growth. In addition, recent evidence suggests that the incidence of distal radial fractures in pediatric patients may be increasing due to greater sports participation and higher rates of childhood obesity.[96,172] The vast majority of distal radial fractures occurs from a fall onto an outstretched upper limb. The wrist position (extension versus flexion) and amount of force imparted influence the ultimate fracture pattern and displacement.

Preoperative Evaluation

As in adults, fractures of the scaphoid may be subtle in clinical presentation. There may be minimal deformity or swelling, but the presence of focal, reproducible tenderness at the anatomic snuffbox or scaphoid tubercle should alert the examiner to a possible carpal fracture. Axial loading of the thumb metacarpal, loading the scaphoid during forceful pinch, and the scaphoid compression test have also been used to elicit clinical signs of a scaphoid fracture.[188]

A suspected scaphoid fracture requires dedicated radiographic evaluation in addition to standard AP and lateral wrist radiographs. An AP radiograph of the wrist with ulnar deviation and oblique views of the wrist allow better visualization of the scaphoid. A frequently encountered clinical scenario is anatomic snuffbox tenderness and negative plain radiographs, raising the question of an occult scaphoid injury. In these situations, brief immobilization in a thumb spica cast or splint is recommended, followed by repeated clinical and radiographic evaluation in 2 to 3 weeks. If persistent tenderness is noted, advanced imaging with computed tomography (CT) or magnetic resonance imaging (MRI) may confirm or exclude the diagnosis of a scaphoid fracture (Figure 41.18).[52,114,176] Immediate MRI evaluation of all children presenting with snuffbox tenderness and negative radiographs is not recommended; the majority of these injuries are not scaphoid fractures, making such imaging and its associated time and cost unnecessary.[52,87,176]

Similarly, patients with other fractures of the carpus may present with subtle complaints after relatively innocuous traumatic injuries. Careful observation and systematic clinical examination—with specific palpation of each bony structure of the carpus and wrist—should guide the subsequent diagnostic workup and treatment.

Unlike fractures of the carpus, the diagnosis of distal radial fractures is not subtle. Patients present with pain, swelling, and deformity of the affected wrist following trauma, such as a fall onto an outstretched upper limb. Clinical examination of the skin is performed to assess for open injuries. A neurovascular examination is similarly performed to assess for injury or impending compartment syndrome.[200] Compartment syndrome is particularly prevalent in "floating elbow" injuries (Figure 41.19).[159] Plain wrist radiographs usually confirm the diagnosis and guide treatment. A thorough radiographic evaluation should be performed because relatively innocuous findings, such as ulnar styloid fractures or plastic deformation resulting in proximal or distal radioulnar joint disruption, can affect treatment.[105] For example, Galeazzi fracture-dislocations are uncommon in children; instead, distal radial fractures are accompanied by distal ulnar physeal or styloid fractures. Identification of these associated injuries guides decisions regarding both nonoperative and surgical treatment strategies. In general, imaging of the entire forearm, including the elbow, is performed to evaluate for concomitant ipsilateral upper extremity fractures, which may occur in up to 13% of cases.[174]

Distal radial fractures are generally characterized according to anatomic location (metaphysis, physis, epiphysis, intraarticular) and amount of displacement, angulation, and rotation.

FIGURE 41.19 Plain radiograph depicting ipsilateral distal radial and supracondylar humeral fractures, the so-called floating elbow injury. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

Physeal fractures are typically categorized according to the Salter-Harris classification.[161] Salter-Harris type I and II patterns predominate, although Salter-Harris type III and other intraarticular fracture patterns may occur in children.[105] In general, it is important to remember that the metaphyseal Thurston-Holland fragment in type II fractures lies opposite the disruption in the periosteum; this anatomic point assists fracture reduction maneuvers and guides the surgical approach when open operative treatment is necessary.

PERTINENT ANATOMY

Ossification Centers

The radiographic appearance of the carpal centers of ossification occurs in a predictable, ordered sequence.[72,177] The capitate and hamate typically appear at 6 to 8 months of age. The triquetrum ossifies at 2 to 3 years of age, followed by the lunate at 4 years. The scaphoid becomes radiographically apparent at 4 to 5 years of age, followed by the trapezium and trapezoid at 5 years. The pisiform is the last carpal bone to ossify, typically at 6 to 8 years of age.

The scaphoid ossific nucleus appears between age 4 and 5 years.[177] The bony scaphoid forms via enchondral ossification from distal to proximal until the bone is fully ossified, typically by age 14 to 16 years. Multiple ossification centers may appear, and bipartite scaphoids have been described. As discussed earlier, the gradual distal to proximal ossification process may explain the predisposition for distal pole fractures in young children and more adult patterns of scaphoid fractures (waist and proximal pole fractures) in older children and adolescents.

The secondary center of ossification of the distal radial epiphysis becomes radiographically apparent by the first year of life, whereas the distal ulnar epiphysis appears at approximate 6 years of age.[136] The distal ulnar epiphysis often arises from two distinct centers of ossification, giving rise to a bipartite appearance that may be confused with an ulnar styloid fracture. In general, the distal ulnar physis closes at 16 years in females and 17 years in males, with the distal radial physis closing, on average, 6 months later.[72] Knowledge of this timing and the variable patterns of ossification may assist in distinguishing acute skeletal injuries from developmental norms. Although the radiographic appearance of the distal radius and ulna changes with development, similar parameters delineate "normal alignment" in both children and adults. Evaluation of radial inclination, radial length, ulnar variance, and volar tilt is appropriate in all but the youngest patients.

Growth

Because the distal physis contributes approximately 70 to 80% of the longitudinal growth of the radius and 40% of the upper extremity, distal radial fractures have tremendous inherent remodeling potential.[72] Prior investigations confirmed that up to 10 degrees of dorsal volar angulation per year may remodel with continued skeletal growth.[62,83,214,219] As with other fractures of the developing skeleton, remodeling potential is dependent on the amount of skeletal growth remaining, distance from the bony injury to the adjacent physis, magnitude of the deformity, and plane of the deformity. Fractures close to the distal radial physis with mild to moderate angulation in the sagittal plane in younger patients have the greatest remodeling potential. Therefore, in patients younger than 10 to 12 years, 20 to 30 degrees of angulation in the sagittal plane and 50 to 100% translation of the distal radial fracture fragment may remodel with continued skeletal growth.[50,83,201] Radioulnar angulation in the coronal plane is less well tolerated and has less remodeling capacity. Therefore, angulation of more than 10 degrees in the AP plane may not remodel with continued skeletal growth.

Soft Tissue Structures

A number of soft tissue structures impart stability to the wrist and must be considered in the treatment of skeletal injuries. Carpal stability is imparted by both extrinsic and intrinsic ligaments, with anatomic and pathologic considerations similar to those in adults. A discussion of carpal instability due to ligamentous injury is beyond the scope of this chapter; see Chapter 13 for further information. Owing to the relative mechanical strength of these ligaments in relationship to the adjacent bony structures, intrinsic carpal ligamentous injuries are far less common in children than in adults. Furthermore, due to the gradual ossification process of the carpus in skeletally immature patients, the "normal" radiographic parameters used to identify intrinsic ligament disruptions (e.g., scapholunate ligament tears) may not be applicable in younger children.[89]

The triangular fibrocartilage complex (TFCC) refers to a confluence of structures on the ulnar side of the wrist, including the triangular fibrocartilage, dorsal and volar radioulnar ligaments, meniscal homolog, ulnolunate and ulnotriquetral ligaments, and subsheath of the extensor carpi ulnaris tendon.[140]

Functionally, the TFCC provides a smooth articular surface in support of the ulnar carpus and stabilizes the distal radioulnar joint (DRUJ). In ulnar-neutral wrists, approximately 20% of the axial load across the wrist is borne by the ulnar carpus through the TFCC.[139] Small changes in ulnar variance, as might be seen with traumatic or posttraumatic deformity, may result in considerable alterations in loads transmitted across the TFCC and ulnar wrist.

Types of Operations for Wrist Fractures

Scaphoid Fractures

As in adults, treatment of scaphoid fractures in skeletally immature patients is dependent on the fracture location, fracture pattern, and degree of displacement.[39] Distal pole fractures have excellent healing potential owing to the vascularity of the distal pole of the scaphoid and their extraarticular locations. Thumb spica cast immobilization for 4 to 6 weeks is adequate, particularly in cases of incomplete or avulsion injuries (Figure 41.20).

Nondisplaced waist fractures can be treated with cast immobilization, with union rates greater than 90% (see Figure 41.17).[53,67] However, cast immobilization for 2 to 3 months may be required in these situations, owing to the limited and retrograde vascular supply to the scaphoid body, which is the same as in adults.

The optimal type of cast immobilization continues to be debated.[51] Incorporation of the thumb into a spica cast has been advocated by some to eliminate forces across the scaphoid, which may inhibit healing or cause displacement.[29] In addition, immobilization of the elbow eliminates forearm rotation, which has been demonstrated to induce scaphoid fracture motion.[92] Gellman and associates performed a prospective randomized study comparing long-arm versus short-arm thumb spica casting for the treatment of acute nondisplaced scaphoid waist fractures.[66] Patients treated with long-arm casts for the first 6 weeks had a faster time to healing (9.5 versus 12.7 weeks) and lower nonunion and delayed union rates than those treated with short-arm casts alone. Other recent investigations have demonstrated no significant differences in times to union between short-arm and long-arm casts.[11,29] Several biomechanical and clinical studies evaluated the effect of wrist position on scaphoid healing during casting. Arguments have been made for casting with wrist extension, wrist flexion, and radial and ulnar deviation.

FIGURE 41.20 Twelve-year-old boy fell playing ice hockey and complained of right wrist pain. Radiograph revealed a distal pole scaphoid fracture with slight comminution. It was successfully treated with 4 weeks of cast immobilization. (Courtesy of Shriners Hospital for Children, Philadelphia.)

As in adults, there is growing enthusiasm for percutaneous screw fixation for nondisplaced injuries, given contemporary expectations of a faster return to sports and activities in younger patients.[1,28,122,211] It is unclear whether these adult principles apply to the pediatric patient with scaphoid fractures, and there is some evidence that percutaneous screw fixation of nondisplaced injuries in children and adolescents does not decrease the time to union.[67] Discussion of percutaneous screw fixation is beyond the scope of this chapter; however, considerations and surgical techniques are similar to those in adults (see Chapter 18).

In cases of displaced waist fractures or fractures of the proximal pole, surgical treatment with open reduction and internal stabilization is recommended, as in adults. Because these injuries tend to occur in older children and adolescents, the treatment principles and surgical techniques are similar to those in adults. Internal stabilization with smooth Kirschner wires, headed compression screws, or variable-pitch headless compression screws has been used safely and effectively in children.[67]

Scaphoid fracture nonunion does occur in skeletally immature patients, owing either to late presentation or to inadequate immobilization of acute injuries (Figure 41.21).[129,137,202] Indeed, in their retrospective analysis of 351 scaphoid fractures in children and adolescents, Gholson and coworkers noted that 29% of patients presented more than 6 weeks from injury.[67] Typically, patients are older adolescents with waist or proximal pole fractures. Treatment options for established pediatric scaphoid nonunions are quite varied. Historically, cast immobilization has been advocated in injuries that present late.[53,205] Bone grafting via the Matti-Russe technique, Kirschner wire fixation, and compression screw fixation have also been reported, with successful outcomes in the majority of cases, consistent with the published adult literature (Case Study 41.1).[67,129,157,160,182,202] The use of autologous bone graft is common to provide structural support and facilitate healing.

Osteonecrosis of the proximal pole of the scaphoid may occur in children, typically in waist or proximal pole fractures in patients nearing skeletal maturity. Reconstructive procedures using pedicled vascularized bone graft from the distal radius have been recommended in these rare but difficult situations.[44,169,202]

Little is known of the natural history of scaphoid fracture malunions (e.g., humpback deformity) in skeletally immature patients. Although reports of spontaneous correction of secondary carpal instability and remodeling of scaphoid malunions have been published, no definitive statement can be made owing to the infrequency of these situations and the paucity of data available.

CASE STUDY 41.1

A 10-year-old right-handed patient had hurt his left wrist 6 months previously. He complains of persistent pain and decreased range of motion (eFigure 41.1, *A* and *B*). The diagnosis was scaphoid nonunion. The treatment options included a long-arm cast, electrical stimulation, open reduction and vascularized bone grafting, and open reduction and nonvascularized bone grafting. The option of open reduction and nonvascularized bone grafting (eFigure 41.2, *A* to *F*) was performed. Postoperative and 3-month follow-up x-rays are shown (eFigures 41.3, *A* and *B*, and 41.4, *A* and *B*).

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Fractures of the distal pole of the scaphoid are treated with short-arm thumb spica cast immobilization for 4 to 6 weeks, followed by gradual resumption of activities with the return of wrist motion and strength.

Nondisplaced fractures of the scaphoid waist, confirmed by CT scans with reconstructed images in the plane of the scaphoid, are treated with short-arm thumb spica cast immobilization until there is radiographic evidence of healing (see Figure 41.18). Routine CT scans are not performed if there is clinical and radiographic evidence of fracture healing, including bridging trabeculae on multiple radiographic views. In situations in which prolonged cast immobilization is not a viable treatment option (e.g., bilateral upper extremity fractures, high-level athletes), percutaneous screw fixation via a dorsal approach is considered.

Displaced fractures of the scaphoid waist and fractures of the proximal pole are treated with open reduction and internal fixation via standard volar and dorsal approaches, respectively. Internal fixation is performed using a headless, cannulated, variable-pitch compression screw.

Scaphoid nonunions of the waist are treated with open reduction, bone grafting, and internal fixation. In cases of dorsal humpback deformity and dorsal intercalated segment instability, interpositional tricortical iliac crest bone graft is used to restore normal scaphoid architecture and reconstitute carpal alignment. Intraoperative pinning of the radiolunate joint to reduce the lunate out of its dorsiflexed position is often performed, although the pin is removed on completion of the case (see Figure 41.21 and Video 41.2).[183] Provided appropriate alignment and stability are achieved, patients are placed in a short-arm thumb spica cast, followed by wrist immobilization after radiographic evidence of bony healing.[67]

Capitate Fractures

Capitate fractures are rare and typically result from high-energy mechanisms of injury, such as motor vehicle collisions or falls from great heights during sports.[68,143,213] Occasionally, they may be seen in association with a greater-arc perilunate fracture-dislocation injury. Thus, the x-ray should be inspected for concomitant lesser- or greater-arc injuries. Radiographs usually confirm the diagnosis, but advanced imaging studies (e.g., CT, MRI) are helpful to identify fracture displacement and associated wrist pathologic conditions (Figure 41.22).

Treatment is predicated on fracture pattern and displacement. Nondisplaced capitate fractures are effectively managed with cast immobilization. Displaced injuries require open reduction and internal fixation using smooth pins or compression screws. Associated pathologic conditions (e.g., lesser- or greater-arc perilunate fracture-dislocations) should be addressed simultaneously.

Triquetrum Fractures

Although triquetral body fractures are rare and may be seen in the setting of greater-arc perilunate fracture-dislocations, dorsal avulsion fractures do occur, particularly in older adolescents (Figure 41.23). The former require open reduction and internal fixation, but the latter do well with splint or cast immobilization for 3 to 4 weeks until symptoms subside.

Hamate Fractures

Hamate fractures are relatively uncommon in the pediatric population.[154] Fractures of the hamate hook predominate,

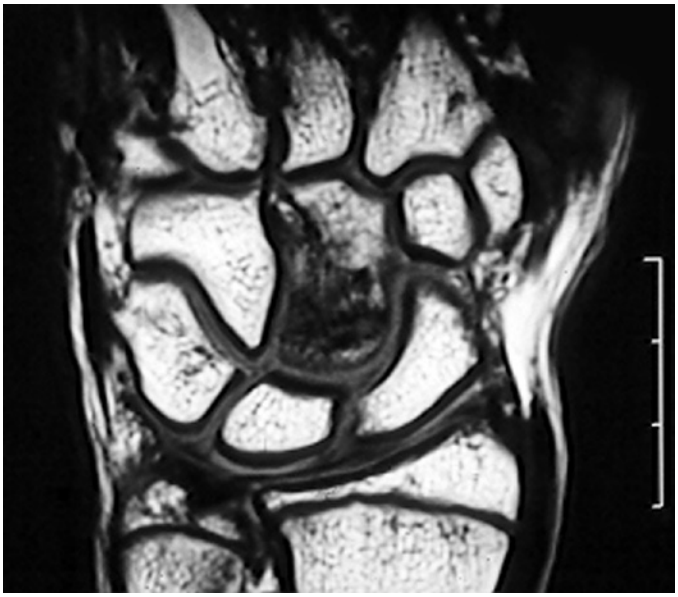

FIGURE 41.22 Thirteen-year-old boy with persistent midcarpal pain after a fall. Magnetic resonance image shows a capitate fracture treated with immobilization. (Courtesy of Shriners Hospital for Children, Philadelphia.)

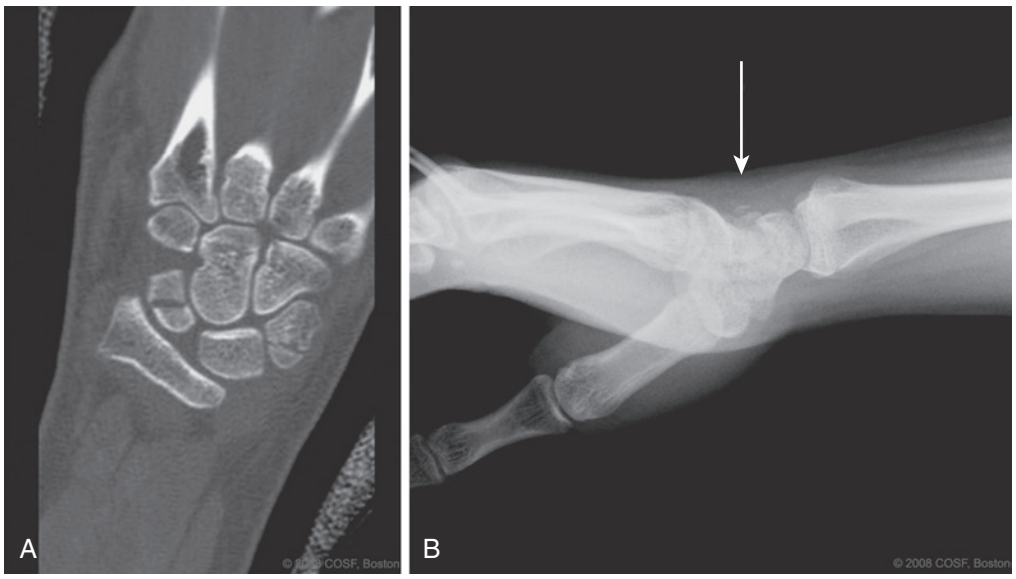

FIGURE 41.23 **A,** Computed tomographic scan depicting a triquetral fracture seen in the setting of a greater arc injury. Also note the scaphoid waist fracture. **B,** Lateral wrist radiograph of a dorsal triquetral avulsion fracture (*arrow*). (Courtesy of the Children's Orthopaedic Surgery Foundation.)

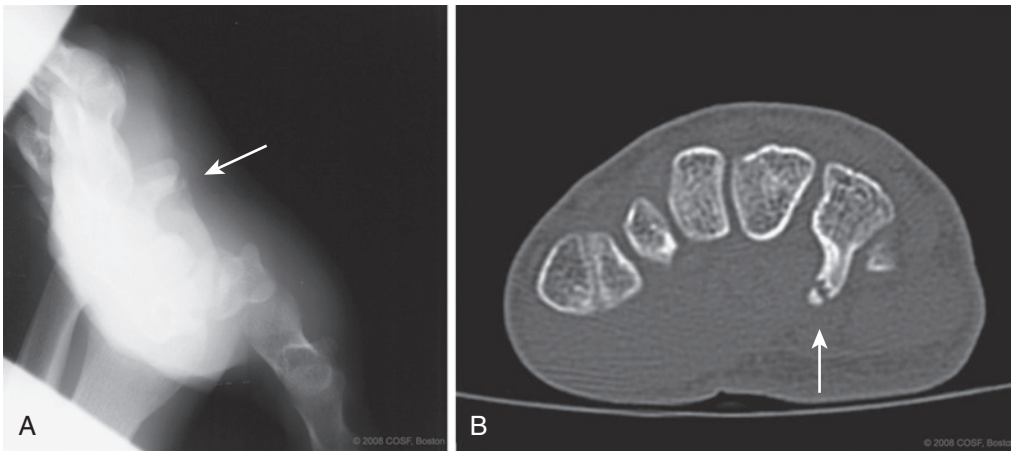

FIGURE 41.24 Carpal tunnel view radiograph **(A)** and CT scan **(B)** of a 14-year-old boy with a hook of hamate fracture (*arrows*). The patient remained symptomatic despite cast immobilization and attempted return to activities. Fracture nonunion was excised via a carpal tunnel incision, resulting in symptomatic relief and return to full activities. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

secondary to a fall. Patients present with point tenderness along the palm and hook of the hamate, along with mild swelling or localized ecchymosis. In acute or chronic cases, patients may complain of paresthesias or weakness in an ulnar nerve distribution or discomfort with small and ring finger flexion, owing to the proximity of the neurovascular and tendinous structures to the hamate hook. Standard radiographs may not delineate the fracture, and the carpal tunnel view may be helpful in suspected cases. CT is becoming the standard of care for the diagnosis of these fractures (Figure 41.24). Although open reduction and internal screw fixation have been advocated by some, short-arm cast immobilization for 4 to 6 weeks often alleviates the symptoms and allows a full return to activities, despite persistence of a radiographic fibrous nonunion. In persistent cases of symptomatic nonunion, fracture fragment excision is performed for relief of symptoms, although athletes should be advised of the possibility of scar irritation or sensitivity. The surgical approach for either fixation or excision is a standard zigzag approach to the Guyon canal or through a carpal tunnel release incision.

Pisiform Fractures

Pisiform fractures are rare and typically result from either a direct blow to the volar ulnar base of the wrist or hyperextension mechanisms (Figure 41.25). Although there is little published information to guide treatment, most patients demonstrate symptomatic relief with cast immobilization for 4 to 6 weeks followed by range-of-motion exercises.[116]

CRITICAL POINTS ***Carpal Fractures***

- The scaphoid is the most commonly fractured carpal bone in children. Distal pole fractures can be treated successfully with cast immobilization. Proximal pole and displaced waist fractures warrant surgical treatment.
- Brief cast or splint immobilization is sufficient for dorsal triquetral fractures.
- Special radiographic imaging is often needed to diagnose hook of hamate fractures. Cast immobilization is recommended acutely. Surgical stabilization or excision may be considered for symptomatic nonunions.

Distal Radial Fractures

Distal radial fractures are characterized by their anatomic location, fracture pattern, and magnitude of displacement, angulation, and rotation. Fractures may involve the distal radial metaphysis or physis. Metaphyseal injuries can be further subdivided into torus, or "buckle," fractures and bicortical fractures. Each fracture pattern has its own set of treatment principles and considerations.

Torus Fractures. In torus fractures of the distal radial metaphysis, cortical failure occurs in compression (Figure 41.26). As a result, these injuries present with minimal deformity and are inherently stable. Brief immobilization with a short-arm cast or a wrist splint for 3 weeks provides adequate symptomatic relief. Multiple randomized prospective trials have demonstrated that true torus fractures can be treated safely and effectively with splint immobilization removed by the parents after 3 weeks, with no need for additional clinical or radiographic follow-up.[46,173,178,194,207,208]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Torus fractures are treated with short-arm splint immobilization for 3 weeks, followed by resumption of activities. Radiographs are not routinely obtained at the time of cast removal owing to the inherent stability of these injuries. Likewise, no follow-up clinical evaluation is necessary after cast immobilization is discontinued.

Bicortical Metaphyseal Fractures. Bicortical fractures of the distal radial metaphysis occur because of bending, rotational, or shear forces imparted on the wrist. Fractures may be transverse, spiral, or oblique and may present with considerable displacement (Figure 41.27). Although bayonet apposition will remodel reliably in young children, fractures with unacceptable angulation or translation are typically treated with closed reduction and cast immobilization.[41] Depending on the patient and care setting, this may involve hematoma block, conscious sedation, or even general anesthesia. Because of the thick periosteum in younger patients, reduction maneuvers consist of exaggeration of the deformity, followed by longitudinal traction and reversal of the mechanism of injury (Figure 41.28). Although the thick, intact periosteum acts as a tension band in

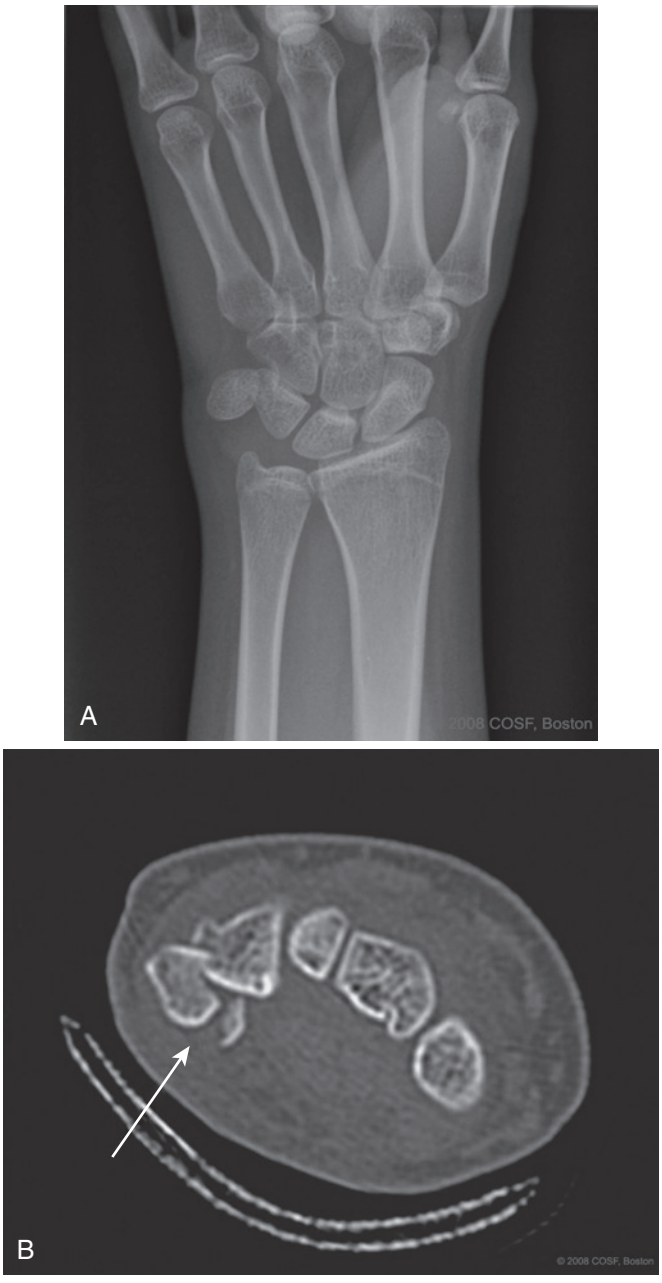

FIGURE 41.25 Radiograph **(A)** and computed tomographic scan **(B)** of a comminuted pisiform fracture in a 15-year-old girl. After 4 weeks of cast immobilization, the patient's symptoms resolved, and she returned to full activities. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

facilitating reduction and conferring stability, if the deformity is not exaggerated first, the intact periosteum limits the ability to restore length or alignment with straight traction alone. Application of a well-molded cast with three-point bending or an appropriate interosseous mold is critical in maintaining reduction and minimizing the risk of late displacement. Excessive wrist flexion should be avoided.[200]

The optimal position of forearm rotation, if a long-arm cast is used, remains controversial. Some advocate pronation, given that pronation may better correct rotational malalignment and maintain fracture reduction in the more common apex volar injury. Others advocate supination to allow improved fracture molding and relaxation of the brachioradialis. Still others advocate immobilization in neutral, citing an improved ability to apply an interosseous mold and theoretically minimize loss of motion at the extremes of forearm rotation.

Two prospective, randomized clinical trials compared the efficacy of short-arm versus long-arm casts in maintaining reduction following closed fracture manipulation.[24,204] Both investigations concluded that short-arm casts are as efficacious in maintaining fracture alignment as long-arm casts; however, careful analysis of the data reveals a number of important points. First, more important than the length of the cast is the quality of fracture reduction and cast molding. Indeed, in one study of 103 patients, the risk for loss of fracture reduction was higher in patients with a cast index greater than 0.7.[204] In addition, fractures that were incompletely reduced (i.e., had residual displacement or angulation following manipulation) were at higher risk for late loss of reduction, a finding that emphasizes the importance of the reduction maneuver over the type of immobilization.[24] Patients with concomitant fractures of the distal ulna were at higher risk for loss of reduction, regardless of the casting technique. Finally, the effect of long-arm casting on the ability to perform activities of daily living should not be dismissed; short-arm casts were associated with fewer days of missed school and less assistance required during daily activities.[204] Subsequent studies and metaanalyses have confirmed these findings.[78]

Despite successful initial closed reduction and cast immobilization, late displacement of fractures is common (Figure 41.29). Although prior published series reported loss of reduction rates of between 10% and 91%, in general, approximately one third of all distal radial fractures requiring reduction will demonstrate late displacement.[56,69,76,117,118,123,128,146,150,218] Factors implicated in the loss of reduction include initial displacement (bayonet apposition, >50% translation, >30 degrees of angulation), isolated distal radial fracture, associated same-level ulnar fracture, inadequate initial closed reduction, poor casting technique, muscle atrophy, and resolution of initial soft tissue swelling while in the cast. It is therefore imperative that serial radiographic evaluations be performed, initially on a weekly basis, to assess bony alignment and rule out loss of reduction.

Efforts have been made to characterize the quality of fracture reduction and casting techniques to predict which injuries might be more prone to late displacement (Figure 41.30). The cast index refers to the ratio between the diameters of the cast at the level of the fracture, as measured on lateral and AP projections.[36,91] Used as a measure of the quality of the cast mold, cast indices greater than 0.7 have been associated with an increased risk of late loss of fracture reduction.[36,204] A gap index has also been proposed to assess the quality of cast molding, as well as excessive cast padding and resolution of soft tissue swelling.[115] The gap index is calculated by dividing the aggregate distance between the skin and cast material by the overall diameter of the cast. If the sum of the gap indices as measured on both AP and lateral radiographs is greater than 0.15, this is associated with a higher risk of loss of fracture reduction, with a sensitivity of 88%. A three-point index has recently been proposed as a more sensitive and specific radiographic measure of cast mold and predictor of late displacement.[85] Axis deviation has also been proposed to assist in risk stratification and is discussed in the following section on forearm diaphyseal fractures.

(Courtesy of the Children's Orthopaedic Surgery Foundation.)

Owing to the relatively high rate of lost fracture reduction despite initial closed fracture manipulation and cast immobilization, some have questioned whether all fractures deemed to be at risk for late instability should be treated with surgical stabilization.[38,121,128,217] McLauchlan and colleagues performed a prospective, randomized clinical trial of 68 children treated with closed reduction and cast immobilization versus immediate percutaneous pinning.[121] Although loss of reduction occurred in 21% of the casting cohort and in 0% of pinning patients, equivalent clinical outcomes were reported. Miller and

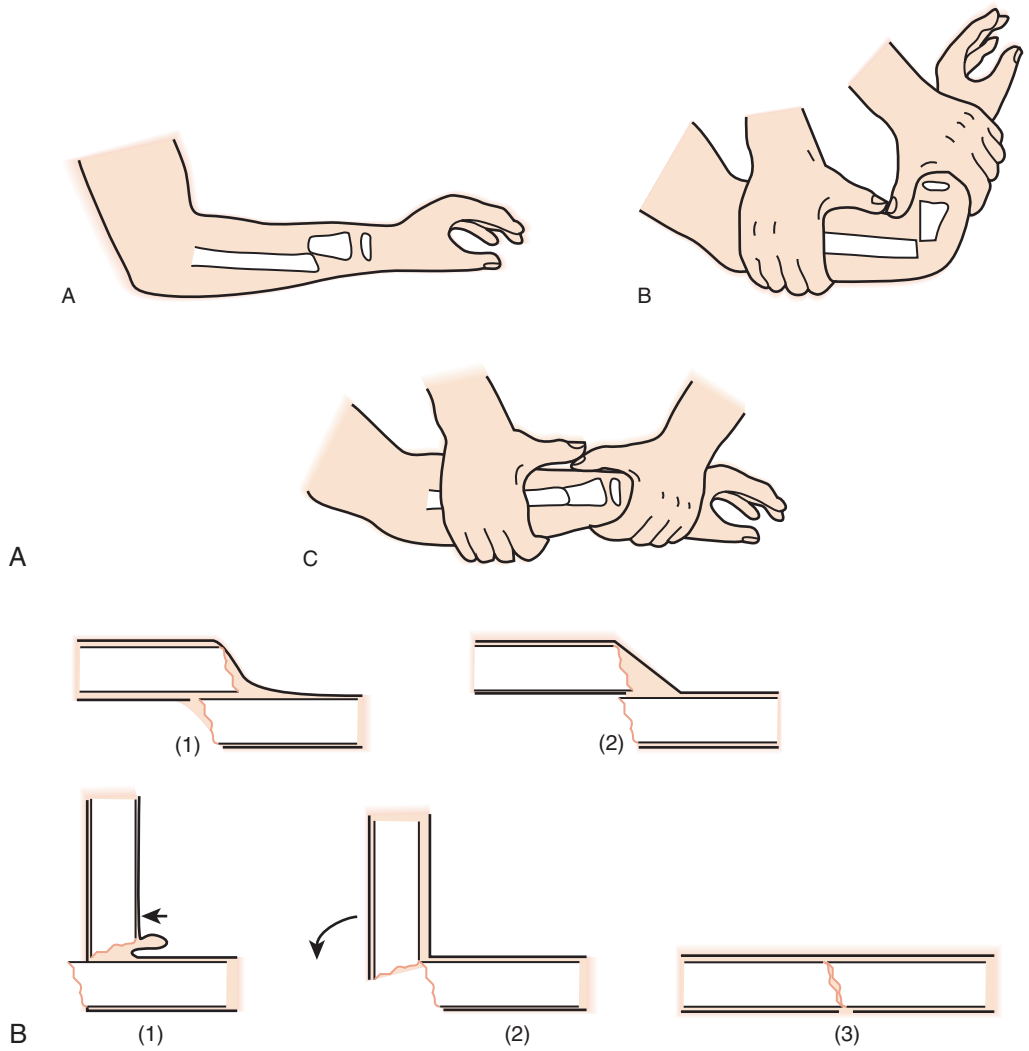

FIGURE 41.28 **A,** Schematic representation of distal radius fracture *(1)* with an intact dorsal periosteum. Longitudinal traction alone *(2)* is insufficient to achieve fracture reduction, given the intact periosteum. **B,** Closed reduction should first begin with exaggeration of the deformity *(1),* followed by longitudinal traction to achieve adequate length *(2).* Following restoration of bony length, a bending moment can be applied to effectuate bony reduction *(3),* with the intact dorsal periosteum conferring additional stability.

associates similarly performed a prospective, randomized trial of closed reduction and cast immobilization versus pin fixation in 34 patients older than 10 years with severely displaced distal radial fractures.[128] Thirty-nine percent of casted patients had loss of reduction requiring remanipulation, and 38% of the pinning cohort had minor pin-related complications, including superficial pin tract infections and superficial radial sensory nerve irritation. Clinical outcomes were equivalent, however, and there was no significant difference in overall cost analysis. Broad treatment recommendations cannot be made based on the limited evidence available. Certainly, when performed with meticulous technique, pinning of severely displaced distal radial fractures is safe and efficacious. However, owing to the frequency of these injuries, the remodeling potential of the distal radius, and equally efficacious results with proper cast immobilization, routine pinning of all displaced pediatric distal radial fractures is not currently recommended.

Indications for surgical treatment of pediatric distal radial fractures include open fractures, unstable or irreducible fractures, floating elbow injuries, and fractures with soft tissue or neurovascular compromise precluding cast immobilization (see Figure 41.29).[38,159,200] Open reduction and surgical stabilization are also indicated in the rare displaced Salter-Harris type III or IV or triplane fractures to reconstitute the articular surface and restore the integrity of the physis. Despite the growing enthusiasm for and experience with open reduction and volar locking plate fixation for displaced extraarticular and intraarticular fractures in adults, the majority of pediatric distal radial fractures can be managed successfully using percutaneously placed pins. Smooth pin fixation is typically performed with an oblique pin directed distal to proximal and radial to ulnar, entering the radial metaphysis proximal to the physis in an effort to avoid iatrogenic injury to the distal radial physis. A second oblique pin or dorsoulnar pin entering between the fourth and fifth extensor compartments can be added to provide additional fracture stability, but this is not always necessary.[106,175] In cases in which adequate fixation cannot be achieved with physis-sparing pinning techniques, transphyseal pinning and intramedullary fixation across the physis into the epiphysis have been reported, with successful outcomes and a low rate of

(Courtesy of the Children's Orthopaedic Surgery Foundation.)

complications.[30,80,141,165,217] In addition, intrafocal pinning in the fashion of Kapandji can be used with success.[187] Although external fixation via wrist spanning constructs is an option and has been used with success in children, it is reserved for cases of extensive soft tissue injury (e.g., crush injuries with soft tissue loss) or to supplement comminuted fractures in which adequate internal fixation is not possible.[201]

In fractures of the distal radius at the metaphyseal-diaphyseal junction, pinning techniques are difficult owing to the obliquity with which the pins must be directed to engage the proximal fracture fragment. In these situations, particularly in adolescents with less than 2 years of skeletal growth remaining, formal open reduction and volar plating may be performed with size- and age-appropriate implants, obtaining four cortices of

fixation in the distal fracture fragment while still preserving the distal radial physis (Figure 41.31). In addition, open reduction may be indicated in open fractures and in fractures in which soft tissue interposition precludes the achievement of an acceptable closed reduction. The most common offending structures in apex volar angulated fractures are the volar periosteum and pronator quadratus muscle.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

In displaced bicortical metaphyseal fractures of the distal radius, closed reduction and cast immobilization are advocated, typically performed while the patient is under conscious sedation. My preference is to immobilize with long-arm casts to mitigate the motion imparted by forearm rotation. Long-arm casts are also used because a well-molded short-arm cast (cast index <0.7, gap index <0.15) is often difficult to apply, given the soft tissue swelling typical at presentation. Although the position of forearm rotation remains controversial, published information suggests that this position does not affect the final alignment in fractures of the distal radius and ulna metaphysis.[27] I currently use long-arm casts with the forearm in neutral rotation following closed reduction.

Because of the known risk of late displacement, serial radiographs in the cast are obtained at 1 week, 2 weeks, and 4

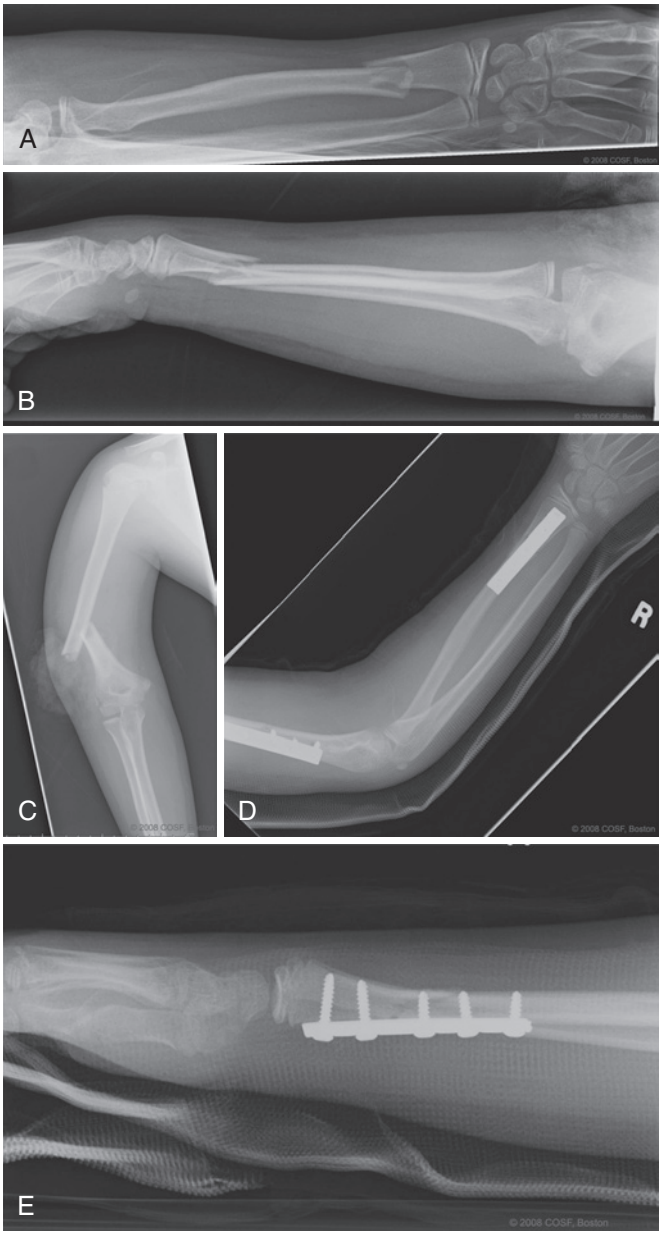

FIGURE 41.31 **A** to **C,** Anteroposterior and lateral radiographs of a distal radial fracture at the metaphyseal-diaphyseal junction in an 11-year-old girl with an ipsilateral open humeral fracture. **D** and **E,** Due to the fracture location, age of the patient, and associated injuries, internal fixation using double-stacked one-third tubular plates was performed in a physis-sparing fashion. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

weeks following fracture manipulation. If adequate alignment is maintained and fracture callus is radiographically apparent, patients are transitioned to a short-arm cast at 4 weeks following the injury. Following 2 weeks of short-arm casting, final radiographs are obtained, and cast immobilization is discontinued.

In cases in which fracture reduction is lost, I prefer to proceed with remanipulation and percutaneous pin fixation (see Figure 41.29). Although prior studies supported the notion that transphyseal pinning can be performed without high risk of physeal injury or growth arrest, I attempt to pin the fracture obliquely in a physis-sparing fashion. With the patient under general anesthesia, the fracture is manipulated and bony alignment is restored. A small 1-cm incision is made along the radial border of the distal radius, roughly at the level of the distal radial physis. Careful blunt dissection in the subcutaneous tissues is performed, and the superficial radial sensory nerve is retracted and protected at all times. Smooth Kirschner wires are passed from the distal fracture fragment just proximal to the physis, traversing the fracture and engaging the far proximal ulnar cortex. A single pin is often sufficient; however, additional pins can be placed for greater stability, taking care to avoid crossing the pins at the fracture site and thus failing to obtain rotational stability. Pins are bent and cut outside the skin in the usual fashion, followed by application of a long-arm cast. The pins are removed in the office at 4 weeks after radiographic confirmation of fracture callus formation, at which time the patient is transitioned to a short-arm cast for an additional 2 weeks.

Physeal Fractures of the Distal Radius. Distal radial physeal fractures represent approximately 20% of all growth plate fractures in children, second in frequency only to those of the phalanges.[145] Remodeling potential, treatment principles, and surgical indications are similar to those for distal radial metaphyseal fractures, with several additional considerations. Specifically, reduction maneuvers should be performed gently, with adequate analgesia or sedation, to avoid iatrogenic physeal injury and growth disturbance of the distal radial physis. Similarly, multiple reduction attempts or repeated late reduction attempts are discouraged to minimize the risk of physeal arrest.[105] If fracture reduction is lost late during the period of cast immobilization, the deformity is often observed for bony remodeling with skeletal growth. If adequate alignment is not achieved, late corrective osteotomies are considered to correct the deformity and avoid secondary carpal instability patterns. Prior studies suggested that fractures with less than 15 degrees of angulation and up to 1 cm of shortening will demonstrate complete remodeling without functional impairment in skeletally immature patients.[36]

The overall risk of physeal arrest after distal radial physeal fracture, even following the foregoing principles, is approximately 4%.[16,32] In displaced distal ulnar physeal fractures, the risk of posttraumatic growth disturbance is higher, approaching 50%.[32,133] Patients and families should be counseled about this risk, and follow-up radiographs are mandatory to assess for physeal arrest.

Distal radial physeal arrest may lead to ulnar overgrowth, abnormal wrist mechanics, ulnocarpal impaction, TFCC tears, and DRUJ instability. In symptomatic patients, surgical treatment options include physeal bar resection, ulnar epiphysiodesis, ulnar shortening osteotomy, corrective radial osteotomy, or combinations thereof, depending on the pattern of arrest, severity of deformity, and amount of remaining skeletal growth (Box 41.2).[84,199]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Displaced fractures of the distal radial physis are initially reduced while the patient is under conscious sedation and then immobilized in a long-arm cast with appropriate three-point molding. Fracture reduction is usually stable and maintained in a cast. Excessive wrist flexion in the cast is avoided to minimize the risk of neurovascular compromise due to swelling in the

BOX 41.2 Physeal Fractures of the Distal Radius

Approximately 4% incidence of posttraumatic distal radial physeal arrest
- Perform closed reduction with adequate sedation or analgesia for displaced injuries
- Avoid late or repeated manipulations
- Surgical treatment recommended for irreducible fractures, open fractures, floating elbow injuries, or neurovascular compromise precluding circumferential cast immobilization

Reconstructive options for posttraumatic distal radial physeal arrest
- Ulnar shortening osteotomy
- Distal ulnar epiphysiodesis
- Corrective distal radial osteotomy
- TFCC repair
- DRUJ stabilization

DRUJ, Distal radioulnar joint; *TFCC*, triangular fibrocartilage complex.

acute fracture setting (Figure 41.32). If late loss of reduction is noted on serial radiographs, the deformity is accepted, and families are counseled regarding remodeling potential. The possibility of corrective osteotomy for persistent malalignment is addressed near skeletal maturity. Repeated forceful manipulations are not attempted. Owing to the risk of physeal arrest, patients with distal radial physeal fracture are reexamined 9 to 12 months after injury with repeat radiographs.

Surgical indications for distal radial physeal fractures include irreducible fractures or fractures associated with soft tissue compromise or neurovascular injury precluding cast immobilization. Closed reduction and pinning techniques are similar to those described for metaphyseal injuries (Video 41.3).

Distal ulnar physeal fractures are often seen in association with distal radial fractures and carry a high risk for subsequent growth arrest (Figure 41.33).[32,133] Although appropriate reduction of the radial fracture usually reduces the ulnar fracture, intervention is recommended for persistent translation greater than 50% or angulation greater than 20 degrees. Failure to obtain a closed reduction is often indicative of soft tissue interposition at the fracture site; in these situations, open reduction and fixation are required. Smooth pin fixation for 4 weeks typically suffices.

The principles for treating distal ulnar styloid fractures are similar to those applicable to adults. Fractures through the base are associated with injury to the TFCC and DRUJ instability. Unstable injuries are best treated with open reduction and internal fixation to avoid late DRUJ instability. These injuries occur in older adolescents, and smooth pinning with tension band fixation is recommended (Figure 41.34).

Physeal arrest is often discovered when a patient presents with persistent ulnar wrist pain in the setting of long-standing distal radial physeal arrest. Surgical intervention is recommended to improve symptoms, correct wrist mechanics, and avoid progressive pain and deformity (see Figure 41.33).[199] The overall goals of surgical reconstruction include (1) restoration of neutral ulnar variance, (2) restoration of volar tilt and at least 10 degrees of radial inclination of the distal radius, (3) repair or débridement of any traumatic TFCC tears, (4) reconstitution of a stable and congruent DRUJ, and (5) prevention of recurrent deformity. Surgical options include wrist arthroscopy and possibly arthroscopic-assisted TFCC repair, ulnar shortening osteotomy to restore neutral ulnar variance, distal ulnar epiphysiodesis to avoid recurrence, and, when appropriate, corrective osteotomies of the distal radius (Figure 41.35). A symptomatic ulnar styloid nonunion or DRUJ instability is treated at the same surgical setting with either ulnar styloid nonunion excision or internal fixation or open reduction of the DRUJ with radioulnar joint ligament reconstruction.

Ulnar osteotomy is performed via a longitudinal ulnar incision between the extensor carpi ulnaris and flexor carpi ulnaris. Parallel oblique osteotomies are created, removing a segment of bone for the desired amount of ulnar shortening. In older children, a specialized ulnar shortening system can be used. Osteotomy is performed at the metaphyseal-diaphyseal junction, which is vascular and increases the healing potential. It is advantageous to apply the desired plate and predrill and tap the screw holes distal to the osteotomy site before creating the osteotomy. Internal fixation is achieved with size-appropriate plates to obtain four to six cortices of fixation distal and proximal to the osteotomy site. In patients with remaining skeletal growth, the distal portion of the ulnar incision is used to expose the distal ulnar physis, and an epiphysiodesis is performed using curets or drill bits. Local bone graft may be placed in the physis to promote bony bar formation. Intraoperative fluoroscopy confirms the restoration of normal ulnar variance. Following ulnar shortening, wrist arthroscopy is often performed. With visualization in the standard 3-4 portal, TFCC débridement or repair is performed using standard techniques. If ulnar styloid nonunion is present, excision (or, less commonly, internal fixation) is performed. Patients are immobilized in long-arm casts (with the forearm supinated after the TFCC is repaired) for 4 weeks, followed by 2 weeks of short-arm casting. Therapy is then initiated.

Postoperative Expectations and Management

Torus fractures reliably heal without functional deficits. Displaced distal radial fractures require reduction and cast immobilization for realignment; healing is generally uneventful. Open reduction for irreducible distal radial fractures results in union and an acceptable outcome.

Excellent functional outcome is expected with adherence to the foregoing principles and meticulous surgical technique. Complications of distal radial and ulnar fractures include fracture malunion, nonunion, synostosis, physeal arrest, and neurovascular compromise.

Owing to the relatively high rate of late fracture displacement following initial closed reduction attempts, distal radial malunions also occur. Given the tremendous remodeling potential of distal radial fractures, observation is recommended for established malunions. In cases of persistent deformity of the distal radius or ulna, corrective osteotomy is performed to restore motion and avoid the risk of secondary carpal instability or arthrosis.[57,151]

Fracture nonunions are rare in children. Nonunion of the distal radius or ulna is due to disruption of the biologic healing potential, which may be seen in open fractures or intrinsic bone pathologic conditions (e.g., neurofibromatosis, congenital pseudarthrosis). In these situations, open reduction and internal fixation with autogenous corticocancellous bone graft or vascularized bone grafts is needed to promote healing and return to function.[17]

Posttraumatic radioulnar synostosis is uncommon following distal radial and ulnar fractures in children and is commonly associated with TFCC or ulnar styloid pathologic conditions.[13,220] Cross-union is seen, including open fractures or fractures with excessive soft tissue or periosteal stripping of same-level fractures. In established synostosis with functional limitation resulting from loss of forearm rotation, resection with or without soft tissue interposition should be considered.[196]

Physeal arrest occurs in 4% of distal radial physeal fractures and 50% of distal ulnar physeal fractures. Furthermore, there have been case reports of growth arrest after metaphyseal fractures. Monitoring and treatment of posttraumatic physeal arrest should follow the principles and techniques previously described. In cases of established distal radial growth arrest and ulnar overgrowth, corrective osteotomies with or without associated soft tissue procedures can alleviate symptoms due to ulnocarpal impaction, TFCC tears, or DRUJ instability[90,199] (Case Study 41.2). Distraction osteogenesis and physeal bar resection have also been advocated in selected patients.[110,138] Waters and coworkers published their results in 30 adolescents with posttraumatic distal radial growth arrest.[199] Combinations of ulnar shortening osteotomies, ulnar epiphysiodeses, and radial corrective osteotomies were performed to restore normal bony alignment and wrist mechanics. Considerable improvements in wrist motion, pain, and function were noted, with minimal complications.

CASE STUDY 41.2

An 11-year-old right-handed boy had hurt his left wrist 2 years previously while catching a wet Nerf ball. He complains of left wrist prominence (eFigures 41.5 through 41.8). The diagnosis was physeal bar radius with growth arrest and ulnar-positive variance. The treatment options were observation, bar resection, radial lengthening, and ulnar epiphysiodesis. Because of the patient's age and sick physis, the treatment selected was ulnar epiphysiodesis and radial lengthening (eFigure 41.9, *A* to *H*).

Postoperative and 3-month follow-up x-rays are shown (eFigures 41.10, *A* and *B*, and 41.11, *A* and *B*). Clinical photographs are shown in Figure 41.35, *M* and *N*, and eFigure 41.12, *A* and *B*.

CRITICAL POINTS *Distal Radial Fractures*

- Torus fractures can be safely and effectively treated with brief splint or cast immobilization.
- Late displacement is seen in approximately one third of complete distal radial fractures following closed reduction and cast immobilization.
- Repeated or late reduction attempts are discouraged in displaced distal radial physeal fractures.
- Posttraumatic growth disturbance occurs in approximately 4% of distal radial and 50% of distal ulnar physeal fractures.
- Epiphysiodeses, ulnar shortening osteotomies, radial corrective osteotomies, or TFCC and DRUJ repairs can be performed to treat symptomatic distal radial growth arrest and ulnar overgrowth.

FOREARM DIAPHYSEAL FRACTURES

Forearm fractures are among the most common injuries presenting to orthopedic surgeons and the most common childhood skeletal injury requiring surgical care.[34,39] Despite the frequency with which they occur and the plethora of information available regarding their management, the treatment of forearm fractures remains challenging. There is a range of fracture patterns and presentations, a diversity of nonoperative and surgical techniques, issues of skeletal growth and bony remodeling, and ever-changing patient and family expectations. Furthermore, interpreting the published information regarding treatment and outcomes of forearm diaphyseal fractures is fraught with difficulty. Often, diaphyseal fractures are included with distal metaphyseal fractures of the radius and ulna, which represent a distinct category of clinical injuries, treatment

options, and expected outcomes. Historically, almost all pediatric forearm fractures were treated nonoperatively; however, more recent information regarding functional outcome has challenged the traditional tenets of forearm fracture care. Adding to treatment challenges are the desire for a more expedient return to full activity and expectations of immediate and normal motion and strength. Furthermore, with the advent of new instrumentation and techniques of fracture fixation, surgical treatment options have expanded.

Epidemiology

Forearm fractures are common, occurring in approximately 1 of 100 children each year.[39] When fractures of the distal radius and ulna are considered as a distinct injury, diaphyseal forearm fractures represent the third most common long bone fracture in children, following distal radial and supracondylar humeral fractures.[34] The peak age of incidence is 12 to 14 years. Diaphyseal forearm fractures are the most common open fractures of the upper extremity and represent the most common location of refracture in the pediatric population.[124]

The mechanism of injury is usually a fall onto an outstretched upper limb, imparting both axial loads and rotation or bending forces to the forearm. The position of the limb at the time of injury and the forces applied dictate the pattern of diaphyseal fracture. Radial and ulnar fractures at the same level result from predominantly bending forces, whereas fractures at different levels occur due to rotational forces. Extrapolated further, high-energy torsional mechanisms can cause both

skeletal injuries and soft tissue disruption of the ligamentous complexes stabilizing the proximal and distal radioulnar joints (e.g., Monteggia and Galeazzi fracture-dislocations).[14,64,131]

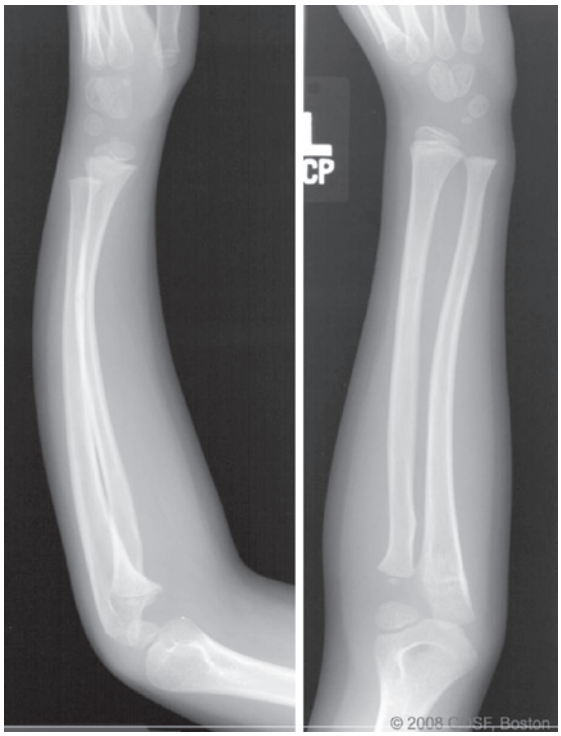
Preoperative Evaluation

Patients present with pain, deformity, swelling, and limited forearm motion after a fall onto an outstretched upper limb. Inspection of the overlying skin and soft tissue is mandatory to assess for an open fracture. Furthermore, a thorough neurovascular examination is performed to rule out associated nerve palsies, vascular insufficiency, or impending compartment syndrome.[47,74,113] The wrist and elbow are also carefully assessed for a possible ligamentous injury (e.g., Monteggia fracture-dislocation) or concomitant ipsilateral upper extremity fracture (e.g., floating elbow).[159,174]

Standard AP and lateral radiographs of the forearm, including visualization of the wrist and elbow, are performed in all cases of suspected forearm fracture. The x-rays are evaluated to ensure that there is no disruption of the DRUJ or radiocapitellar articulation. A congruent relationship should exist between the distal radius and ulna on both AP and lateral projections, and the longitudinal axis of the radius should bisect the capitellar ossification center on all views.

Diaphyseal fractures of the forearm are classified according to anatomic location (proximal, middle, or distal third), fracture displacement and angulation, and fracture pattern. In general, three patterns of diaphyseal fractures occur: plastic deformation, greenstick or incomplete fractures, and complete fractures. Each fracture pattern has its own set of treatment considerations.

Plastic deformation, or traumatic bowing, macroscopically presents as bones that are "bent but not broken."[25] Typically, this type of injury occurs during the first decade of life, and there is often little gross deformity, swelling, or ecchymosis and



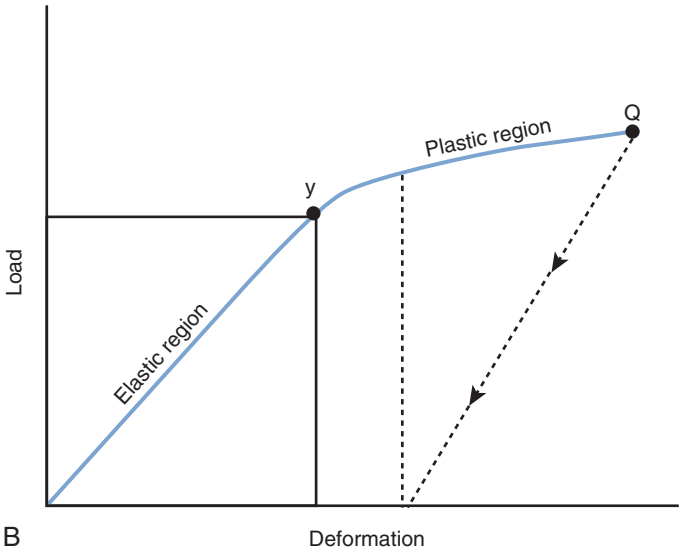


FIGURE 41.36 **A,** Radiographs depicting plastic deformation of the forearm in a 6-year-old boy. **B,** Stress-strain curve depicting the biomechanical mechanism of plastic deformation injuries. The *y* signifies the yield point, and the *Q* denotes the ultimate failure point.

varying degrees of pain and tenderness. Radiographic findings may be subtle, characterized by abnormal curvature of the radial or ulnar shafts in association with narrowing of the interosseous space (Figure 41.36, *A*). Understanding of the normal radiographic appearance of the radius and ulna, particularly the normal radial bow, is imperative in identifying plastic deformation injuries.[58] Histologically, plastic deformation injuries are characterized by slip lines, parallel zones of disruption between bent or wrinkled fiber bundles, and disruption of canaliculi. Biomechanically, plastic deformation injuries occur as the load applied to the bone exceeds the bone's elastic limits but does not exceed its ultimate strength. As a result, the material properties of the bone enter the plastic region of the stress-strain relationship. As the load is withdrawn, plastic deformation results, along with deformity (see Figure 41.36, *B*).[25]

Greenstick fractures represent the intermediate stage of bony failure between plastic deformation and complete fractures (Figure 41.37). Radiographically, one to three cortices may be disrupted on orthogonal views, with the remaining cortices intact or demonstrating traumatic bowing. These injuries result from torsional mechanisms, and the apex of the bony angulation provides insight into the rotational deformity. In general, apex dorsal fractures are caused by hyperpronation and therefore are reduced with forearm supination.[124] Conversely, apex volar fractures are due to hypersupination and are best reduced with pronation. The "rule of thumbs," in which the thumb is rotated toward the apex of the deformity, has been proposed to guide care providers in choosing the appropriate reduction maneuver. For example, in the common apex volar angulated fracture, rotating the thumb imparts pronation of the distal fracture fragment, thus counteracting the hypersupination injury. In situations in which the radius and ulna are fractured at the same level, pure bending is more likely to be the mechanism of injury, and reduction can be achieved with simple three-point molding. Complete fractures involve complete cortical disruption and are akin to their adult counterparts in terms of mechanism of injury, clinical presentation, and radiographic appearance.

Although a number of classification systems exist to describe pediatric forearm fractures, few are practical for guiding treatment or providing prognostic information. For this reason, anatomic descriptions of the fracture location, fracture pattern, degree of angulation and displacement, and associated soft tissue injuries are typically employed. In general, there are two bones (radius, ulna), three levels (proximal, middle, distal), and four fracture patterns (plastic deformation, greenstick, complete, comminuted).[124] Although rotational alignment is important to consider and may affect the ultimate outcome in terms of forearm rotation, malrotation is difficult to quantitate using radiographic indices and may be off by as much as 45 degrees.[42,148]

PERTINENT ANATOMY

The radius is a complex, "S"-shaped bone with approximately 15 degrees of apex ulnar angulation in the region of the radial neck and a gentle bow of 10 degrees of apex radial angulation in the middiaphyseal region.[58] The bicipital tuberosity and radial styloid lie approximately 180 degrees from each other, an important relationship that aids in the assessment of rotational malalignment. The ulna is triangular in cross section and predominantly straight in its longitudinal alignment, with the exception of a mild apex radial bow in the proximal olecranon region. The ulnar styloid and coronoid process lie approximately 180 degrees from each other, likewise aiding in the estimation of rotational deformity. Normal forearm rotation averages 150 to 180 degrees and occurs around an axis between the radial head and distal ulna.

The nutrient artery of the radius enters in the volar proximal half of the radius and travels in a distal ulnar direction.[70] The nutrient artery of the ulna enters in the volar proximal half and courses distally and radially. Awareness of the location of these

nutrient vessels helps avoid misdiagnosing these radiolucencies as fractures.

Soft tissue connections between the radius and ulna impart stability and are implicated in limiting forearm rotation in patients with stiffness despite near-normal radiographic alignment. These connections constitute the ligamentous stabilizers of the distal and proximal radioulnar joints as well as the interosseous ligament (see Chapter 14 for further discussion of these soft tissue restraints and their disorders).

Historical Review

Much of the available literature guiding diaphyseal fracture treatment and anticipated outcomes is based on the desire to promote adequate bony healing and avoid loss of forearm motion or aesthetically displeasing results.[22,82,135,186]

Aesthetic problems following diaphyseal malunion are caused by deformity of the ulna, owing to its subcutaneous location and straight longitudinal shape. Conversely, loss of forearm rotation is a result of a radial malunion, with or without

concomitant ulnar deformity. Although loss of pronation is typically compensated for by shoulder abduction, forearm supination is poorly accommodated owing to the blocking effect of the thorax with attempted shoulder adduction.[148] Multiple published series have demonstrated that diaphyseal fracture malunions contribute to loss of forearm rotation and functional impairment.[45,125,148,186] Cadaveric studies have demonstrated that whereas 10 degrees of angulation results in little if any loss of forearm rotation, greater than 10 degrees of angulation is a considerable impediment to forearm rotation. Recently, it has become increasingly apparent that more proximal forearm deformity imparts greater restrictions in forearm rotation. As a result, less angular or rotational deformity is tolerated in more proximal fractures than in more distal ones.

Rotational deformities, though difficult to quantify by x-ray, cause concomitant loss of forearm rotation.[45,94] For every degree of rotational deformity, 1 to 2 degrees of forearm rotation is lost. In general, ulnar malrotation does not alter the overall arc of forearm rotation but does change the "set point" of forearm motion. Conversely, radial malrotation affects the overall range of forearm supination-pronation. Ultimately, however, clinical outcomes in terms of forearm rotation are not always directly correlated to radiographic alignment.[135]

Adding to the complexity of treating pediatric diaphyseal fractures of the radius and ulna is the potential for bony remodeling with continued skeletal growth. Remodeling occurs as a result of reorientation of the adjacent physis with continued physeal growth; bony lengthening, which reduces the apparent angulation between the proximal and distal diaphyseal segments; and appositional periosteal bone formation at the concavity of the deformity. As with bony remodeling of other long bones, remodeling is greatest in younger patients, with fractures close to the adjacent physis, and with deformity in the plane of adjacent joint motion. In general, up to 20 degrees of diaphyseal angulation can remodel in children younger than 8 years. Beyond the age of 10 years, more than 10 degrees of angulation is unlikely to remodel.

Review of the literature provides guidelines as to how much radiographic deformity will remodel with growth. Up to 1 cm of shortening may be accepted, with little impact on forearm rotation, perhaps due to relaxation of the interosseous membrane.[50,148] Complete or 100% translation reliably remodels in younger patients with fractures of the middle and distal thirds.[42,50,148] Radioulnar angulation or translation is less well tolerated, particularly in older children with less remaining growth, owing to narrowing of the interosseous space and potential bony impingement resulting in loss of forearm rotation. Mehlman and Wall proposed the "20-15-10" rule for determining acceptable angulation in radial and ulnar fractures.[124] Dividing the forearm into thirds, 20, 15, and 10 degrees of angulation may be accepted in the distal, middle, and proximal thirds of the forearm, respectively.

In addition to radiographic parameters of angulation, displacement, and translation, other measurements have been proposed to predict the final position of diaphyseal forearm fractures following reduction and cast immobilization and the ultimate outcome. Younger and associates proposed that axis deviation be used to predict outcomes following forearm diaphyseal fractures and thus guide when closed reduction or surgical intervention is required (see Figure 41.30).[214,215] Axis deviation is defined as the distance between the fractured and anatomic axes of the bone measured at the fracture site, divided by the total length of the bone multiplied by 100. An axis deviation greater than 5 at the time of bony healing (i.e., cast removal) has been correlated with restricted forearm motion even after completion of skeletal growth and bony remodeling. The theoretical advantages of the axis deviation index are that it eliminates the confounding variables of radiographic projection, magnification, and fracture location and does not rely strictly on radiographic angulation or translation to predict functional loss.

Because clinical motion does not directly correlate with radiographic alignment, perhaps a more compelling and relevant question is how much deformity is acceptable for

a reasonable functional outcome. Historically, studies have demonstrated that 10 degrees of angulation, complete translation, and 30 to 45 degrees of malrotation may be well tolerated without functional limitations.[148] These data require careful interpretation, however, and it must be recognized that it is difficult to quantify "reasonable function" in the setting of objective losses in forearm rotation.

Types of Operations for Wrist Fractures

Treatment goals for pediatric radial and ulnar diaphyseal fractures are to achieve bony union while preserving forearm motion and minimizing complications. Although surgical techniques and implants have improved, the importance of skilled closed reduction and artful cast application cannot be overemphasized.

Plastic Deformation

Some authors believe that closed reduction should be attempted for all plastic deformation injuries with more than 20 degrees of angulation in patients older than 4 years, given the limited remodeling potential owing to the fact that the periosteum is not elevated or disrupted and the apex of the deformity and the fracture are often a distance from the adjacent physes.[25,163,197] Prior studies demonstrated that forces as high as 30 kg sustained over several minutes are required to correct traumatic bowing.[163] As a result, controlled three-point bending under general anesthesia or well-administered conscious sedation over a fulcrum (e.g., sandbag or rolled towel) is recommended to achieve correction. Analgesia and sedation options include hematoma block, inhalational anesthesia, and intravenous conscious sedation.

Good casting technique is imperative for maintaining reduction and optimizing outcome. Casts should be applied with a straight ulnar border, interosseous mold, and three-point molding over the apex of the deformity.[91] The resulting cast is often aesthetically displeasing to the patient and family; however, "curved plaster is necessary in order to make a straight limb."[33] With appropriate reduction and casting, up to 85% correction of the deformity can be expected, with minimal long-term restrictions in forearm motion.

In rare situations, a large amount of plastic deformation is not correctable, despite vigorous closed reduction. In these situations, percutaneous pin or drill osteoclasis at the apex of the deformity is performed, followed by correction of longitudinal alignment and appropriate cast immobilization. This technique converts a plastic deformation injury into an incomplete or complete fracture to effectuate reduction.

Greenstick Fractures

Greenstick fractures are effectively treated with closed reduction and well-molded cast immobilization in the majority of cases. Following an analysis of the radiographic findings and understanding of the causative mechanism of injury (e.g., pronation, supination, bending), closed reduction is performed by reversing the rotational deformity, followed by correction of the angulation. An appropriately applied cast with appropriate interosseous and three-point molding is critical in maintaining fracture reduction during bony healing (see Figure 41.37, *C* and *D*). There continues to be controversy regarding the need to complete the greenstick fracture by disrupting the intact cortex at the concavity of the deformity. Proponents of fracture completion cite the theoretical advantages of easier anatomic realignment, lower risk of loss of reduction, and lower refracture rate owing to the exuberant periosteal callus formation that ensues. Opponents cite the greater fracture instability and difficulty in maintaining reduction with fracture completion.

Complete Fractures

In patients with complete fractures of the radius and ulna diaphyses and unacceptable deformity, closed reduction is initially recommended. With adequate analgesia and sedation, closed reduction is performed by first exaggerating the deformity to relax the intact periosteum, applying longitudinal traction, and correcting the rotational malalignment; then the angular deformity is reversed. A long-arm cast with appropriate interosseous and three-point bending mold is applied.

The position of cast immobilization is debated. Although the majority of casts are applied with the elbow flexed 90 degrees, long-arm extension casts have been used with great success in proximal third fractures with apex posterior or apex ulnar angulation (Figure 41.38).[198] If extension casts are used, addition of a thumb spica component and placement of a "D"-ring with neck strap help prevent distal migration of the cast with walking and upright activity.

The optimal position of forearm rotation is even more open to debate, with little published information to provide guidance. Theoretically, fractures of the proximal one-third of the radius may be better immobilized in supination; the distal fragment is rotated into position in relation to the proximal fragment, which is typically supinated by the action of the biceps and supinator muscles. Similarly, middiaphyseal fractures occurring proximal to the insertion of the pronator teres may be better immobilized with the distal segment supinated, again matching rotational alignment. Conversely, fractures distal to the pronator teres insertion on the radius may be best immobilized in neutral rotation or forearm pronation.

Serial radiographs are recommended weekly for the first 2 to 3 weeks to ensure maintenance of reduction and identify unstable fractures. Loss of reduction may be seen in 5 to 25% of fractures and may occur up to 4 weeks after injury. Cast wedging may be considered in patients with loss of reduction and fracture angulation.[162] Provided adequate fracture reduction is maintained, patients can be safely transitioned to short-arm casts at 4 weeks. Short-arm casting is continued until 6 weeks after injury. Some recommend a brief period of splint immobilization after cast removal, and patients and families are counseled about refracture risk and judicious choice of activities.[25,26,164]

Surgical indications for diaphyseal fractures of the forearm include open fractures, soft tissue swelling or neurovascular compromise that precludes circumferential cast immobilization, floating elbow injuries, and irreducible or unstable fractures that fail nonoperative treatment. In addition, refracture is considered a relative indication for surgical stabilization, given the difficulties in achieving and maintaining fracture reduction in these situations. Although there are numerous surgical options, percutaneous pinning techniques are generally insufficient, and external fixation is poorly tolerated (Figure 41.39). As a result, most forearm diaphyseal fractures are currently

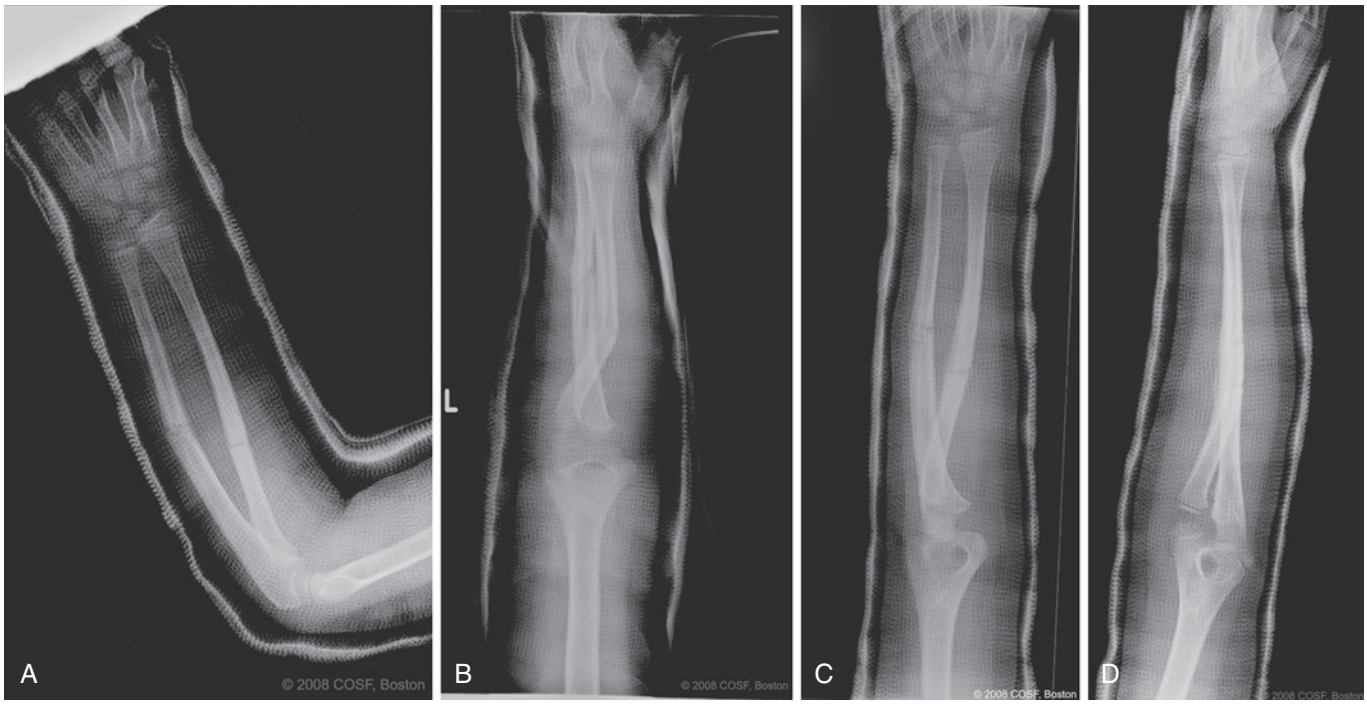

FIGURE 41.38 Anteroposterior **(A)** and lateral **(B)** radiographs of diaphyseal fractures of the radius and ulna in a 6-year-old child. treated with intramedullary fixation or internal fixation with plate and screw constructs.

Intramedullary fixation is well accepted and is becoming the preferred technique for forearm diaphyseal fracture stabilization in children and adolescents. [12,60,104,105,112,192,195,217] Smooth stainless steel Kirschner wires, titanium elastic nails, Rush rods, and Steinmann pins have all been used with reported success, emphasizing the importance of surgical principles over choice of implant. All radial implants can be prebent to facilitate restoration of the normal radial bow. Although length and angular correction is achieved by fracture reduction and intramedullary stabilization, rotational stability is typically conferred by the intact periosteum and surrounding soft tissues. These intramedullary devices are introduced into the intramedullary canal via small incisions and passed across the fracture site after closed reduction or limited open reduction. This technique avoids deep tissue dissection and extensive periosteal stripping, thus preserving the robust biologic healing potential in children and leading to expedient bony healing.

Radial intramedullary implants are typically introduced into the distal metaphysis either just proximal to the Lister tubercle or between the first and second extensor compartments. Ulnar intramedullary devices are introduced in the proximal ulnar metaphysis dorsally or through the olecranon apophysis (Figure 41.40). Maximal stability is achieved if the intramedullary nails are passed to within 1 cm of the far physis. Following intramedullary fixation, implants are typically bent and trimmed close to the cortical margin, with enough implant prominence to facilitate staged removal after bony healing. Less commonly, implants may be bent and cut outside the skin to allow easy removal in the office setting. Early removal of implants left outside the skin may obviate the need for a second anesthetic, but there are greater risks of refracture and superficial or deep pin tract infections. If implants are cut beneath the skin, elective removal is recommended 6 to 12 months after the index procedure.

In young patients, single-bone fixation of both bone fractures has been proposed. After intramedullary nailing of either the ulna (more commonly) or the radius, if acceptable alignment of the other bone is achieved and adequate fracture stability is demonstrated by intraoperative fluoroscopic evaluation of elbow and forearm motion, the remaining bone can be treated with supplemental cast immobilization.[46]

Formal open reduction and internal fixation using plate and screw constructs can also be performed, but this is usually reserved for older adolescents with less than 2 years of remaining skeletal growth (i.e., boys older than 14 and girls older than 12). The surgical technique is similar to that in adults, with several modifications. First, adequate stability may be achieved with four cortices of fixation proximal and distal to the fracture site, particularly if supplemented by postoperative cast immobilization. In addition, given the smaller size of the radius and ulna in children and adolescents, size-appropriate implants (2.4- or 2.7-mm compression plates, one-third tubular plates) should be used. The theoretical advantages of plate and screw fixation include the ability to achieve anatomic reduction and maximize return of full forearm rotation, particularly in older adolescents with little skeletal remodeling potential. Furthermore, given the mechanical stability achieved, early motion can be initiated, perhaps mitigating the soft tissue contractures that may contribute to loss of motion. Disadvantages of plate fixation include the need for more extensive dissection, slower bony healing, and increased scarring.

Note that the pins cross at the fracture site, failing to impart rotational control. **D** and **E,** Final position at the time of bony healing, with a 40-degree angular malunion of the radius. Because of the patient's age and fracture location, little skeletal remodeling is expected. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

The need for implant removal after bony healing remains controversial.[97,103,111,144] Some advocate the routine removal of plate and screw constructs after bony healing of forearm fractures, citing the risks of refracture, growth alteration, metallic allergies, and adverse effects on bone density due to mechanical stress shielding. Others cite the low frequency of symptomatic implants and complication rates of up to 40% as arguments against implant removal from the upper extremity in children.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

For children and younger adolescents, intramedullary fixation is performed for open fractures, unstable fractures, floating elbow injuries, and fractures in which circumferential casting is impossible or undesired. General anesthesia and intravenous antibiotics are used. Attention is first turned to the ulna. Fluoroscopy is used to assess the ability to achieve a closed reduction, and the intramedullary canal size is evaluated to ensure use of the proper size of Kirschner wire or titanium elastic nail. The narrowest canal diameter is best seen on the lateral projection of the radius and ulna. If titanium elastic nails are used, the surgeon should recognize that the tips of the nails are typically curved. This curve facilitates intramedullary manipulation and capture of the distal fracture fragment, but it also increases the effective working diameter of the nail.

The ulna is treated first, in part because of the ease of intramedullary rod placement and because restoring ulnar length and alignment improves the alignment of the radius via soft tissue connections. A small stab incision is created over the tip of the olecranon process, just radial to the center of it to account for the apex radial bow of the proximal ulna (Figure 41.40). The triceps is incised in line with the surgical incision, and a drill or smooth wire is used to create a corticotomy for intramedullary rod placement. Care is taken to avoid penetrating the ulnohumeral joint, which typically requires drilling more dorsally than initially anticipated. The appropriately sized implant is then

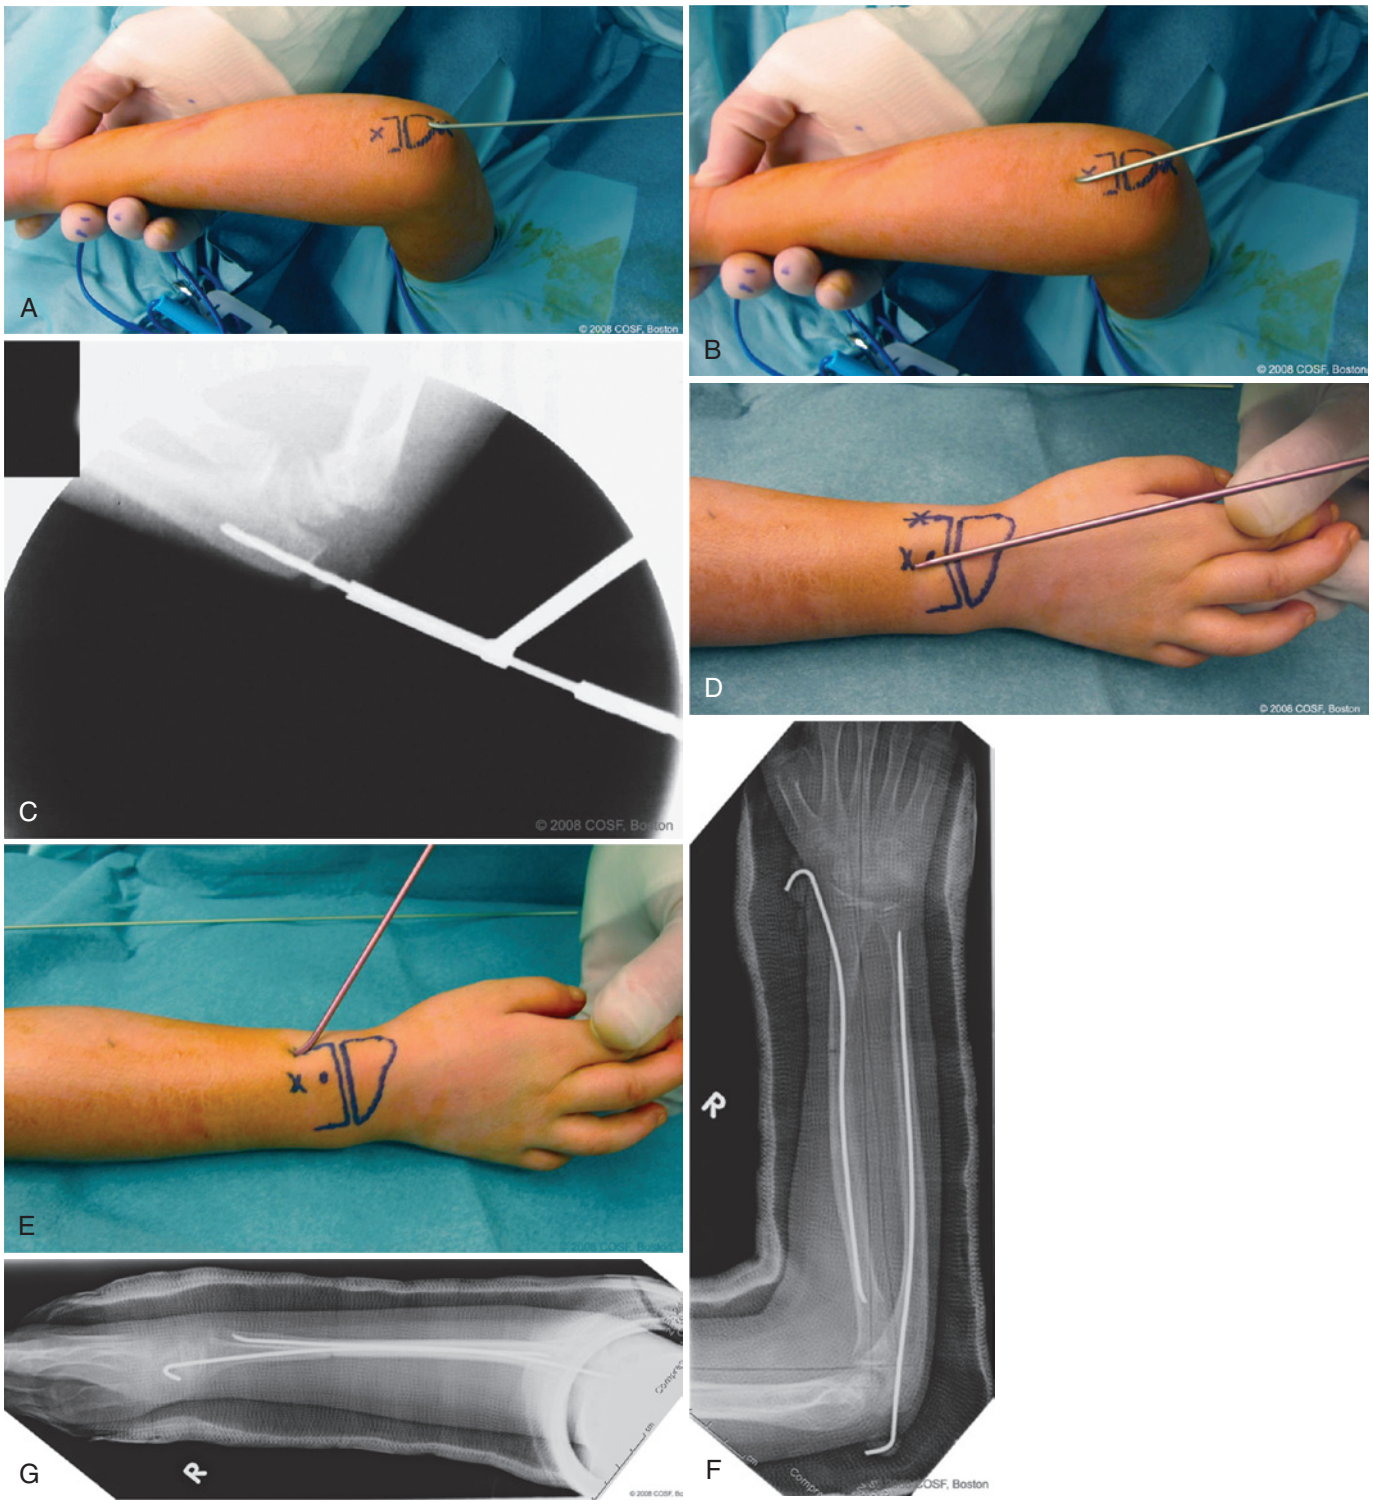

FIGURE 41.40 Technique of intramedullary fixation of diaphyseal fractures of the radius and ulna. The entry point for ulnar intramedullary rods may be through the olecranon apophysis **(A)** or proximal ulnar metaphysis **(B)**, just distal to the olecranon apophysis. **C,** Intraoperative fluoroscopy illustrating creation of the entry site for the ulnar rod. The entry point for the radial rod may be dorsally, just proximal to the Lister tubercle **(D)**, or radially between the first and second extensor compartments **(E)**, just proximal to the radial physis. **F** and **G,** Intraoperative fluoroscopy demonstrating fracture reduction and intramedullary rod placement for a middiaphyseal forearm fracture. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

passed in an antegrade fashion down the canal of the ulna until it reaches the fracture site. The ulna is reduced, and the nail is passed down the canal of the distal fragment. The implant is passed down until the tip of the rod resides 5 to 10 mm from the distal ulnar physis.

Attention is then turned to the radius (see Figure 41.40). I favor a radial entry site between the first and second extensor compartments. A small 2-cm incision is made over the "bare spot" of the dorsal radial metaphysis, just proximal to the distal radial physis. Subcutaneous dissection is performed to identify and retract the superficial sensory branch of the radial nerve. The retinaculum overlying the first dorsal compartment is identified and incised. A small periosteal window is created, and a drill is used to create a corticotomy for nail placement. Creation of an oblique path (distal radial to proximal ulnar) greatly facilitates nail placement. The appropriately sized nail is then precontoured to restore the radial bow and passed up the intramedullary canal in a retrograde manner to the level of the radial fracture. Closed reduction is performed, and the nail is passed into the canal of the proximal radial fracture fragment until the tip lies at the level of the bicipital tuberosity. Multiplanar fluoroscopic images are obtained to confirm the adequacy of reduction, stability, and implant placement.

Multiple forceful attempts at closed reduction and nail passage are discouraged, owing to the risk of increased soft tissue swelling and subsequent compartment syndrome.[112,113,216] If closed reduction and intramedullary nail passage cannot be achieved after several attempts, an open reduction is performed through a small incision centered over the radial fracture, using the brachioradialis–flexor carpi radialis or brachioradialis–pronator teres interval distally or proximally, respectively.

Although the majority of surgeons cut the nails under the skin until elective removal 3 to 6 months postoperatively, I prefer to bend them and leave the rods extending outside the skin.[95] The theoretical risk of soft tissue irritation and infection has not been a considerable problem, given that a sterile bandage is applied and the limb is immobilized with a long-arm cast following surgery. Buried nails result in a small incidence of soft tissue irritation and tendon disruption, particularly if a dorsal entry site is used for the radius. Furthermore, removal of buried rods may not be a trivial procedure.

The cast is bivalved to allow for postoperative swelling, and the intramedullary nails are removed at 4 to 6 weeks in the office or in the operating theater with sedation or brief general anesthesia, followed by an additional 2 weeks of cast immobilization. Although early rod removal theoretically increases the risk of refracture, this has not been a common occurrence, and families are counseled about refracture risk and appropriate activity modification.

In rare situations, particularly in younger children, single-bone fixation may suffice.[60] If the radius assumes an acceptable position after ulnar rod placement, single-bone fixation can be considered. Although alignment may be improved, it is imperative that the stability of the radial reduction be checked with elbow and forearm motion under fluoroscopic visualization. If the radius is unstable, nailing of both bones is performed.

For patients with less than 2 years of skeletal growth remaining, I favor open reduction and internal fixation using plate and screw constructs for middle and proximal third fractures with more than 15 and 10 degrees of angulation, respectively. In adolescent patients, 3.5-mm implants may be too wide or too large for the radius or ulna, so smaller implants are used. Typically, two one-third tubular plates are stacked on each other to increase the bending rigidity. Four to six cortices of fixation are achieved with standard cortical screws; locking screws are rarely needed in this patient population for fractures of the radius and ulnar diaphysis. If adequate stability is achieved, patients are immobilized in a bivalved short-arm cast or splint, and early supervised range of motion is initiated. I do not routinely remove plate and screw constructs after healing is achieved; I believe that the morbidity and risk of plate removal in the upper extremity outweigh the benefits.

Single-Bone Fractures

True single-bone fractures of the radius or ulna (i.e., without associated soft tissue disruption of the distal or proximal radioulnar joints) result from direct blows. Due to the stabilizing effect of the adjacent intact bone, reduction maneuvers are difficult. With fracture displacement and angulation, particularly when the apex of deformity is directed toward the interosseous space, failure to correct the bony alignment may result in loss of forearm rotation due to bony abutment. Reduction maneuvers consisting of longitudinal traction, varus-valgus strain using the intact bone as an indirect means of controlling the distal fracture fragment, and subsequent direct pressure at the fracture site to correct translation have been proposed in these situations.

Open Fractures

Open fractures merit special comment. Several issues distinguish the treatment of these injuries from their closed counterparts. First, open fractures result from higher energy forces with greater periosteal and soft tissue disruption. This leads to greater instability and the need for surgical stabilization. Second, there is a higher incidence of associated neurologic injuries and compartment syndromes with open fractures.[113] Surgical stabilization obviates the need for circumferential cast immobilization and allows care and monitoring of the soft tissues. In addition, when intramedullary fixation is performed, prolonged or repeated forceful attempts to achieve reduction before passage of the intramedullary implant are discouraged to lessen the risk of compartment syndrome.[216] Finally, open fractures carry the inherent risk of soft tissue contamination and subsequent infection. Although the overall rate of infectious complications is low, early and thorough irrigation and débridement are requisite components of open fracture care.[54,171]

Monteggia Fracture-Dislocations

Monteggia fracture-dislocations are fractures of the ulna associated with proximal radioulnar joint dissociation and radiocapitellar dislocation.[14,131] These injuries constitute less than 1% of all pediatric forearm fractures, typically affecting patients between 4 and 10 years of age. The mechanism of injury is classically described as a fall onto an outstretched hand with forced rotation of the forearm.

Acutely, patients present with pain, swelling, deformity, and limitations in elbow motion. A neurovascular examination is critical, as 10 to 20% patients have evidence of a neurologic deficit at presentation, usually involving the posterior interosseous nerve as the radial head commonly dislocates in an

anterior direction. Accurate diagnosis and timely intervention allow reduction and soft tissue healing with excellent functional outcomes. Unfortunately, despite the increased awareness and understanding of Monteggia fracture-dislocations, the initial diagnosis is often missed; late reconstruction is technically challenging, and outcomes are often suboptimal. Therefore, a high index of suspicion is paramount.

The radiocapitellar articulation must be assessed during the radiographic evaluation of any pediatric forearm fracture. Normally, the longitudinal axis of the radius should bisect the capitellar ossification center on all radiographic views. Careful assessment of the radiocapitellar joint is particularly critical during the initial treatment of "isolated" ulnar fractures. Similarly, in cases of presumed isolated radial head dislocations, abnormal ulnar bowing or plastic deformation must be sought.[108] Although congenital radial head dislocations occasionally present as "acute" injuries, the presence of a hypoplastic capitellum and convex radial head usually confirms the diagnosis.

Understanding of the pathoanatomy of Monteggia fracture-dislocations is critical in providing appropriate treatment. In the majority of cases, the annular and quadrate ligaments are disrupted at the proximal radioulnar joint; however, much of the interosseous membrane between the radius and ulna remains intact, as does the TFCC. Anatomic reduction of the ulna, therefore, often restores proximal radioulnar and radiocapitellar joint congruity. For this reason, treatment is predicated on the nature of the ulnar fracture.[155,158] Historically, the Bado classification has been used to describe these injuries, based on the direction of the radial head dislocation and the apex of the associated ulnar fracture.[14] This classification scheme may aid in both describing the pattern of injury and guiding care.

In acute lesions, the method of treatment is determined by the pattern of ulnar fracture (Table 41.1). In patients with plastic deformation, proximal varus buckle, or greenstick fracture of the ulna, closed reduction under general anesthesia is recommended. In these situations, closed reduction of the ulna is typically performed with a combination of longitudinal traction, forearm rotation, and direct pressure applied to the apex of the fracture. The radiocapitellar joint usually reduces spontaneously with this maneuver. The need to apply substantial force to the radial head should raise the suspicion of interposed soft tissue blocking radiocapitellar joint reduction.[180] In the most common Bado type I lesions, for example, the radial head is anteriorly dislocated, and the ulna has apex volar angulation. Correction of the ulnar deformity followed by posteriorly directed pressure on the radial head, elbow flexion, and forearm supination is performed. Typically, the ulnar fracture and radiocapitellar joint are stable after reduction of plastic deformation or incomplete fractures. A well-molded above-elbow cast is then applied for 4 to 6 weeks. After radiographic and clinical healing, range-of-motion exercises are initiated.

In patients with complete transverse or short oblique fractures of the ulna, closed reduction alone can result in loss of reduction in a cast.[155] Therefore, closed reduction and intramedullary fixation of the ulna are recommended to maintain ulnar alignment and radiocapitellar reduction (Figure 41.41). In these cases, an age- and size-appropriate stainless steel Kirschner wire or flexible titanium nail is selected. Via a small longitudinal split in the triceps tendon overlying the olecranon process, this nail is inserted into the intramedullary canal of the ulna and advanced in an antegrade fashion to the fracture site. The ulnar fracture is reduced, and the nail is advanced into the intramedullary canal of the distal fracture fragment, allowing restoration of both ulnar length and alignment. During ulnar reduction and fixation, closed reduction of the radiocapitellar dislocation is also performed. Intraoperative fluoroscopy confirms appropriate ulnar and radiocapitellar reduction. An

TABLE 41.1 Treatment Recommendations Based on the Pattern of Ulnar Deformity for Acute Monteggia Fracture-Dislocations

Pattern of Ulnar Fracture	Recommended Treatment
Plastic deformation	Closed reduction, casting of ulna
Greenstick fracture	Closed reduction, casting of ulna
Complete fracture (transverse, short oblique)	Intramedullary fixation of ulna
Complete fracture (long oblique, comminuted)	Open reduction, plate fixation of ulna

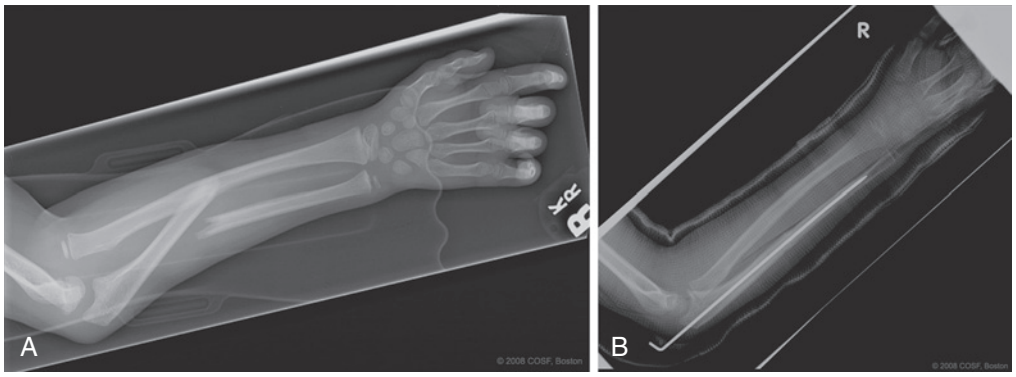

FIGURE 41.41 **A,** Preoperative lateral radiograph of a Monteggia fracture-dislocation in a 7-year-old girl. **B,** Postoperative radiograph following intramedullary fixation of the ulna and closed radiocapitellar reduction. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

above-elbow cast is then applied with the elbow in 90 degrees of flexion and the forearm in supination, which confers additional stability to the radiocapitellar articulation. Cast immobilization and intramedullary fixation are continued for 4 to 6 weeks to allow annular ligament and bony healing. After radiographic confirmation of bony healing, the cast is discontinued, the intramedullary nail is removed, and range-of-motion exercises are begun.

Long oblique or comminuted ulnar fractures cannot be adequately stabilized with intramedullary devices.[155] In these cases, open reduction and internal fixation with plate and screw constructs are necessary, even in young patients with open physes (Figure 41.42). Through a longitudinal incision based on the subcutaneous border of the ulna and centered on the fracture site, reduction is performed, and a one-third tubular or small fragment plate is applied in the standard fashion. Four to six cortices of fixation proximal and distal to the fracture provide adequate stability in pediatric patients. Radiocapitellar joint congruity is achieved during reduction and fixation of the ulna fracture. If closed reduction of the radiocapitellar joint is unattainable, an open reduction may be facilitated by extending the ulnar incision proximally over the posterolateral aspect of the elbow. Cast immobilization for 4 to 6 weeks with the forearm in supination is required following surgery.

Galeazzi Fractures

Galeazzi fractures are fractures of the distal radius associated with DRUJ disruption.[64] Although such injuries are rare in children, Galeazzi equivalents may present with distal ulnar physeal fractures or ulnar styloid avulsions.[73] These injuries result from falls onto an outstretched upper extremity with a combination of axial load and rotational moment. Patients present with pain and restrictions in forearm rotation. Radiographs reveal incongruity of the DRUJ, best seen on a true lateral view of the wrist. Descriptions of Galeazzi fractures are based on the direction of ulnar displacement. However, it is important to remember that the axis of forearm rotation lies from the radial head to the ulnar styloid, and in fact, it is the radius that displaces in relation to the ulna.

Unlike in adults, Galeazzi fracture-dislocations and their equivalents in children can be successfully treated nonoperatively.[73] In general, restoration of anatomic radial alignment using the reduction maneuvers described earlier yields a congruent and stable DRUJ. Closed reduction maneuvers are predicated on the pattern of injury. In situations in which the ulna is dorsally displaced in relation to the radius and there is apex dorsal angulation of the radial fracture, three-point bending combined with forearm supination is the reduction maneuver. Conversely, for apex volar radial fractures in which the ulna is volar, pronation is applied.

If anatomic reduction is achieved, a long-arm cast is applied for 6 weeks, with weekly radiographic evaluation to confirm maintenance of reduction. In cases in which reduction cannot be achieved or in older adolescents with less than 2 years of growth remaining, formal open reduction and internal fixation of the radius with appropriate treatment of the DRUJ dislocation are recommended, as in adults.

Postoperative Expectations and Management

The outcome following a forearm fracture is dependent on the injury and reduction, but adherence to the previously stated principles and techniques results in bony healing and restoration of motion in the majority of patients. Acceptable realignment of the radius and ulna results in union and restoration of forearm motion. Fixation of irreducible, open, or unstable forearm fractures reliably restores anatomy and motion. Monteggia fracture-dislocations require prompt recognition and appropriate treatment for an acceptable outcome.

With careful inspection, some loss of forearm rotation may be observed, even in surgical patients whose radiographs demonstrate anatomic bony alignment.[12,82,135,148,214] Typically, these differences are subtle and are not associated with any complaints or functional limitations.[45,135]

In cases in which the previously stated principles are not followed, fracture malunion may result (see Figure 41.37). Price and colleagues reported on a series of 39 children with malunions following closed treatment of displaced forearm fractures.[148] Average patient age at the time of injury was 9.3 years (range, 1 to 16 years). Average follow-up was 5.7 years, with a minimum 2-year follow-up in all. Malunion was defined as radiographic angulation greater than 10 degrees, greater than 50% displacement, malrotation, or encroachment of the interosseous space. Results were characterized as excellent (no limitations in activity, loss of forearm rotation <10 degrees), good (mild complaints with strenuous physical activity, loss of forearm rotation <30 degrees), fair (mild complaints with activities of daily living, 31- to 90-degree loss of forearm rotation), and poor. Overall, 82% of patients had excellent results, 10% had good results, and 8% had fair results; there were no poor outcomes. All patients were reportedly "satisfied" with

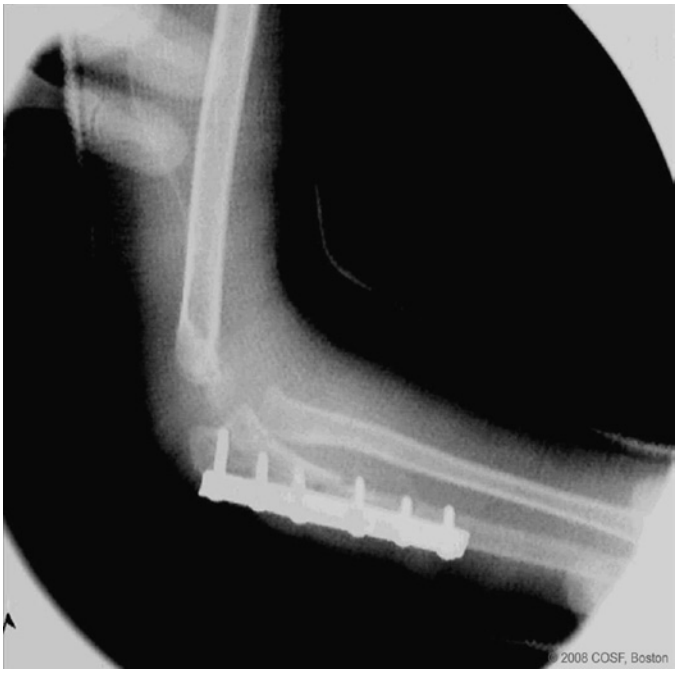

FIGURE 41.42 Postoperative radiograph after open reduction and plate fixation of the ulna and closed radiocapitellar joint reduction in a 4-year-old boy. Plate fixation was necessary to restore ulnar length and alignment owing to the proximal location and comminuted pattern of the ulnar fracture. (Courtesy of the Children's Orthopaedic Surgery Foundation.)

aesthetics and function, regardless of age or radiographic findings, which did not correlate with final clinical motion. Although no correlation was seen between age or fracture displacement and outcome, the authors observed that angulation, shortening, narrowing of the interosseous space, and proximal fracture location were associated with worse functional results. Based on their observations, the authors concluded that up to 10 degrees of angulation, complete translation, complete loss of radial bow, and 45 degrees of malrotation may be well tolerated with minimal aesthetic or functional consequences. Similar findings have been reported by others.[42,45,63]

Malunions that impede functional forearm motion and exceed the amount of deformity that might be anticipated to remodel with remaining growth should be considered for corrective osteotomies (see Figure 41.37).[22,147,186] Closing wedge osteotomies at the apex of the deformity of both the radius and the ulna are recommended to restore a straight ulna and a more normal radial bow. Surgery on the radius and ulna is performed via standard Henry volar and ulnar approaches. The radius is addressed first. After the apex of the deformity is confirmed on intraoperative fluoroscopy, a closing wedge osteotomy is performed sequentially in the radius and ulna. Proximal and distal cuts are made orthogonal to the longitudinal axis of the radius, allowing subsequent rotational correction. Closing wedge osteotomies are preferred because they are technically more reproducible than single-cut oblique osteotomies; they also avoid bony lengthening, which may cause difficulties with internal fixation and alter the proximal and distal radioulnar joints. Plate and screw fixation using size-appropriate implants is preferred, obtaining four to six cortices of fixation in the proximal and distal segments. Rotational alignment is confirmed by the radiographic appearance of the radial styloid and ulnar styloid 180 degrees opposite the bicipital tuberosity and coronoid process, respectively. Long-arm cast immobilization for 4 weeks is followed by 2 weeks of short-arm casting.[147]

Refracture of diaphyseal fractures of the forearm occurs in 4 to 8% of patients; this typically occurs in males more commonly than in females approximately 6 months after the index injury.[18,26,101,185] Patients and families should be counseled about the refracture risk at the time of cast removal, and a transitional period of splint immobilization should be considered to minimize refracture risk. In cases of refracture in which adequate alignment cannot be achieved with closed manipulation, surgical treatment is recommended. Even if intramedullary fixation is to be performed, open reduction and drilling of the intramedullary canal to create an appropriate path for subsequent nail passage are often needed, given the prior fracture callus and healing. In these situations, internal fixation with plate and screw constructs may be used.

Compartment syndrome is a rare but potentially devastating complication of diaphyseal forearm fractures, whether treated nonoperatively or surgically.[74,88,216] Early recognition and prompt treatment with forearm fasciotomies are critical to avoid permanent sequelae.[93] Diagnosis may be difficult, particularly in a young, agitated, or nonverbal child. In addition to the traditional signs of compartment syndrome in adults, a rising analgesic requirement, increasing agitation, and anxiousness are evidence of an impending compartment syndrome.[15,93]

CRITICAL POINTS *Forearm Fractures*

- Adequate sedation or anesthesia and properly molded casts are critical in achieving and maintaining reduction of plastic deformation injuries.
- During intramedullary fixation of open or unstable forearm fractures, multiple forceful attempts at intramedullary nail passage are discouraged to minimize the risk of postoperative compartment syndrome.
- Treatment of Monteggia fracture-dislocations is dictated by the pattern of ulnar fracture.
- Refracture occurs in approximately 5% of children following successful nonoperative treatment of diaphyseal forearm fractures.

Replantation

James P. Higgins

No single conceptual development has had an impact on the field of hand surgery as profound as the advent of microsurgical techniques. The ability to repair blood vessels that could not be seen without visual assistance led to an accelerated phase of discovery and innovation that continues to this day. The availability of microsurgical techniques has expanded the extent and type of injuries that can be considered correctable and have made operations for these corrections relatively commonplace.

After the coaptation of blood vessels was first performed by Dr. Alexis Carrell in 1902, modifications followed in techniques for suturing and instrumentation and their applications. The great pioneers of microsurgery developed instrumentation and other techniques that allowed the anastomosis of blood vessels. After the techniques were deemed feasible experimentally, their initial applications were in treatment of the traumatized hand, with replantation being one of the earliest milestones.

In 1962, Malt and McKhann performed the first replantation of a completely severed arm in a 12-year-old boy in Boston.[29] In 1963, Chen and colleagues performed the first successful replantation of an amputated hand in Shanghai, China.[7] In 1968, the first replantation of an individual digit, a thumb, was achieved by Drs. Komatsu and Tamai in Japan. [25] As centers became increasingly more familiar with the technique and as experience around the globe expanded, replantations of increasing complexity were performed. This has led us to the current day, in which the initial procedures for replantation have been adapted, refined, and extended and include repair of distal tip amputations,[38] ectopic banking of amputated parts,[17,21] and, ultimately, vascularized composite allotransplantation.[13,20,23,31]

GENERAL CONSIDERATIONS IN REPLANTATION

Epidemiology

Few studies have evaluated the impact of amputations and replantations on society. A study from Sweden determined the incidence to be 1.9 per 100,000 person-years (males 3.3, females 0.5). Eighty-six percent occurred in males and 9% in children (age 0 to 14 years). The majority occur in males 45 to 54 years of age. Factory workers (26%) and carpenters (14%) were most commonly injured.[3] A large national database study of upper extremity amputation and replantation cases in the United States demonstrated that the patients undergoing replantation were younger (average age 36 years) than those suffering amputation but not undergoing replantation (average age 44 years). Replantation was most often performed in teaching hospitals and larger urban hospitals.[14]

Emergency Management

The patient sustaining an upper extremity amputation should be rapidly and efficiently transported to a specialty center capable of replantation. The patient's candidacy for replantation should be determined after he or she has been assessed in the emergency department. The field trauma care of such a patient should follow the principles of global trauma management. It may be easy to overlook more urgent basic trauma protocols in the setting of the distracting, and sometimes dramatic, appearance of extremity amputations. The ABCs of trauma management should never be neglected.

Specific management of the amputated parts should include collection of all amputated parts in the field, regardless of the degree of contamination or quality of tissue. These parts should be wrapped in a sponge saturated with saline, placed in a plastic bag, and subsequently placed in a bag of ice or on a bed of ice. The goal is to cool the part but avoid freezing of the tissue. The bag should be labeled with the patient's demographic information and transported with the patient to the hospital setting. The amputated stump should be treated with pressure dressings and elevation to control bleeding. Tourniquets should be avoided as well as attempts at ligation of blood vessels in the field, if possible.

In the emergency department, the amputated parts and the amputated stump should be evaluated for the purposes of operative planning and decision making. The patient's limb and amputated parts should be evaluated radiographically. Tetanus prophylaxis should be provided.

Patient Selection

Very few indications or contraindications for replantation are absolute. The most compelling indications for replantation include thumb amputations at any level (Figure 42.1), multiple-digit amputations (Figure 42.2), any amputation in the pediatric population, and amputations through the wrist, forearm,

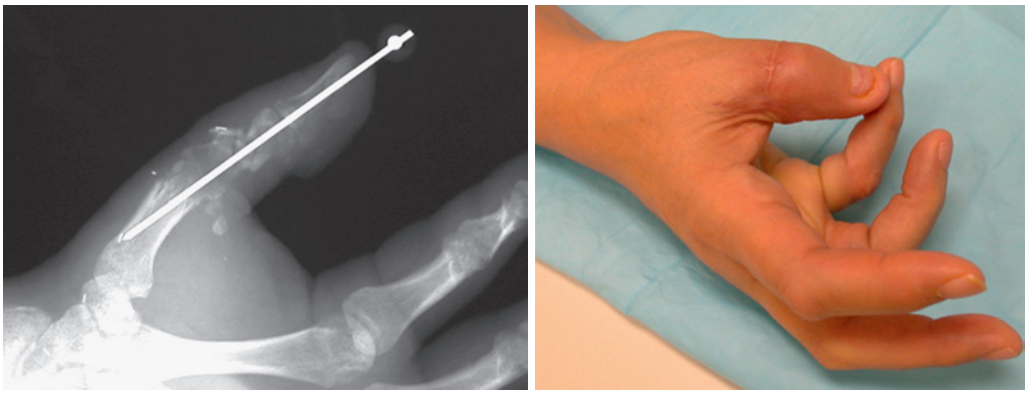

FIGURE 42.1 Example of indication for replantation. This thumb replantation was performed despite extreme comminution and bone loss. Although minimal motion is achieved at the metacarpal or interphalangeal joints, the thumb replantation is a functional success because of the preserved motion at the carpometacarpal joint.

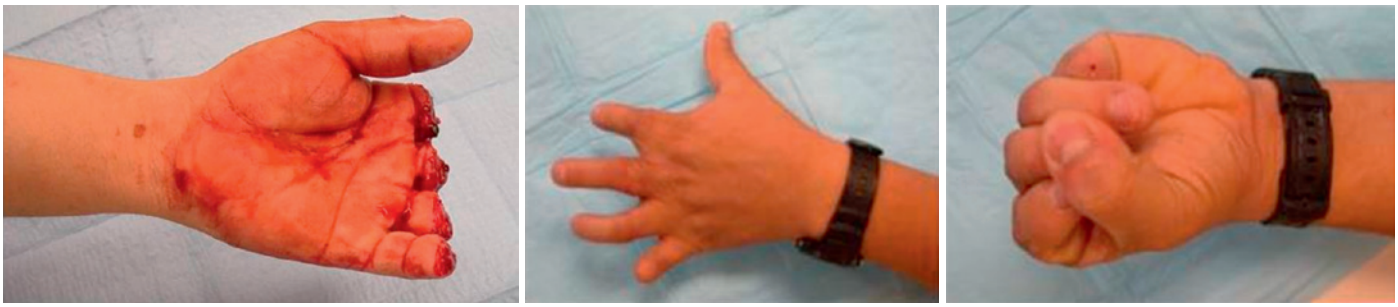

FIGURE 42.2 Example of indication for replantation: multiple-finger amputations. Note the significant shortening of all digits to achieve primary nerve coaptation. Despite the shortened length, the replantation is a functional success.

and elbow. Contraindications for replantation include medical instability that would make lengthy surgical intervention excessively risky. Relative contraindications include single-digit amputations through zone 2 of the flexor tendon sheath, multilevel segmental amputations, and ring finger avulsion amputations. These are felt to be relative contraindications because the procedures are difficult to perform and satisfactory functional results are difficult to achieve. Reports of series of patients in these categories have been published demonstrating surprisingly good results, with authors questioning whether these conditions should be considered relative contraindications.[1,5,6,22,33]

A relative indication for replantation is a single digit distal to the flexor digitorum superficialis insertion. Although the functional loss from such an amputation in a digit other than the thumb is not great, surgical replantation of such an amputated digit can be performed quite speedily and the functional outcomes are good. Lack of involvement of the proximal interphalangeal joint and preservation of the flexor digitorum superficialis insertion will likely provide good proximal interphalangeal motion and an overall satisfying functional result even without significant return of distal interphalangeal flexion. For this reason, amputations at this level are felt to have a more favorable prognosis than those through zone 2 (Figure 42.3).

Special consideration should be given to major replantation cases. Good functional outcomes can be achieved with replantation through the midpalm, wrist, and forearm. The more proximal the amputation, however, the less promising will be the result because of the amount of nerve regeneration needed to achieve protective sensation and the potential for stiffness of the elbow joint; also, myonecrosis may occur in proximal replantation cases with a prolonged ischemia time.

The length of the ischemia time is a much less critical issue in digit-level amputations because muscle sensitive to ischemia is not present. At the level of the midpalm or wrist, the intrinsic muscles may be débrided if injured. If they are uninjured and are left intact despite a prolonged ischemia time, the resultant fibrosis and dysfunction may be manageable. In more proximal injuries, however, the muscle burden of an amputation through the proximal forearm or transhumeral level is quite significant. In these cases, the ischemia time becomes paramount.

Digit replantation is considered feasible if the warm ischemia time is limited to 6 to 12 hours. With a well-preserved, cooled part, cold ischemia can likely be tolerated for up to 24 hours after digital amputation prior to replantation.[28] Sporadic cases of delayed digit replantation have been reported after 33 hours and 94 hours of warm and cold ischemia, respectively.[9,45] Successful hand replantation has been reported in one case after 54 hours of cold ischemia.[42] The limits of tolerated ischemia time in distal amputations are thus poorly defined. Indeed, Lin and colleagues studied ischemia time in 31 cases of hand and finger replantation that exceeded 24 hours and found no correlation between ischemia time and postoperative outcome.[28]

In amputations involving the forearm, even 2 to 3 hours of warm ischemia time can result in substantial muscle necrosis, which can produce a coagulopathy after reperfusion. Venous outflow from the reperfused extremity contains toxic compounds such as oxygen-free radicals that can cause tissue damage and vasospasm. In these cases, cooling the amputated

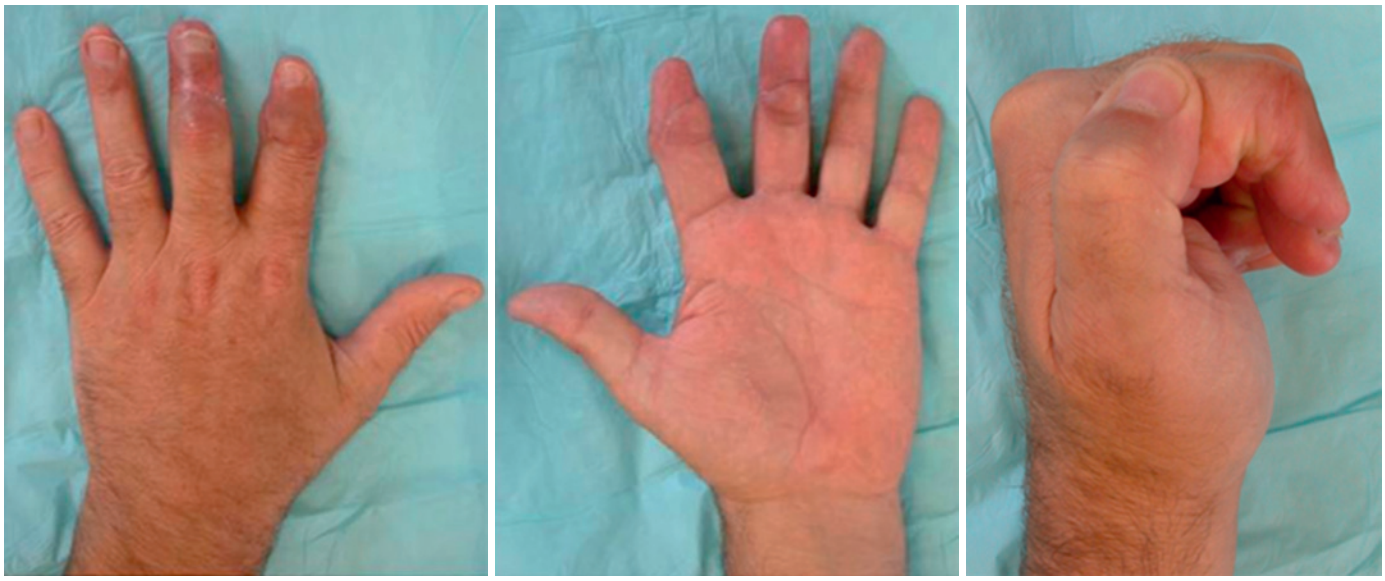

FIGURE 42.3 Example of replantations performed distal to the flexor digitorum superficialis insertion. Despite achieving no significant distal interphalangeal motion, the replantation is a functional success because of the preserved proximal interphalangeal motion.

part (to 4°C) can dramatically prolong the time between injury and successful replantation. Cooling must be performed to the appropriate level because excessive cooling below 4°C can cause formation of intracellular crystals that can cause tissue damage similar to frostbite.

Properly cooled parts have been replanted up to 36 hours after the time of injury; however, the survival rate of an amputated part decreases with the delay to replantation.

It is these considerations of muscle burden, ischemia time, distance of required nerve regeneration, and degree of skeletal injury, as well as the mechanism of injury, that need to be considered in every case of major replantation.

Technical Considerations in Preparing for Replantation

Whether at the digit level or transhumeral level, replantation is best performed with a team effort. The efficiency, speed, and quality of replantation are enhanced using a team approach. Two teams enable simultaneous work on the amputation stump and the amputated parts. In lengthy cases (such as multiple-digit amputations), the team model allows surgeons to work in shifts; each shift of well-rested surgeons works with a fresh perspective and relieves the fatigued surgeons on the shift before them.

This approach should be used as soon as the decision to operate has been made. The amputated parts should be brought to the operating room so that débridement, dissection, and preparation can begin before the patient arrives in the operating room. This will minimize the patient's anesthesia time and allow the surgical team to assess the quality of the part and thus the likelihood of replantation or technical requirements.

INTRAOPERATIVE TECHNIQUE

Preparation of the Amputated Part

The amputated parts are treated with a surgical prep solution and placed on a back table with full sterile technique. Midaxial incisions are made on both the radial and ulnar sides of the digit. The volar and dorsal skin flaps are elevated. The neurovascular bundles are dissected in the radial and ulnar sides and assessed for their quality, caliber, and length. The flexor tendon is prepared with a locking 3-0 suture, with the loose ends protruding through the severed end of the tendon. The extensor tendon is elevated but is not affixed with sutures. The bone is shortened generously to enable primary nerve coaptation. Osseous shortening is preferentially performed from the level of the amputated part so that failure of the replantation would not result in excessive shortening of the amputation stump. If the shortening of the bony structure requires resection back to the adjacent joint, the joint is prepared for arthrodesis by removal of the cartilage and subchondral bone and preparation for a cup-and-cone relationship between the amputated part and the stump.

Anticipated osseous fixation is prepared. This is usually performed with longitudinal nonparallel Kirschner wires driven from proximal to distal in an antegrade fashion through the tip of the digit and then recessed to the level of the proposed osteosynthesis site. Pin balls are applied to the Kirschner wires and protrude through the tip of the digit so that they do not constitute a hazard to the surgeon during the remainder of the operation. The pin balls will later be removed, and the pins driven retrograde to achieve fixation.

We usually remove the nail plate at the time of digit preparation and discard it. This can be helpful if the digit demonstrates venous insufficiency following operation and requires heparin pledget application in the nail bed or leech application. This will avoid the need for nail removal at the bedside in an awake postoperative patient.

An attempt is made to separate the nerves and arteries as minimally as necessary for assessment and preparation. Preserving surrounding subcutaneous tissue may minimize desiccation thoughout the case.

The vessels need to be assessed with a microscope to evaluate the intima in the lumen. Avulsive injuries will often cause

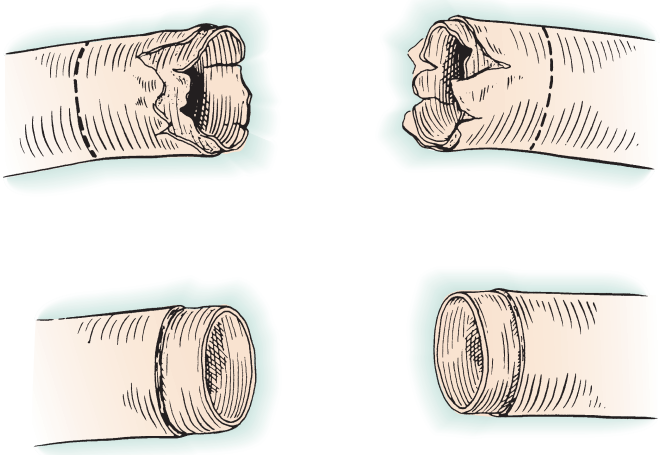

FIGURE 42.4 Damaged microvessels must be sharply incised back to completely normal intima. The intima should be evaluated under magnification through the operating microscope.

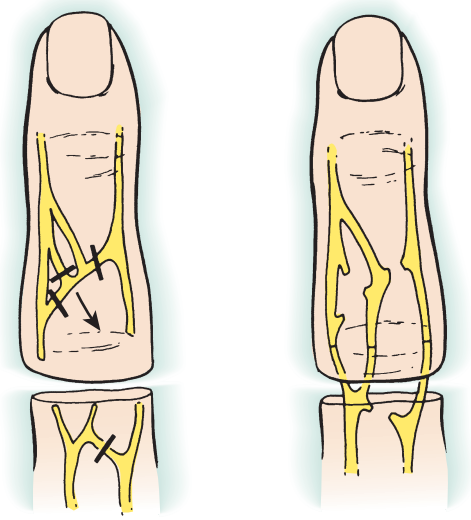

FIGURE 42.5 Vein dissection. The mobilization or harvesting of veins is a useful method of obtaining ease of approximation for vein reconstruction in a complete amputation.

significant dissection of the vessel wall layers or fracturing of the intima near the zone of injury (Figure 42.4). This will require resection of the distal vessel until a normal vessel is observed. If a single arterial reconstruction is being performed, the distal vessel of better quality will be used. This can be performed in a crossover fashion to the contralateral digital artery if length and caliber facilitate it. Additionally, the second distal artery could be considered as a source of venous outflow if no dorsal veins are available, so this vessel should be preserved in the field, and both vessels should be dissected in preparation for replantation.

In the dorsal subcutaneous fat, the veins are assessed. This is also performed with the least amount of initial dissection of the veins possible. The quality and number of available veins are assessed under the microscope.

Preparation of the digit can sometimes be difficult if the surgeon does not have an assistant available. Placement of the longitudinal Kirschner wires can facilitate unassisted dissection. The nonparallel Kirschner wires protruding through the tip of the digit can be held stable with a surgical clamp to prohibit pronation/supination of the part during dissection.

Preparation of the Hand

Information about the osseous level of shortening is shared by the surgical teams. If arthrodesis of either the proximal interphalangeal or distal interphalangeal joint will be performed, the amputation stump is fashioned into a convex cone configuration in preparation for the arthrodesis. If extraarticular fixation is planned, the bone may be prepared so that it is aligned to simplify reduction. The simplest configuration is a transverse osteosynthesis site so that fixation and rotational alignment can most easily be achieved.

The proximal tendon is prepared by retrieving it through the fibroosseous sheath, resecting the edge back to a healthy transverse tenotomy, and preparing it with a 3-0 locking suture similar to the preparation of the distal flexor tendon.

The dorsal extensor tendon is elevated and prepared but does not require presuturing for preparation. The radial and ulnar neurovascular bundles are assessed via radial and ulnar midaxial incisions, and the dorsal skin is elevated with subcutaneous fat for preparation of the veins. A microscope is brought into the field at this point to assess the vessels. Considerations about the quality of the proximal vessels are the same as those described for the distal part. Ultimately, the quality of the proximal artery will be determined by the spurt test, which is performed after the tourniquet is released.

The digital nerves are resected back to a healthy fascicular pattern with great care taken to attempt to achieve primary nerve coaptation after osseous shortening.

Dorsally, the veins are assessed. The proximal veins are usually easier to find and prepare than the distal veins because of their larger caliber. If additional length is needed for vein coaptation, side branches may be ligated to elongate and transpose veins to reach the anastomosis site (Figure 42.5).

It should be noted that the preparation of the amputated part is typically done under tourniquet control. For this reason, all of these processes in preparation of the amputation stump and ultimate replantation should be done as efficiently and rapidly as possible. The surgeon needs to assess, prepare, and plan each sequential phase with a premium placed on speed and a constant awareness of the duration of tourniquet time that has elapsed.

Replantation

Different surgeons favor significant variations in digital replantation technique. There is not a consensus about the "correct" way to perform replantation because there are benefits with many different strategies. Several common concepts are seen in all of the techniques, however.

If multiple digits have been amputated, it is always more efficient to perform the replantations sequentially. For example, the osseous structures in all digits may be addressed and replanted prior to moving forward with the tendinous structures. In this way, structures that are best repaired during tourniquet control can be repaired rapidly digit by digit and structures that are more easily addressed with tourniquet release can also be repaired digit by digit.

Structures that require microscopic procedures are generally repaired last so that the delicate repairs are not damaged by the more disruptive tendon or bone repairs.

The tourniquet time also influences the sequence of events because some procedures may require tourniquet control and others are easily performed without the benefit of a tourniquet.

In our center, we perform digital replantations in the following sequence:

Under tourniquet control we perform osseous fixation, extensor tendon repairs, flexor tendon repairs, digital nerve repairs under the microscope, and dorsal vein repairs under the microscope if time permits.

After tourniquet release we perform any remaining dorsal vein repairs that have not been performed under tourniquet control, arterial repairs under the microscope after adequate inflow has been ensured, and loose approximation of skin.

There are many reported variations in the sequence of the structures repaired in digital replantation. Some surgeons prefer to repair all dorsal structures (extensor tendon and veins) first, followed by all volar structures (flexor tendons, digital nerves, and arteries), for the benefit of positioning efficiency. Other surgeons will purposefully plan the vein repairs last in an effort to achieve arterial inflow first. Surgeons who advocate this technique have reported the benefit of arterial inflow in assessing and locating dorsal veins with the engorgement of venous return. Lastly, some surgeons have advocated repairing flexor tendons before extensor tendons because they feel they are better able to reproduce the position of the replanted digit within the cascade of the hand.

A particular note should be made of the sequence of events for major replantation. When a significant muscle burden exists in the amputated part, the degree of urgency in achieving perfusion is significantly more acute than with a digital replantation. In this case, most surgeons would advocate moving toward arterial repair as quickly as possible. In our center, if we feel that the part was managed with appropriate cooling and has been brought to the operating room with a very short ischemia time, we will perform osseous fixation first in an efficient and rapid manner and then move toward arterial reconstruction. However, if either ischemia time or temperature has been compromised and we feel that there is extreme urgency in achieving revascularization, we will elect to use an artificial arterial shunt. Shunts rapidly achieve distal perfusion by cannulating both the proximal and distal ends of the vessel(s) requiring repair (Figure 42.6). In this setting, a catheter is placed both proximally and distally and is secured, usually with insufflation of balloon cuffs. This can be further secured with an exterior suture ligation of the vessel on top of the shunt to achieve a watertight seal. After arterial inflow is established, the extent of venous bleeding is assessed. A second shunt may be used in the venous system so as to minimize the amount of blood loss. If the muscle burden

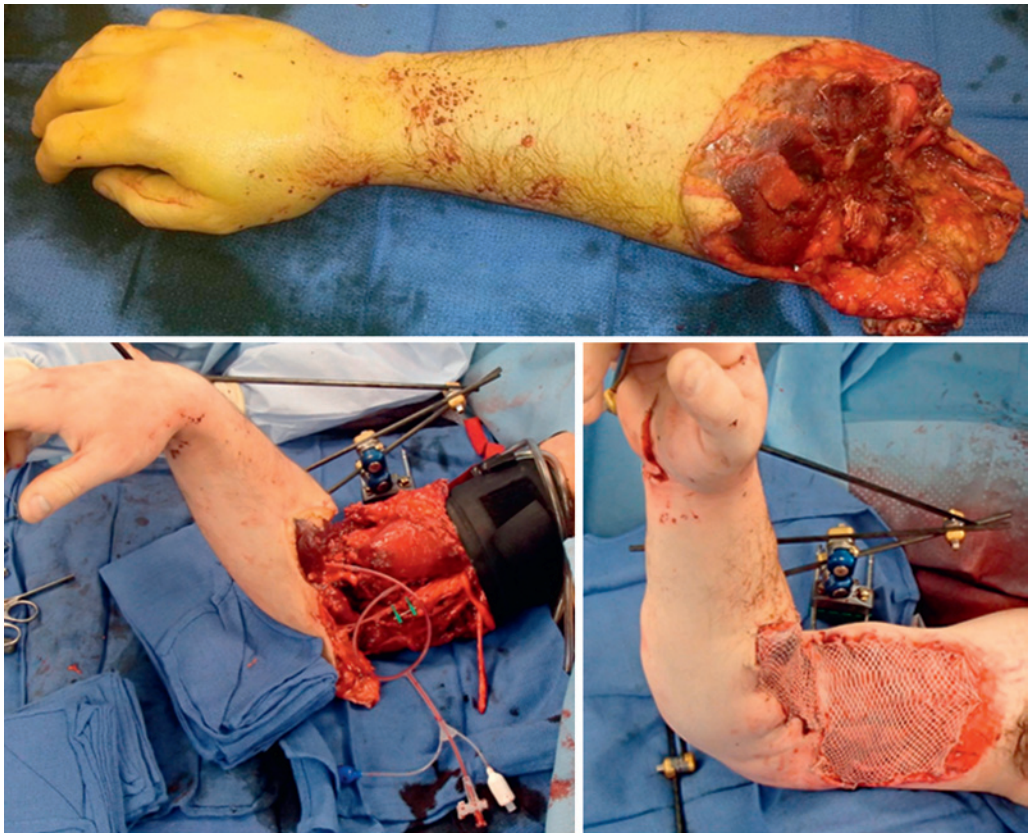

FIGURE 42.6 Example of "major replantation" of amputation through the elbow joint. Due to the significant muscle burden of the amputated part, this arm was replanted with rapid placement of an external fixator followed by the use of an arterial shunt to reperfuse the part. While the shunt was in use, additional steps in the replantation procedure were completed (i.e., repair of tendons and nerves, fasciotomies). Because the sharp amputation preserved much of the elbow joint, skeletal shortening was not favorable. Primary nerve coaptation was achieved with elbow flexion and nerve transposition.

of the amputated part is significant, the anesthesiologist must be prepared to address this with appropriate hydration and fluid cardiovascular monitoring.

We attempt to reperfuse for 20 minutes for every hour of ischemia sustained prior to reperfusion. When this is achieved, one can consider removal of the shunts, exsanguination, and tourniquet application so as to move forward with the rest of the replantation procedure under tourniquet control. Within this time frame, the team may rapidly achieve osseous fixation (typically, plating of the radius, ulna, or humerus or external fixation if there is a significantly complex intraarticular amputation through the elbow). The surgeon may proceed with repair of additional structures such as tendons and nerves with the shunts in place as reperfusion time requires.

Osseous Fixation

At the level of the digit, osseous fixation has often been performed with nonparallel longitudinal Kirschner wires driven retrograde after they had previously been placed in the prepared amputated digit. They can be driven across an osteosynthesis site in a phalanx or across a planned arthrodesis site. Although there is a sense of the need for speed and urgency in these cases, one should always take great care to assess for malrotation or angulation. A successful replantation can be made a functional failure with poor osseous alignment.

Other techniques that have been advocated include interosseous wiring, screw fixation, and plate fixation. Although these techniques provide a more stable construct than longitudinal Kirschner wires, they also require more operative time and, more importantly, more significant osseous exposure. Attempts should be made to minimize soft tissue stripping of the area surrounding the osteosynthesis site. A useful technique that provides stability with minimal stripping is interosseous wire fixation. This is particularly useful when replantation is performed very close to the proximal interphalangeal joint line. Interosseous wire technique, although somewhat more time-consuming than Kirschner wire fixation, can enable the surgeon to avoid hardware crossing the proximal interphalangeal joint.

When performing thumb replantation, the longitudinal Kirschner wire technique may also provide additional benefits. These amputations commonly occur in the region of the metacarpophalangeal joint where the ulnar digital vessels are difficult to visualize with the microscope regardless of hand positioning. In this setting, initial fixation is achieved by driving one of the two prepared Kirschner wires across the osteosynthesis site and leaving the second wire in position at the margin of the osteosynthesis site. This permits the surgeon to temporarily hyperpronate the distal thumb. The surgeon may elect to access the distal ulnar digital artery for primary anastomosis or vein graft distal anastomosis in this position. When this is complete, the thumb may be rotated into anatomic position on the single wire. When rotation is deemed accurate, the perched second wire may be cautiously driven across the osteosynthesis site, completing the fixation and controlling rotation.

Extensor Tendon Repairs

Extensor tendon repairs are rapidly performed with figure-of-eight 3-0 braided permanent sutures. This is usually performed in an attempt to coapt the tendons tightly so as to diminish the degree of extensor lag experienced postoperatively.

Flexor Tendon Repairs

Flexor tendons are repaired using the preaffixed locking sutures. This configuration will leave two 3-0 caliber suture ends protruding through the tenorrhaphy site distally and an additional two suture ends protruding through the tenorrhaphy site proximally. This will result in two knots within the repair site. If the sutures have been tied with this configuration, a two-core suture tendon repair would be achieved. Alternatively, a four-core repair can be achieved by passing the needle from each of the protruding sutures through the opposite tendon with a locking suture technique, returning to the tenorrhaphy site, and completing the suture knots. This results in a four-core, two-knot tendon repair that can be augmented with an epitendinous suture if desired by the surgeon.

Management of the flexor digitorum superficialis tendon in zone 2 replantations is optional. We typically perform digit replantations using FDP tendon repairs only.

Digital Nerve Repairs

Under microscope control, the digital nerves are assessed. We prefer to perform this with the benefit of tourniquet control. The nerves are resected back to healthy fascicles and primarily coapted if possible. Primary coaptation of the nerves is an important benefit of osseous shortening. The functional success of a successfully replanted part will often be determined by the level of sensation that is regained. For this reason, this step should be performed carefully and all attempts should be made to achieve primary nerve repair.

Great emphasis should be given to primary nerve coaptation in the setting of major replantation. At the transhumeral, transelbow, or transforearm level, bony shortening should be pursued if possible to focus on primary nerve coaptation because this will play an even more critical role in the ultimate functional success or failure of the replantation.

Digital Vein Repairs

Venous repair is often the most technically challenging and critical aspect of digital replantation. As many venous anastomoses as possible should be performed in a tension-free manner without the need for interpositional vein grafts. In zone 1 replantations, this is particularly challenging. Finding dorsal veins of reasonable quality may be impossible, and one should consider assessment of the volar pulp for superficial volar veins as well as use of the second digital artery for venous outflow if no distal veins can be located.

CRITICAL POINTS ***Techniques for Locating Distal Veins for Replantation***

- Elevate the fibrofatty tissue deep to the dermis and superficial to the extensor tendon; inspection of this translucent layer against operative lighting allows the surgeon to identify the dorsal veins.
- Perform a dorsal midline longitudinal incision and attempt to visualize the veins while raising the skin flaps in a subdermal plane.
- Perform arterial anastomoses and release the clamps on the arteries prior to performing venous anastomoses; engorgement of dorsal veins will make finding their locations easier.

Arterial Repairs

Even with adequate microscopic investigation of the proximal artery, it can be difficult to determine the adequacy of ultimate inflow from an artery without releasing the tourniquet and checking a spurt test. If the spurt test is inadequate, the artery can be resected proximally to a less damaged vessel. Prior to excessive resection, however, the surgeon should always consider topical vasodilators, including warm saline, papaverine, and lidocaine, to relieve vasospasm and provide an adequate assessment of the inflow capability of the proposed artery.

Primary arterial coaptation can be performed in an anatomic fashion from the proximal-to-distal artery as existed prior to injury, or it can be performed in a "crossover" fashion (i.e., the ulnar digital artery to the digit may be anastomosed to the radial digital artery distally). This technique may be problematic, however, if the patient requires further surgery (i.e., tenolysis) in the future which could interrupt the vascular supply to the finger. Interpositional grafting of the artery reconstruction permits the surgeon to resect out of the zone of injury and perform a tension-free repair. The caliber of the veins on the volar aspect of the distal forearm is a good match for the caliber of the digital arteries. The dorsal hand veins and dorsal forearm veins are usually quite large for this task, as are the greater saphenous or lesser saphenous veins.

When performing an interpositional arterial or venous graft for the artery, it is technically easier to perform the distal anastomosis first. This is a smaller-caliber anastomosis and may have less dissectible length of distal artery and thus less mobility for the distal anastomosis. If performed first, the distal anastomosis may be more freely rotated to access the front and back vessel walls, and the vein graft may also be flipped distally after completing the front wall suturing to access the back vessel wall. Once the distal anastomosis has been performed, the vein graft can be repositioned into its anatomic location and the proximal anastomosis performed with relative ease.

Reperfusion

Prior to releasing the clamps, we will typically apply topical vasodilators, including warm saline, lidocaine, and papaverine, to the arteries and veins. The clamps are released on the artery first. If a vein graft is used, the distal clamps are removed first and the proximal clamps second. This allows rapid passage of the blood through the anastomoses and into the digit. Great vigilance should be used here in preserving a warm and nondesiccated environment for the recovering vessel because it will tend to go into vasospasm if traumatized.

We usually await substantial engorgement of the distal veins prior to releasing the clamps on the venous anastomoses. Venous thrombosis is in part instigated by stasis of blood underneath an area of intimal damage. In this regard, any passage of blood underneath the newly performed anastomoses would best be permitted when there is rapid flow of venous return. With all clamps released, the digit is continually warmed and kept moist. The digital tip is assessed for a Doppler signal as well as color and turgor. It is not uncommon for the digit not to demonstrate a Doppler signal in the operating room, but it will often develop an audible signal while the patient is recovering on the evening following surgery or the following day.

Skin Closure

It is of utmost importance that the skin closure be performed loosely. The dorsal and volar skin can be loosely approximated. With skeletal shortening, this can usually be performed without any difficulty. However, we typically leave the midaxial incisions wide open, even in the setting of exposure of the neurovascular structures. This technique will result in surprisingly successful delayed healing with minimal scarring. The tension provided by skin closure will place undue pressure on arterial and venous repairs in the postoperative period, particularly with postoperative swelling.

POSTOPERATIVE PROTOCOL

There are many postoperative protocols used by replantation surgeons. The frequency and vigilance of postoperative monitoring should depend on the surgeon's threshold for surgical reexploration or alterations in postoperative medical management. The surgeon, patient, and patient's family should have an extensive discussion postoperatively regarding the intraoperative findings, potential postoperative outcomes, and future plans. If the surgeon feels that if a thrombosis develops revision surgery would probably not be successful (because of the condition of the amputated part), the surgeon may elect to minimize postoperative monitoring and discuss the plan for postoperative success or failure quite clearly with the family and the patient. If a thrombosis were to develop and surgical reexploration would not be warranted, hourly vascular assessment would likely not be indicated. On the other hand, if the situation warrants exploration regardless of the difficulty of the initial operation (as with pediatric replantation, major replantation, or multiple-digit replantation), the surgeon may request frequent monitoring postoperatively so that if a thrombosis is detected, emergent reexploration can be performed rapidly and efficiently.

Postoperative adjuvant treatment varies in different centers. Use of topical heat (i.e., warming blanket, heat lamp, and heated room), as well as daily aspirin therapy, is nearly universal. Other antithrombotic medications such as dextran, heparin, or warfarin have not had significant efficacy, and their use is quite variable among replantation surgeons.[2,10,24,32]

Management of a failing replantation depends on the appearance and acuity of the changes seen during postoperative monitoring. If the changes in appearance, Doppler signal, or temperature are subtle and vasospasm is suspected, surgeons may try to control these influences nonsurgically. Indwelling analgesic catheters, release of constructive dressings, environmental warming, and pain control can provide limited improvement if vessel thrombosis has not occurred.

Arterial ischemia due to microvascular thrombosis requires emergent reexploration and revision anastomosis if salvage is to be pursued. Resection of the thrombosed segment and vein grafting of the artery are usually required in this setting.

Venous congestion of a replanted digit may be discovered while arterial inflow is still present. The surgeon may elect to use heparin-soaked pledgets or leeches applied to the nailbed to diminish the venous pressure and maintain arterial patency. The patient and replantation team should anticipate using leeches for several days until the digit establishes new venous

drainage channels. This will require antibiotic therapy to cover *Aeromonas hydrophila*, a gram-negative bacteria that is normal intestinal flora in leeches. Blood transfusions are often needed after lengthy periods of treatment with leeches.

EXPECTED OUTCOMES

Reported survival rates of replanted digits have varied widely from 57 to 90%.[4,15,30,34,43,44] Factors with a negative impact on survival rates include mechanism of amputation (crush injuries faring poorly compared with sharp amputations), patient age, and smoking history. Surgical performance of more than one arterial anastomosis and more than one venous anastomosis also increases survival rates.[27,43,44]

Functional outcomes are most affected by the mechanism of injury (crush injuries faring least well), level of injury, and ischemia time. Replantations within zone 2 of the flexor tendon sheath have been shown to achieve dramatically less range of motion than those performed distal to the flexor digitorum superficialis insertion.[36,41] In a study of more than 400 digital replantations, sensory recovery of 8 mm was reported with replanted sharp amputations and two-point discrimination of 15 mm was reported with replanted crush avulsion injuries.[16] Overall, useful two-point discrimination was achieved in 61% of thumb replantations and 54% of digital replantations.

Functional outcomes as measured by the Disabilities of the Arm, Shoulder, and Hand (DASH) scores have been surprisingly good, with one study reporting average scores of 10 for thumb replantation, 11.2 for single-finger replantation, and 16.1 for multiple amputations where at least one digit was replanted.[11] DASH scores have also been better among replantation patients than amputation patients.[19]

Several studies have attempted to provide objective means of estimating outcomes and approaching the initial decision to pursue limb replantation proximal to the wrist. One large study demonstrated the functional superiority of replanted limbs over prosthetics.[18] Objective sensibility testing, however, was excluded as a measured outcome. Studies have demonstrated that younger age and replantation at more distal levels yielded significantly improved functional scores. The mechanism of injury and ischemic time have also been shown to be strongly predictive of functional outcome.[8,44]

FUTURE DIRECTIONS: VASCULARIZED COMPOSITE TISSUE ALLOTRANSPLANTATION

Since its origins in the 1960s, replantation surgery has been focused on improvement in microsurgical technique, postoperative vascular monitoring technologies, thrombosis prevention and management, and nerve repair/reconstruction and recovery. These improvements have been associated with small gains for a procedure still greatly limited in its reliability and functional results.

Our specialty, which has had astounding growth, is the promising new field of vascularized composite tissue allotransplantation (VCA).[20,23,31] Since the first modern-day hand transplantation in 1998, numerous transplantation teams have been assembled, with over 100 upper extremity transplantations performed in over 70 patients worldwide. Although the field seems similar to that of replantation surgery, the techniques are as distinct as the medical considerations. Because an amputated limb can be replaced with a nontraumatized part without compromised or absent skin/bone/nerve/vessel segments, some of the difficult aspects of replantation surgery that limit functional outcomes can be eliminated.

Many issues have been pivotal in the growth of VCA for hand surgery.[13] The first was the successful control of the immunogenic response to allotransplantation of skin; earlier-generation transplantation immunotherapy protocols had indicated that this was not achievable. The second has been unexpectedly favorable results of sensory and motor nerve recovery in transplantation. It has been confirmed experimentally that a commonly employed immunosuppressive medication, FK-506 (tacrolimus), accelerates nerve regeneration.[26,40] This may have contributed to encouraging reports of motor and sensory recovery of transplanted limbs.

Many centers for upper limb transplantation have been established worldwide. Efforts have been made to provide improved communication and exchange of experience and data among these centers. Scientific societies have been established for the advancement of the field. Despite these collaborations, the functional outcomes and risks of these endeavors remain poorly defined. Centers around the globe are not uniform in their methods of measuring success or their transparency in reporting. Furthermore, the field is so new that only speculative predictions can be made about long-term outcomes and lifetime risks.

In a recent comprehensive review of the worldwide upper extremity transplantation experience to date, Shores and colleagues provided an assessment of mortality rates, limb survival rates, and functional outcomes.[39] The overall limb survival rate is 77.6%. In close assessment of all of the databases, however, it appears that rates of limb loss and/or mortality are especially high in Chinese transplantation centers (7 losses of 15 transplanted limbs). The authors speculate that this is due to lack of patient access to immunosuppressive medications or to noncompliance. They also note that *multisite* transplantations (e.g., of the hand and face or the hand and lower limb) accounted for eight of the limb losses and three of the four reported surgical deaths worldwide in cases involving upper extremity VCA. These two subgroups accounted for 62.5% of the upper limb transplant losses. Excluding these two subgroups, the authors state that in cases of *isolated* upper limb transplantations (i.e., bilateral and unilateral cases without concomitant face or lower limb transplantations) in western Europe, Australia, and the United States, there have been no deaths and the limb survival rate has been 90.5% so far (7 limbs acutely or chronically lost or amputated of 74 transplanted limbs).

Assessment of global functional outcomes is limited by the multitude of grading systems employed by the different centers and the lack of applicability of these measures to hand transplantation. In attempting to correlate these outcome reports, Shores and associates[39] found that patients who had undergone distal forearm level transplantation had the best overall results, with measurable sensory discrimination, some intrinsic motor recovery, and the most rapid recovery times. Patients who had undergone midforearm and proximal forearm level transplantation had little or no intrinsic recovery, had protective and sometimes discriminative sensation, and had weaker overall grip strength. Finally, the smaller cohort of

transhumeral transplanted limb patients has had less return of extrinsic function than the cohort that underwent forearm level transplantation, and they cannot expect intrinsic recovery. Thus, functional results have diminished at more proximal levels, as would be expected. Interpretation of the value of these endeavors is subject to debate. Those in favor of the more proximal transplantations view the outcomes as favorable when compared with prosthetic function, use, and durability and view the functional results as markedly improved over the patient's presurgical state. Critics of proximal transplantation question the risk and benefit balance in light of the speculated long-term risks of immunosuppression.

The evolution of immunosuppressive medication regimens is directed toward the goal of minimizing morbidity. Experimental efforts are focused on achievement of immunotolerance with less medication or no lifelong medication.[12,35,37] If the side effect risk profile of the immunosuppressive medications is minimized, a more widespread acceptance and incorporation of this modality will be likely. The success of these strategies will dictate the pace and success of this field in years to come.

CRITICAL POINTS *Digit Replantation*

- No indication is absolute; the most compelling indications are thumb amputations, pediatric digit amputations, and multiple-digit amputations.
- Surgical preparation of the amputated part should begin in the operating room long before the patient arrives to provide a surgical prognosis, increase efficiency, and limit surgical time and anesthetic risk.
- Osseous shortening should be dictated by the length of nerve defects, with a goal of achieving primary nerve coaptation.
- Arterial repairs should be assessed critically to avoid repairs within the zone of damaged intima; liberal use of vein grafts and possible transposition of vessels (i.e., anastomosis of the proximal ulnar digital artery to the distal radial digital artery) should be considered to obtain optimal results.
- Repairs that require microscope use are generally performed last because of the delicacy of the repairs and the benefit of tourniquet release to assess vascular inflow (spurt test).
- In multiple-digit replantations, repairs are performed in a structure-by-structure sequence, not a digit-by-digit sequence (e.g., osseous fixation is achieved in all digits, followed by tendon repairs in all digits).
- In multiple-digit replantation cases, the quality of amputation stumps and amputated parts may suggest advantages in replanting digits in ectopic positions (i.e., index finger replanted in middle finger position).

CRITICAL POINTS *Major Limb Replantation*

- Operative indications should be assessed rapidly; it is critical to assess the anesthesia risk, amount of blood loss, nerve regeneration potential, and functional deficit with replantation and revision amputation at the level of injury.
- A larger muscle burden makes the ischemia time critical.
- Vascular shunts can be used to rapidly reestablish arterial perfusion and limit ischemia to the distal part.
- Osseous fixation may be attempted before, during, or after temporary shunt reperfusion, depending on the duration of cold or warm ischemia.
- Consider distal compartmental releases if needed in anticipation of swelling after reperfusion.
- Osseous shortening should be dictated by the length of nerve defects, with a goal of achieving primary nerve coaptation.

Mangled Upper Extremity

Jeffrey B. Friedrich and Nicholas B. Vedder

Acknowledgment: We would like to recognize our friend and partner Douglas P. Hanel, MD, who was a coauthor on the 6th edition version of this chapter. His contributions to it, and to hand surgery in general, are innumerable, and we are proud to have him as a partner.

PRINCIPLES

Mangling injuries of the hand and upper extremity are, by definition, devastating injuries that involve multiple critical structures of the fingers, hand, arm, or any combination of the three and nearly always lead to significant disability, both directly and through their psychosocial impact. Such injuries can have a dramatic influence on patients' livelihoods and ability to carry out activities of daily living. Because the forces involved in producing mangling injuries of the upper extremity are often great, serious injury to other organ systems and/or other areas of the body are generally also present and nearly always take precedence over extremity injury management.

CRITICAL POINTS *Goals in Treating Upper Extremity Mangling Injuries*

- Preserve life
- Preserve tissue
- Preserve function
- Reconstruct and restore function of both the extremity and the patient

Mangling injuries generally include all or nearly all of the major functional systems of an extremity, including skin and soft tissue, vascular, nerve, muscle and tendon, bone, and joint (Figure 43.1). It is because of this multisystem injury involving all or nearly all layers of the extremity that ultimate function is so much at risk. Despite the best attempts at reconstruction, a scar will form from the skin down through bone and compromise the function of all structures involved and the extremity overall. Peacock elegantly described this as the "one wound–one scar" concept (Figure 43.2).[82,83]

This variable involvement of multiple tissue layers and critical, interdependent structures and systems and the disabling result of the "one wound–one scar" concept led to the "combined injuries" model described by Büchler and Hastings.[17] The eventual impact of the scarring process must therefore be kept in mind throughout planning and reconstruction. Minimizing the negative effects of this process dictates the following general principles in the management of mangling injuries:

- Complete debridement of devitalized tissue
- Restoration of good vascularity
- Rigid skeletal fixation while minimizing additional soft tissue injury
- Stable, vascularized soft tissue coverage

By following these principles, one can allow early mobilization of the extremity, thereby minimizing the impact of "one wound" scarring and maximizing ultimate motion.

The multisystem nature of mangling injuries demands knowledge and expertise in multiple disciplines related to trauma and reconstruction, including trauma surgery, orthopedic surgery, vascular surgery, and plastic surgery, and often benefits from a multispecialty team approach. Because of the diverse nature of mangling injuries, no two cases are alike; in general, there is no single "preferred approach." Rather, a set of principles is determined to guide the surgeon through the application of multiple approaches and techniques that address each of the involved systems while keeping in mind the impact of various treatment decisions on the comprehensive reconstructive plan and final outcome. Many of the specific operative approaches are detailed elsewhere in this textbook, and therefore this chapter concentrates on principles, judgment, and timing.

What is here is an outgrowth of two chapters in a previous edition of this text, "Open Injuries of the Hand" and "Combined Injuries," to which the authors refer the reader as excellent resources on the topic of mangling injuries of the hand,[14,17] as well as several other excellent reviews.[7,11,41,77,85] Sometimes amputation is the most appropriate treatment, and the choice between amputation, partial amputation, and salvage with reconstruction requires looking into the "crystal ball" that shows 6 to 12 months in the future in an attempt to predict the patient's overall function. Which of the various treatment choices is appropriate? After determining that, then a comprehensive reconstructive plan that includes both short- and long-term objectives must be formulated. Optimal management of a mangled extremity is therefore one of the most challenging aspects of hand surgery; it requires a broad knowledge and facility with various techniques and the judgment and experience to know when and how to apply them. It is a true test of one's mastery of the "art" of hand surgery.

CLASSIFICATION

There have been various attempts by hand and upper extremity surgeons to classify mangling hand injuries, but none of the classification systems is predominant. In 1990, researchers in Seattle published the Mangled Extremity Severity Score (MESS), which used objective criteria to predict lower extremity amputation following trauma.[51] Although attempts have been made

CRITICAL POINTS *Factors Necessary to Optimize Ultimate Function*

- Careful and complete evaluation of the injury in which all functional systems are addressed
- Formulation of a comprehensive reconstructive plan tailored to the patient's needs
- Thorough but careful wound debridement of all devitalized tissue
- Meticulous operative reconstruction, often including secondary procedures
- Restoration of good vascularity
- Rigid skeletal fixation while minimizing additional soft tissue injury
- Stable, vascularized soft tissue coverage
- Comprehensive rehabilitation of the extremity and the patient

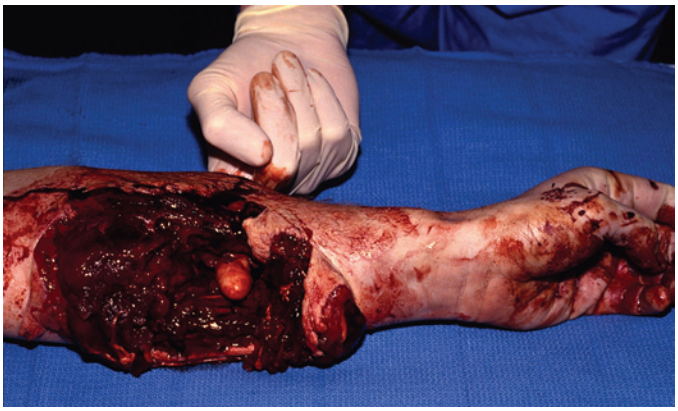

FIGURE 43.1 A mangling injury typically involves all or nearly all of the major functional systems of the extremity, including skin/soft tissue, vascular, nerve, muscle/tendon, bone, and joint.

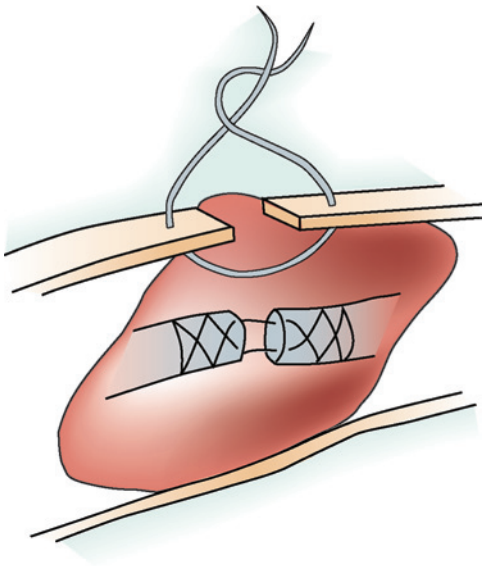

FIGURE 43.2 Classic figure depicting the "one wound–one scar" concept described by Peacock. Despite the best attempts at reconstruction, a scar will form from the skin down to bone and compromise the function of all structures in between and the extremity overall. (Reprinted from Peacock EE, Jr, Van Winkle W, Jr: *Surgery and biology of wound repair*, Philadelphia, 1970, WB Saunders, with permission.)

to apply the MESS to upper extremity mangling injuries, the scoring system in general has not proved helpful in predicting which extremities should be amputated and which should be salvaged.[4,96] One of the reasons why this scoring system is not entirely useful for the upper extremity is that it is not a weight-bearing extremity; therefore, upper extremities with a MESS score of 7 or greater (which in the original study was a predictor for amputation) can often be salvaged and be somewhat useful. Other classification systems, such as the Hand Injury Severity Score (HISS), have emerged, and while they have some utility in predicting time lost from work, they have not been helpful in predicting amputation.[21,107]

MECHANISMS AND PATHOPHYSIOLOGY OF INJURY

A wide variety of mechanisms can produce mangling injuries, including industrial and agricultural machinery, motor vehicles, power tools, explosives, and firearm mechanisms. Most mangling injuries involve some component of a crush injury whereby multiple tissue layers and anatomic systems are injured or destroyed. Certainly, crushing and blast injuries, with their extensive tissue destruction and associated late scarring, are far more difficult to reconstruct and portend a worse outcome than do sharp injuries. As a result of the immediate and delayed tissue necrosis with crushing injuries, the risk for infection is increased, and it often compromises the reconstructive plan. Degloving or avulsion injuries are also frequently mangling in that they involve amputation or partial amputation of one or more critical tissue layers: skin, vessel, nerve, tendon, bone. Abrasion and burn injuries, depending on the extent and depth of involvement, can also be significant components of mangling injuries.

It should be obvious that mangling injuries frequently result in severe wound contamination, depending on the environment and specific mechanism by which they occur. Farming injuries in particular are usually associated with major contamination and require more extensive and often serial debridement and irrigation and special consideration in planning antibiotic management.[36] The combination of a contaminated injury environment with deep, open crushed and devascularized tissue is a dangerous scenario for major life-threatening infection if not recognized and appropriately managed.[75]

A constant element in most mangling injuries is tissue devascularization, which can occur at multiple levels. Crushing, avulsion, degloving, or blast injuries can disrupt major vessels or the branching perforator vessels to muscle and skin, or they can produce endothelial injury that results in thrombosis of large and small vessels, including the microcirculation. Crushing can also cause direct cell disruption and tissue necrosis. Different tissues are more or less susceptible to crushing, with vessels, fat, muscle, and skin being the most severely injured with crushing, in that order. Nerve is unique in that it is often the last structure remaining physically "intact" after a crush or avulsion injury, yet axons themselves are quite susceptible to crushing or stretching, which can lead to a difficult dilemma in distinguishing neurapraxia from axonotmesis in the early stages. Tendon, ligament, and bone tend to be more resistant to crushing/avulsing forces; nevertheless, partial injuries to tendon and ligament can result in significant scarring and functional impairment that

can be minimized only by timely recognition and early and aggressive mobilization.

The metabolic changes after ischemia or traumatic flap elevation are numerous and extreme. Ischemic tissue undergoes a conversion to an anaerobic metabolism with rapid depletion of levels of oxygen, glucose, and adenosine triphosphate, along with a concomitant increase in levels of carbon dioxide and lactic acid. Prostacyclin and thromboxane levels are significantly elevated.[26,50] Associated with the conversion to anaerobic metabolism is the markedly increased production of toxic superoxide radicals.[2,49,50,67] Toxic oxygen radicals can cause direct cytotoxicity, but probably more important, they are a trigger for local acute inflammation, adherence and accumulation of leukocytes, and endothelial injury with the subsequent cellular events leading to microvascular compromise. Levels of the body's key protective enzyme, superoxide dismutase, are decreased in ischemic tissues because the enzyme is consumed when converting superoxide to oxygen in a tissue protective mechanism.[70]

With reperfusion or reoxygenation, toxic metabolites, including superoxide and hydroxyl radicals, are produced, with subsequent tissue injury via two key mechanisms. The first is direct reaction of superoxide radicals with the endothelial membrane, which causes lipid peroxidation, disruption of membrane proteins, increased cell permeability, and consequently, cytoplasmic swelling and dysfunction. The second mechanism is a result of the chemotactic property of oxygen metabolites, primarily superoxide anion, which causes migration of neutrophils into the reperfused area, with the neutrophils actually causing tissue destruction.

There is evidence that a significant proportion of the tissue damage triggered by ischemia frequently may be a consequence of events associated with reperfusion of ischemic tissues (i.e., "reperfusion injury").[101] Rapid intravascular accumulation of neutrophils can lead to progressively decreased perfusion, which may be manifested as the "no-reflow" phenomenon[17,59] or, more precisely, a "diminishing-reflow" phenomenon associated with ischemia and reperfusion.[103] Crushed tissue and traumatically created tissue flaps are a model of "gradient" ischemia in that tissue is progressively ischemic from the base of the normally perfused tissue out toward the ischemic tip with an "ongoing" ischemia-reperfusion injury present. In this setting, too, neutrophil-mediated injury appears to play a major role in tissue necrosis.[102]

There are several mechanisms whereby activated polymorphonuclear neutrophils (PMNs) can cause injury in the setting of ischemia-reperfusion. First, adherent, activated PMNs can cause direct endothelial injury, resulting in the loss of vascular integrity, edema, hemorrhage, and thrombosis (Figure 43.3). Another possible mechanism involves microvascular occlusion and further ischemia resulting from adherence and accumulation of aggregates of PMNs within the vessel lumen. This progressive, inflammatory-mediated injury is largely responsible for the "zone-of-injury" phenomenon associated with mangling injuries; this is another constant element of them.

This concept recognizes that the extent of tissue injury and late scarring associated with a major force often extends well beyond the area of initial injury. The combination of local and regional ischemia, in addition to injury-induced inflammation and the resulting ischemia, extends the zone of tissue necrosis. The extent of the zone-of-injury depends primarily on the force that caused the original injury. This is a critical concept in the management of mangling injuries because it nearly always precludes immediate or one-stage reconstruction and dictates prudent reevaluation and repeat debridement of the wound 24 to 48 h after injury before definitive closure can be considered. The zone-of-injury and related inflammatory responses are also important in planning vascular restoration in the sense that

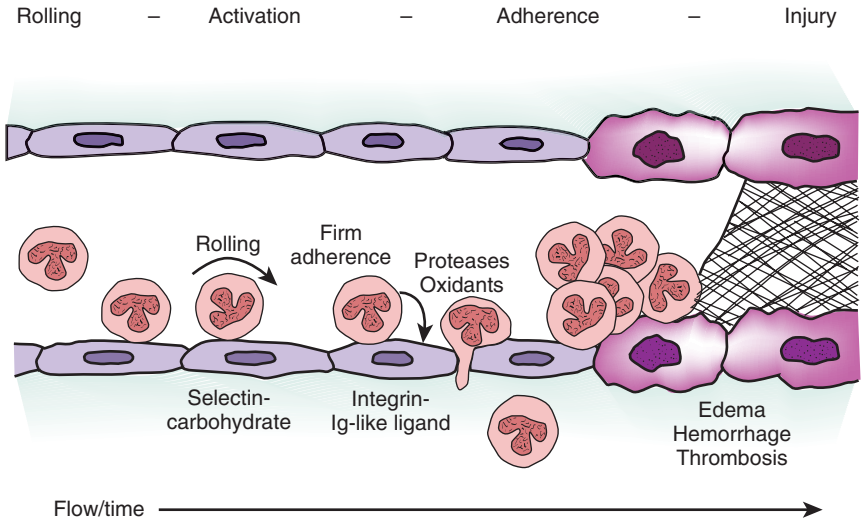

FIGURE 43.3 Diagrammatic representation of the sequential events that occur at a site of neutrophil-mediated microvascular injury. Initial selectin/carbohydrate-mediated rolling along the surface of the endothelium and tethering of neutrophils where local agonists then stimulate integrin-mediated firm adherence lead to neutrophil-mediated endothelial injury with loss of vascular integrity, edema, hemorrhage, and thrombosis. Another mechanism involves microvascular occlusion and further ischemia resulting from adherence and accumulation of aggregates of neutrophils within the vessel lumen. *Ig,* Immunoglobulin. (Reprinted from Vedder NB: Flap physiology. In Mathes SJ, Hentz VR, editors: *Textbook of plastic surgery*, Philadelphia, 2005, Elsevier, © 2003 Nicholas B. Vedder.)

reconstructions performed inside the zone are subject to direct and inflammatory-mediated endothelial injury that can lead to thrombosis of the vascular system.

INITIAL EVALUATION

Because mangling injuries of the hand and upper extremity are often associated with considerable force; it is not uncommon for the patient to have other significant and potentially life-threatening injuries. The mangling extremity injury, although frequently the most obvious, graphic, and visually compelling, rarely leads to loss of life. As always, one must look beyond the obvious extremity injury and evaluate the patient carefully for other serious injuries. The standard Advanced Trauma Life Support approach to any injured patient must be followed, with immediate attention to the airway, breathing, and circulation (ABCs), followed by primary and secondary surveys of the injured patient.[1]

History

As always, the key components of the medical history focus on the "when," "where," and "how."[14] The time of injury is critically important, especially when dealing with devascularizing injuries. Bone, integument, and muscle have, in that order, decreasing tolerances to ischemia, with muscle being able to survive only 4 to 6 h of it, even with the normal tissue cooling that occurs after ischemia.[100] In addition, the longer the duration from the time of injury, the greater the risk for infection, with delays greater than 6 to 12 h precluding primary closure or coverage. If ischemia is present, the temperature of the tissue during the ischemic period is critical inasmuch as extremity tissues devoid of muscle can be successfully revascularized after 12 to 24 h if kept cool. In fact, successful digit replantation has been reported at 94 h.[106]

The "where" of an injury is also important. Farming injuries, for example, tend to be highly contaminated and require more than the usual amount of aggressive debridement, which often precludes primary closure.[75] The presence of caustic industrial chemicals or other contaminated substances can also affect treatment choices. The social and economic aspects of the injury environment must likewise be weighed when planning treatment. A patient living in an area remote from an appropriate medical facility may not be able to follow through with the complex rehabilitation program required for a highly technical reconstruction and may be better served with a more straightforward reconstructive option.

Finally, the "how," or mechanism of injury, can help reveal the force of it and the extent of tissue necrosis or zone-of-injury to anticipate and address during treatment. Sharps injuries tend to involve a limited zone of tissue and are therefore easier to manage, unless the injury is tangential in nature. High-velocity, high-pressure crushing or avulsion injuries have a much broader injury zone and require a modified approach to treatment, which needs to consist of more extensive debridement, thorough evaluation of adjacent tissues, removal of foreign bodies, and assessment for and treatment of compartment syndrome.

The patient's overall health and comorbid conditions must be carefully evaluated in planning any type of complex or lengthy reconstructive procedure. The patient's age and the presence of cardiovascular disease, pulmonary disease, bleeding tendencies, or diabetes can greatly increase the risk for perioperative complications or even mortality; any of these should cause the surgeon to consider simplifying the reconstruction method or at least modifying perioperative treatment plans. Smoking or the use of other vasoactive drugs, such as cocaine, is generally a contraindication to any type of complex microvascular reconstruction.

Perhaps the most important aspect of obtaining a history is determining the patient's functional needs and goals. The age, occupation, socioeconomic environment, and social support systems should all be considered when formulating a treatment plan. Both the risks that the patient is willing to accept and the costs in terms of financial, emotional, and time must be considered. Willingness to endure a protracted reconstructive course and a patient's ability to follow through with the necessary hand therapy are important issues. A self-employed farmer, without workers' compensation insurance, will probably be interested in reconstructive options that offer an expeditious return to work and provide durable function suited for heavy work without multiple complex reconstructive procedures.

An office worker or technology professional may have very different goals and might be more willing and economically able to undergo multiple reconstructive procedures to restore optimal digit function to allow fine manipulation, keyboarding, and other such tasks. Again, the hand surgeon must make decisions based on personal knowledge and experience to try to predict the patient's ultimate function with the available reconstructive options so that the most appropriate option can be selected for that particular patient. Both the patient and the patient's family must be involved in this discussion, although this is often difficult to do when the patient has just suffered a mangling injury, so surgeons frequently must use their best judgment at the time by taking into account all the known variables.

Examination

Because examination of a patient with a severely mangled extremity injury that is wrapped in blood-soaked towels or bandages is often difficult in the emergency department, definitive evaluation often must wait until the operating room. Nevertheless, assessment of injuries to major structures, in particular vascular status, is essential in determining the urgency of definitive treatment and also important in the ability to discuss treatment options and prognosis with the patient and family. Usually, a general assessment of vascular status, sensibility, and muscle–tendon unit function, as well as radiographic evaluation, can and should be done in the emergency department. Preliminary evaluation will also allow adequate preparation of the operating room: microsurgical equipment and supplies, implants and fixation devices, traction and radiographic devices, and other necessities.

The most important system to evaluate is the vascular system of the extremity. Compromised vascularity of the digit or extremity, depending on the duration of devascularization, can dictate whether the digit or limb can be salvaged, whether fasciotomy is required, and the urgency of initiating treatment. Assessment of vascular status is best performed by direct inspection of the patient's affected tissues and comparison to adjacent or similar well-vascularized tissues. Although nail bed capillary refill is traditionally considered a good indicator of peripheral

perfusion, it is in fact a very unreliable indicator of perfusion. A completely devascularized digit can have what appears to be intact capillary refill beneath the nail bed when in actuality stagnant blood is merely being pushed to the sides with compression and then moving back to the center with release of pressure on the nail bed.

A far more reliable area to assess digit perfusion is the dorsal paronychial tissue on the sides of the nail, which should be pink and spongy and have good turgor, compressing with pressure and refilling with release (Figure 43.4). A pink color that returns within 1 to 2 s after the application and release of pressure indicates healthy tissue, whereas a pale color without capillary refill or turgor can represent arterial insufficiency. A dusky color with exceptionally brisk refill can be indicative of venous congestion. Probably the most reliable clinical indicator of tissue vascularity is the color of the blood that oozes from the tissue after sticking it with a needle or scalpel. Bright pink oozing reflects healthy tissue, whereas dark purplish oozing reflects compromised perfusion if it is sluggish or venous insufficiency if it is profuse. Obviously, this should not be performed on the sensate tissue of an awake patient but is often useful in an anesthetized one.

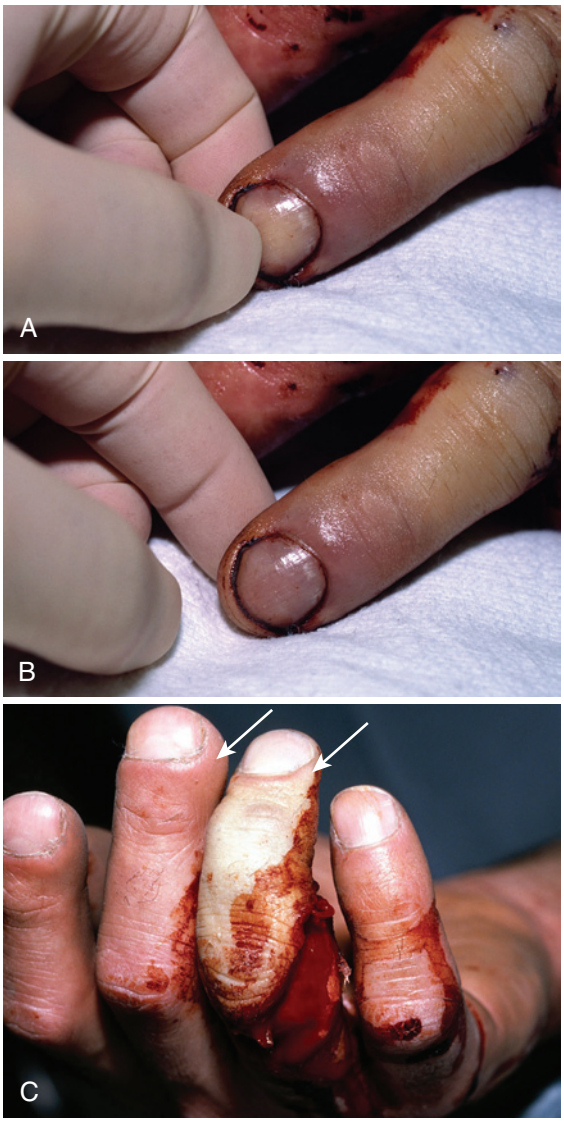

FIGURE 43.4 A completely devascularized digit can have what appears to be intact capillary refill beneath the nail bed when in fact stagnant blood is merely being pushed to the sides with compression **(A)** and then moves back to the center with release of pressure on the nail bed **(B)**. A far more reliable area to assess digit perfusion is the dorsal paronychial tissue on the sides of the nail, which should be pink and spongy and have good turgor, compressing with pressure and refilling with release (long finger, *arrow*), whereas a devascularized digit's paronychial tissue **(C)** will be pale and flat, without turgor (ring finger, *arrow*).

For assessing the status of the major vessels of the upper extremity and even the digital vessels, a handheld Doppler probe is very useful. The standard Allen test, performed by compressing either the radial or the ulnar artery and listening for a signal over the palmar arch or the most distant digital artery, can help determine whether either the radial or ulnar artery has antegrade flow and whether the palmar arch is intact. Angiography has a minimal role in mangling injuries of the forearm, hand, or fingers. In any mangling or crushing injury, a high index of suspicion for compartment syndrome must be maintained.

The diagnosis and treatment of compartment syndrome are covered in Chapter 51, but it is worth reinforcing the importance of recognizing the intense pain of it and, in particular, pain with passive stretch of muscle–tendon units. When suspected, the diagnosis is best confirmed by direct measurement of pressure in the muscle compartment, usually with a handheld device specifically designed for this purpose. The presence of compartment syndrome and attendant tissue ischemia warrants emergency decompression in the operating room.

Although obvious deformity, crepitus, or tenderness on examination can suggest underlying skeletal injury, evaluation of the skeletal system is generally performed radiographically. In most instances, standard plain radiographs are sufficient if care is taken, whenever possible, to ensure that emergency splints or traction devices do not obscure the underlying bones or joints. Sometimes, additional views are needed, including oblique views to assess articular congruity or stress views to evaluate ligament injury (e.g., a clenched fist view to evaluate intercarpal ligamentous integrity). In questionable cases, comparison views with the contralateral extremity, if uninjured, may be necessary.

With most mangling injuries, advanced imaging techniques, such as computed tomography (CT) or magnetic resonance imaging (MRI), are rarely indicated, although at times if the patient is stable, CT scanning of suspected carpal injuries or intraarticular displacement can be useful. If amputated parts are involved and replantation is contemplated, radiographs of the amputated parts should be obtained. Moreover, as always, the joint proximal and the joint distal to the area of injury must be evaluated (Figure 43.5). Ligamentous injuries can be identified by tenderness to palpation or to stress. Stability with the application of stress should also be reevaluated under anesthesia to remove any confounding effect of involuntary muscular splinting.

Evaluation of injury to muscle–tendon units is best performed by having the patient actively flex and extend the digits and wrist. In the presence of pain, and especially with underlying skeletal injury, this examination can be difficult to interpret. For the individual digits, noting aberrations in the normal resting cascade can indicate injury to the underlying flexor muscle–tendon unit. This simple observation can be performed

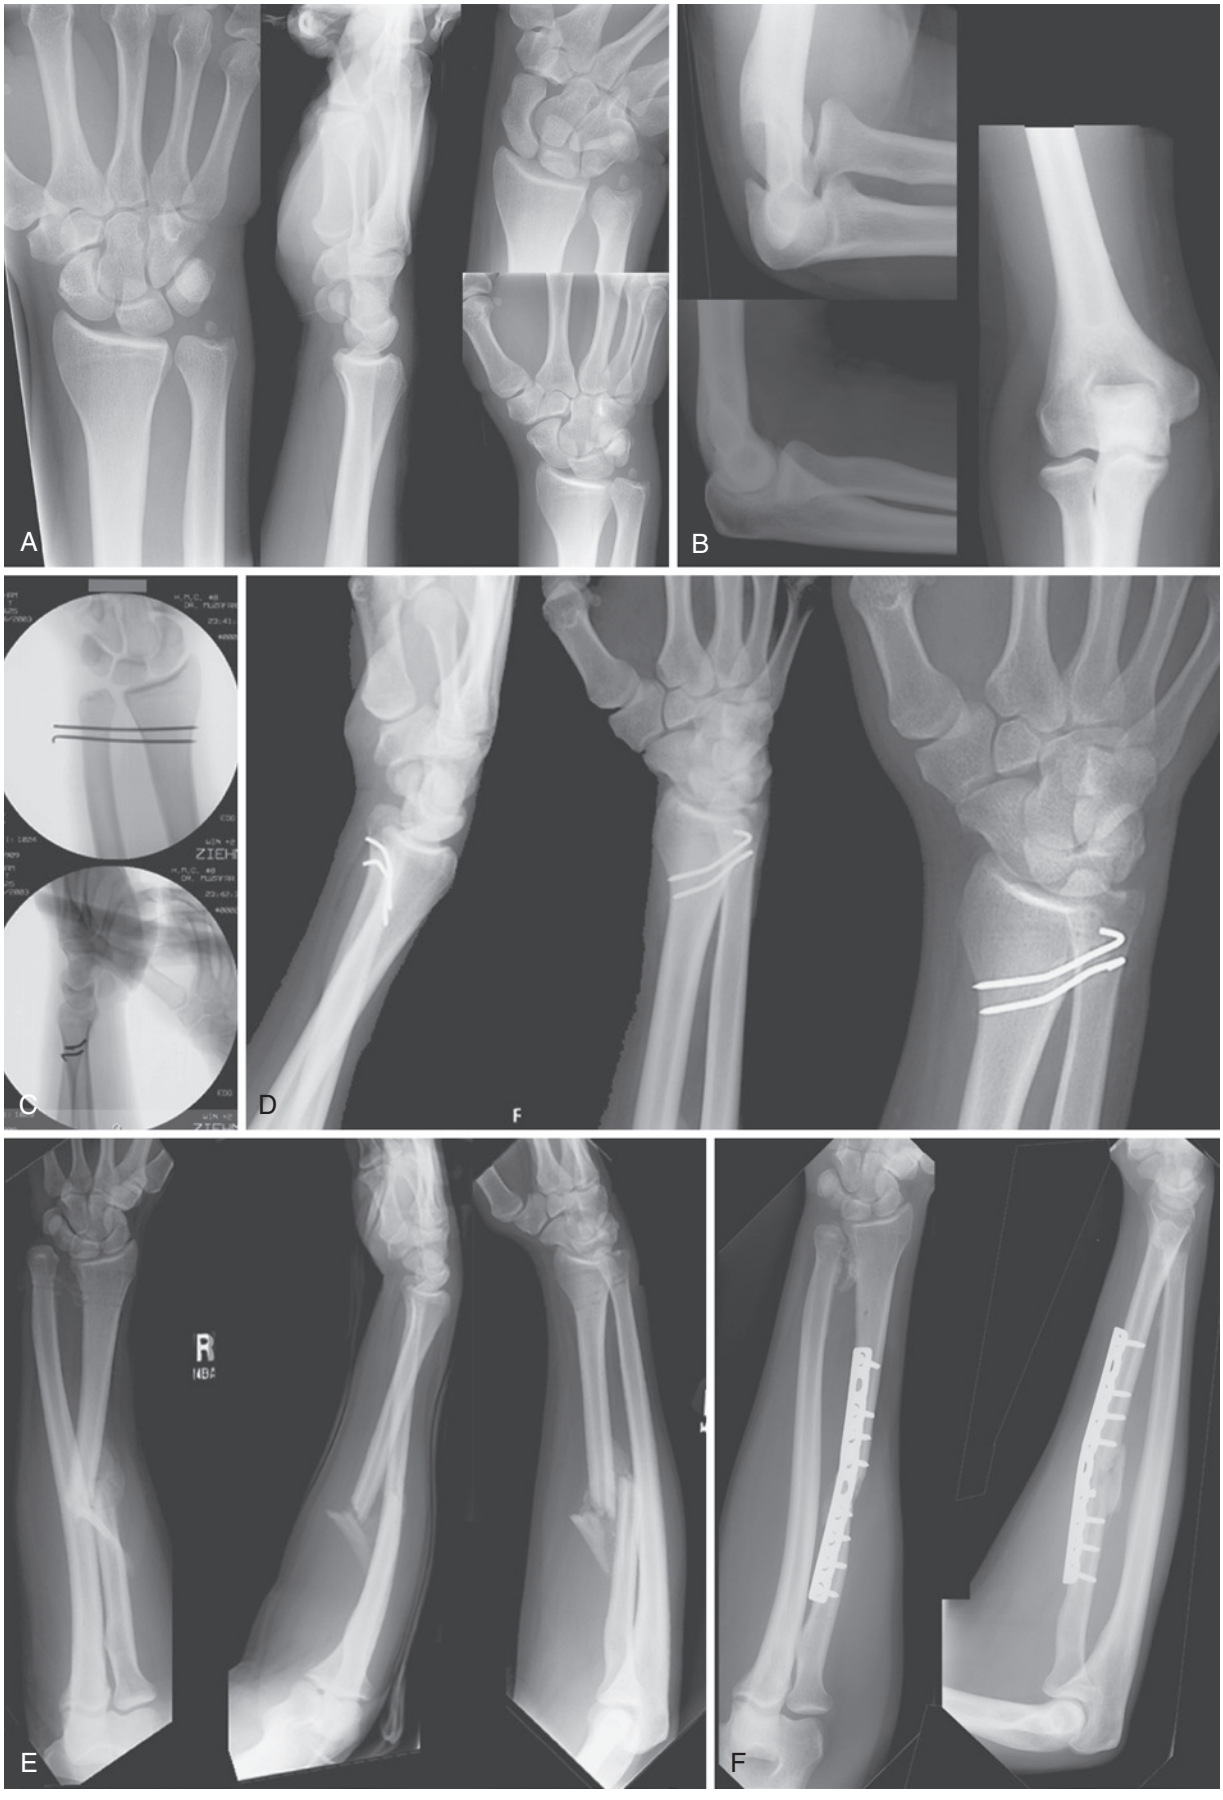

FIGURE 43.5 The importance of obtaining radiographs that include the entire extremity, including a joint above and below the obvious injury, is illustrated in this case of a 22-year-old man who sustained multiple injuries resulting from a motor vehicle accident. **A,** Complaints of wrist pain prompted the radiographs. There is an ulnar styloid fracture and subluxation of the distal radioulnar joint (DRUJ). **B,** Elbow radiographs showed no obvious pathology. **C,** The DRUJ was transfixed with Kirschner wires. **D,** Within 3 weeks the Kirschner wires bent. **E,** The fixation wires were removed, full-length forearm radiographs were obtained, and the culprit—a Galeazzi fracture—was identified. **F,** Restoration of the radius and soft tissue reconstruction of the DRUJ resulted in 80 degrees of pronation and 60 degrees of supination.

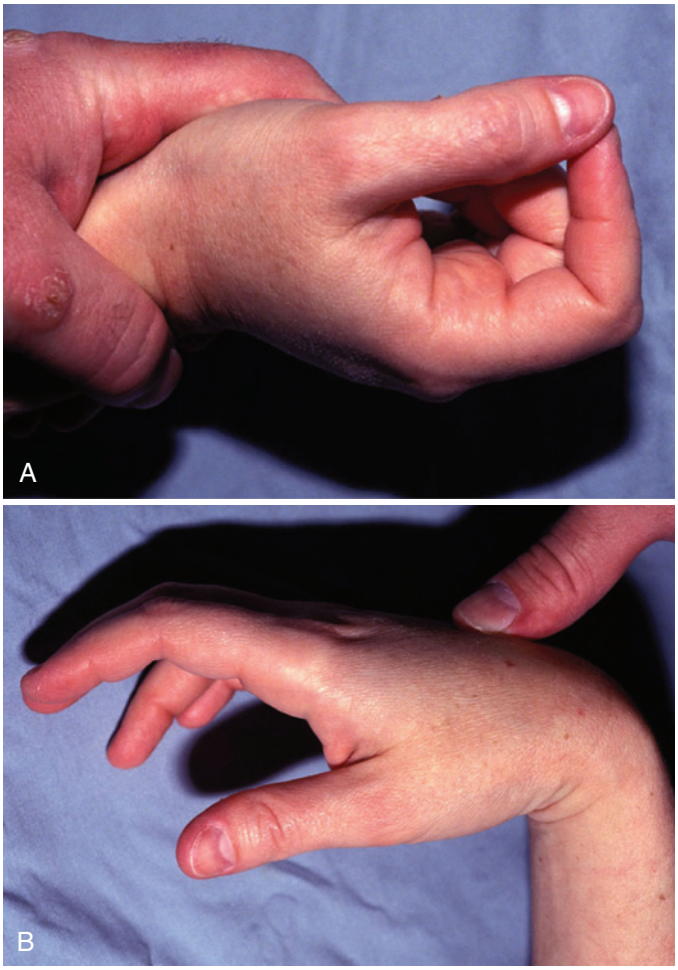

FIGURE 43.6 Evaluation of tendon function by passively extending **(A)** and flexing **(B)** the wrist while observing the normal cascade of digit flexion with wrist extension and digit extension with wrist flexion.

even in a comatose patient, as can evaluation of tendon function by passively flexing and extending the wrist and observing the normal cascade of digit flexion with wrist extension and digit extension with wrist flexion (Figure 43.6). In the end, however, with most mangling injuries, definitive evaluation of tendon injury must wait for careful examination in the operating room.

Nerve injury is evaluated by examining both motor and sensory function. The motor function of the median, radial, and ulnar nerves is assessed by testing both extrinsic and intrinsic muscle function. Three simple maneuvers test motor integrity: (1) resistance to palmar abduction of the thumb reflects median nerve-innervated abductor pollicis brevis function, (2) resistance to flexion of the metacarpophalangeal (MP) joint of the small finger reflects ulnar nerve–innervated flexor digiti quinti function, and (3) resistance to extension of the MP joint of the index finger reflects radial nerve–innervated extensor digitorum communis and extensor indicis proprius function.

Accurate sensory examination is much more difficult, especially in patients with severe injury. By using a light touch and, if questionable, pinprick testing, a reasonable assessment can nevertheless be obtained. If the injury is in the palm or digits, specific attention should be directed to digital nerve function, whereas if the injury is more proximal, attention should be directed to independent areas of sensory function, such as the volar aspect of the index or middle finger, for median nerve function, the volar aspect of the small finger for ulnar nerve function, and the dorsum of the first web space for radial nerve function.

With sharps or penetrating injuries, if you "think the nerve is probably OK," it usually is not. Equivocal results on examination generally indicate an underlying injury that warrants exploration, whereas normal sensory results, with the patient not looking, usually indicate an intact nerve. With blunt or blast injuries, however, nerve contusion and neurapraxia with the nerve in continuity are not uncommon. The threshold of suspicion for exploration of nerves in patients with sharps or penetrating injuries should therefore be much lower than with blunt or blast injuries.

Laboratory studies should be obtained at this time, including a complete blood count with platelets, electrolytes, and any other tests appropriate to the clinical situation (e.g., blood gas analysis, toxicology screen, amylase, and others). In addition, if there has been significant bleeding or considerable bleeding is anticipated during surgery, blood for typing and cross-matching should be obtained at this time.

GOALS OF TREATMENT: BIOMECHANICS OF THE INJURED HAND

In developing a treatment plan for mangling injuries of the hand and upper extremity, the surgeon must keep in mind the seven basic functions of the hand: precision pinch, opposition pinch, key pinch, chuck grip, hook grip, span grasp, and power grasp. Depending on the severity of the injury, some of these functions may not be restored. The basic units that underlie hand function are the following:

1. An opposable thumb
2. The index and long fingers, which serve as the stable fixed unit of the hand for fine manipulation and power pinch
3. The ring and small fingers, which serve as the mobile unit of the hand for grasping functions
4. The wrist (Case Study 43.1)

Restoring these units should therefore be the general goal of reconstruction, with restoration of an opposition digit and a stable opposition post being the bare minimum (reviewed by Moran and Berger[74]). Preservation of length should be a goal, but only functional length should be preserved, not stiff, insensate, potentially painful units with unstable coverage. Durable, stable soft tissue coverage is a necessity, as is at least protective sensation. Without these, chronic breakdown, infection, and failure of the reconstruction can be expected. Not all patients are best served by complex digit reconstruction, especially if the digit is going to be stiff or painful. Sometimes, a prosthesis customized to the patient's occupation is the best option (Figure 43.7). Highly functional, durable mechanical prostheses, as well as advanced myoelectric prostheses, allow excellent return of function and are discussed in Chapter 50.

Amputation/Skeletal Contribution

According to the guidelines of the American Medical Association (AMA) for evaluation of permanent impairment,[25] the thumb accounts for 40% of hand function, the index and

CASE STUDY 43.1

A 57-year-old male was using a chop saw when his left hand became caught in it. The patient presented with the amputated part in saline gauze on ice (eFigure 43.1).

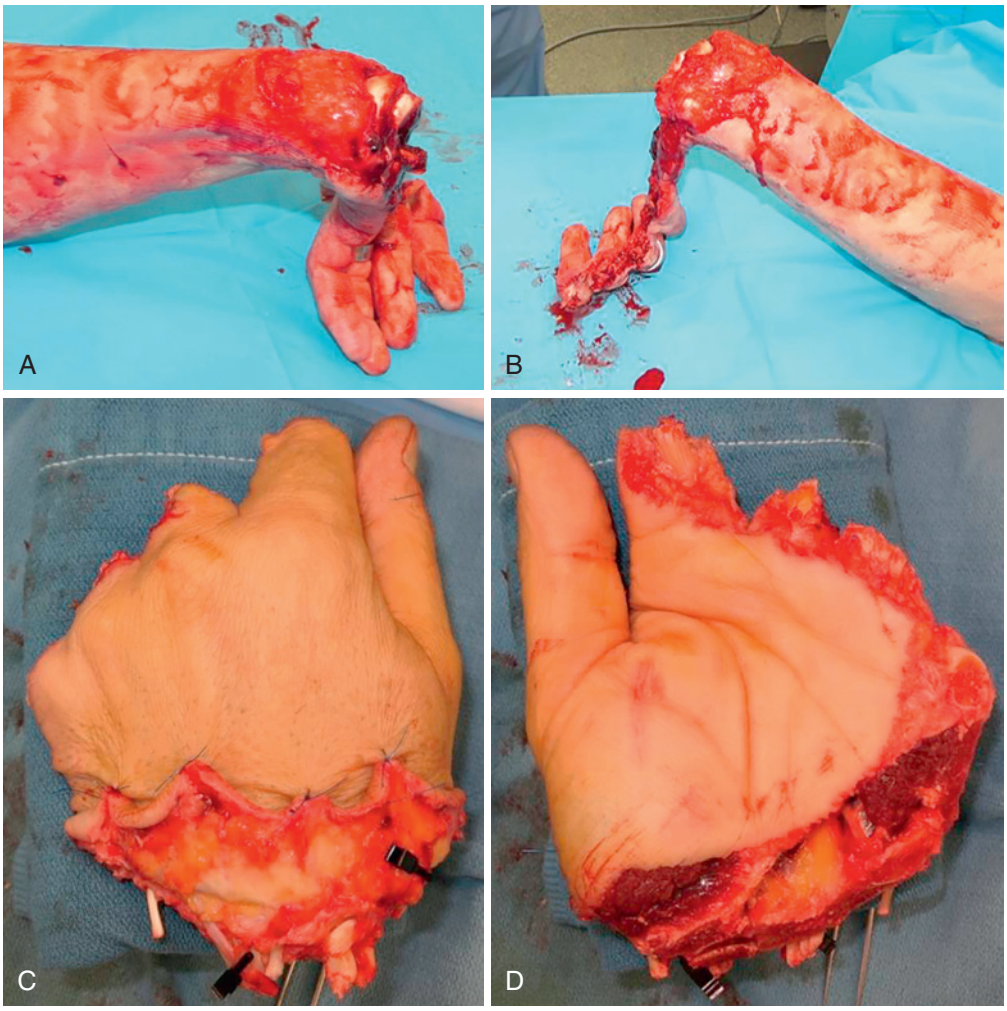
After assessing the patient and speaking with him, he indicates a desire for replantation. Based on the injury pattern, you recommend:

a. Revision amputation through wrist
b. Replantation of thumb/hand part only
c. Replantation of thumb/hand part, plus index finger
d. Replantation of thumb/hand part, plus middle finger

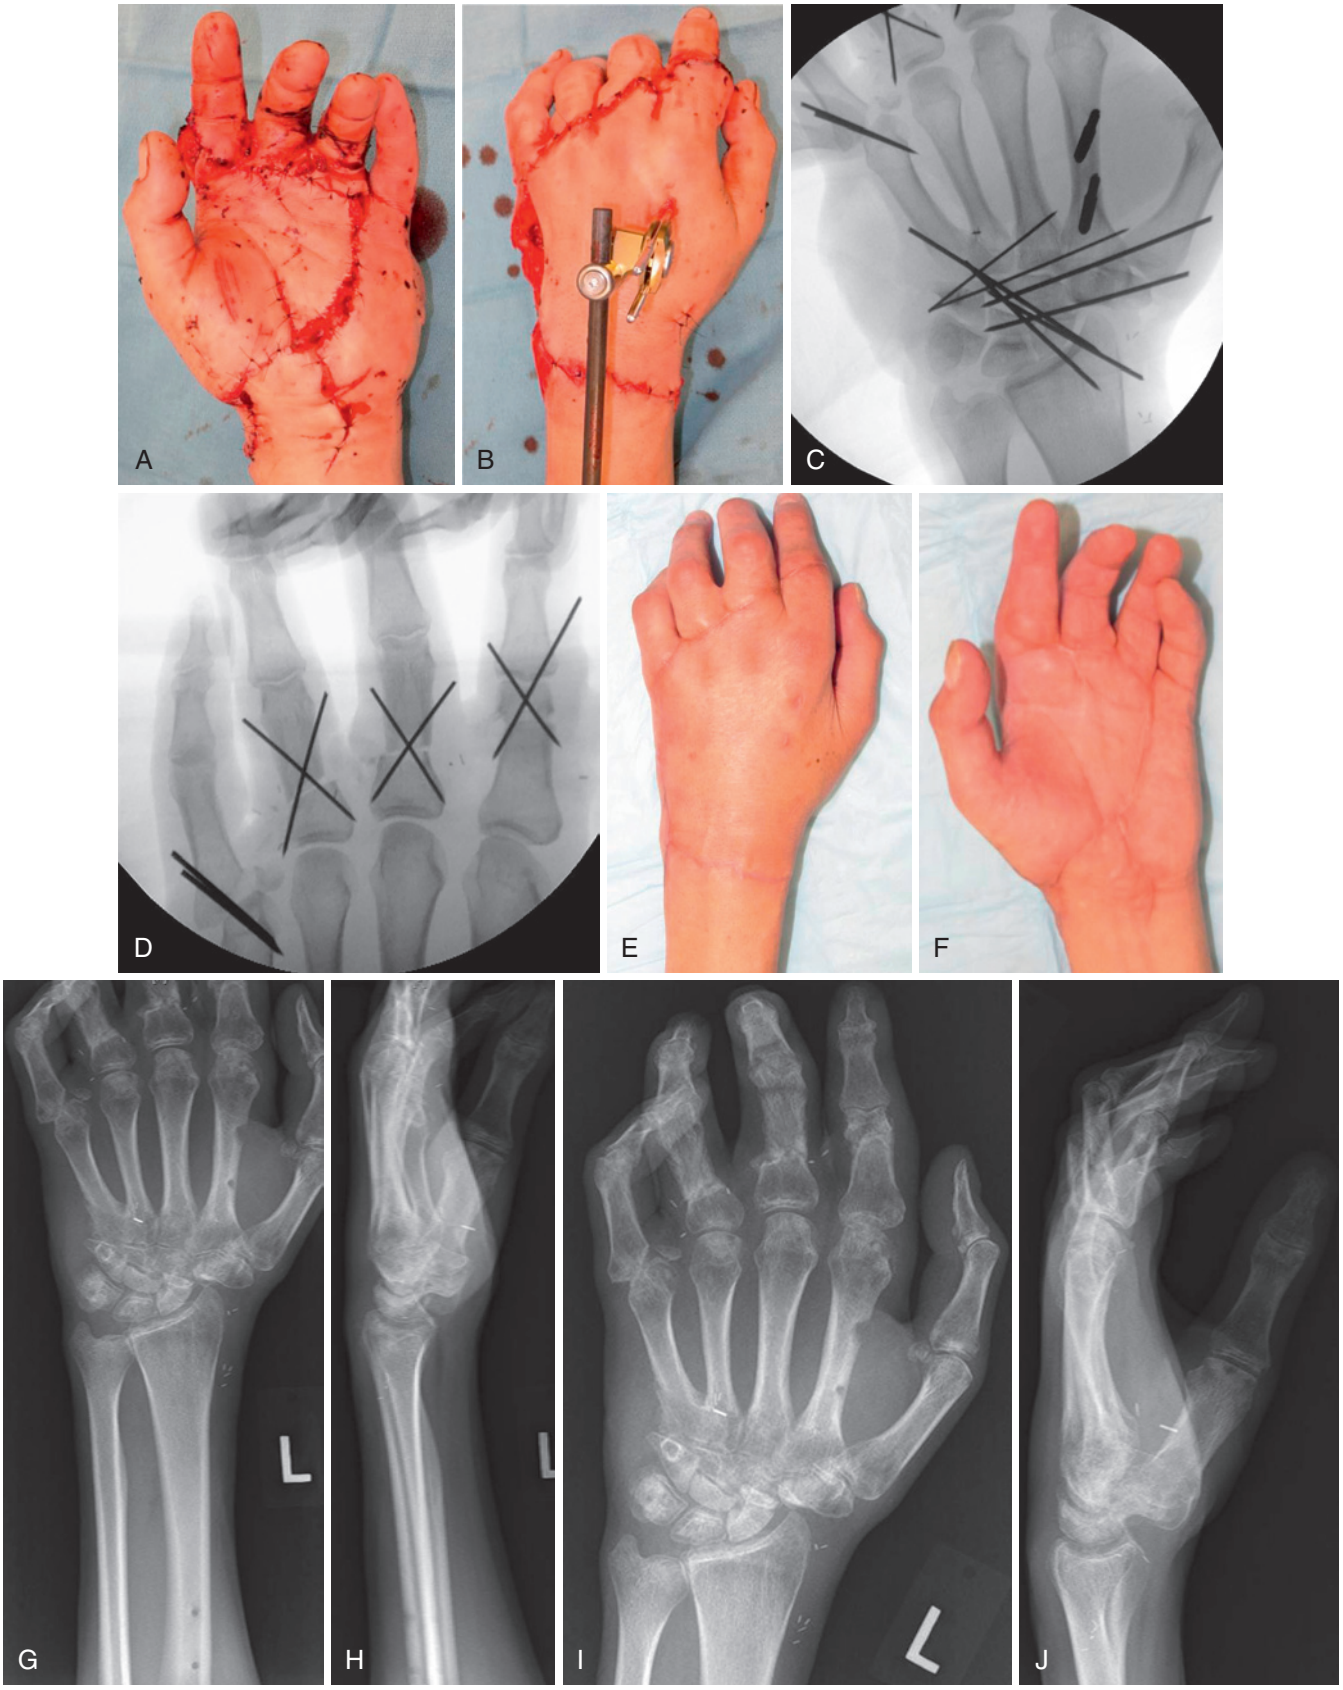
Answer: (d) Replantation of thumb/hand part, plus middle finger

Rationale: While a wrist-level amputation would allow the fastest recovery, it would be functionally limiting. Replantation of the thumb/hand part would not be very functional as the thumb would not have anything against which to pinch/grasp. When choosing between replantation of the index versus middle finger, the middle is typically chosen because the index is considered expendable in multiple-digit replantations.

See postoperative photos and images in eFigure 43.2.



eFIGURE 43.1 **A** through **D,** Amputation injury.



eFIGURE 43.2 **A, B,** Clinical photos immediately following replantation. **C, D,** Immediate postoperative radiographs. **E, F,** Clinical photos following hardware removal. **G** through **J,** Radiographs following hardware removal.

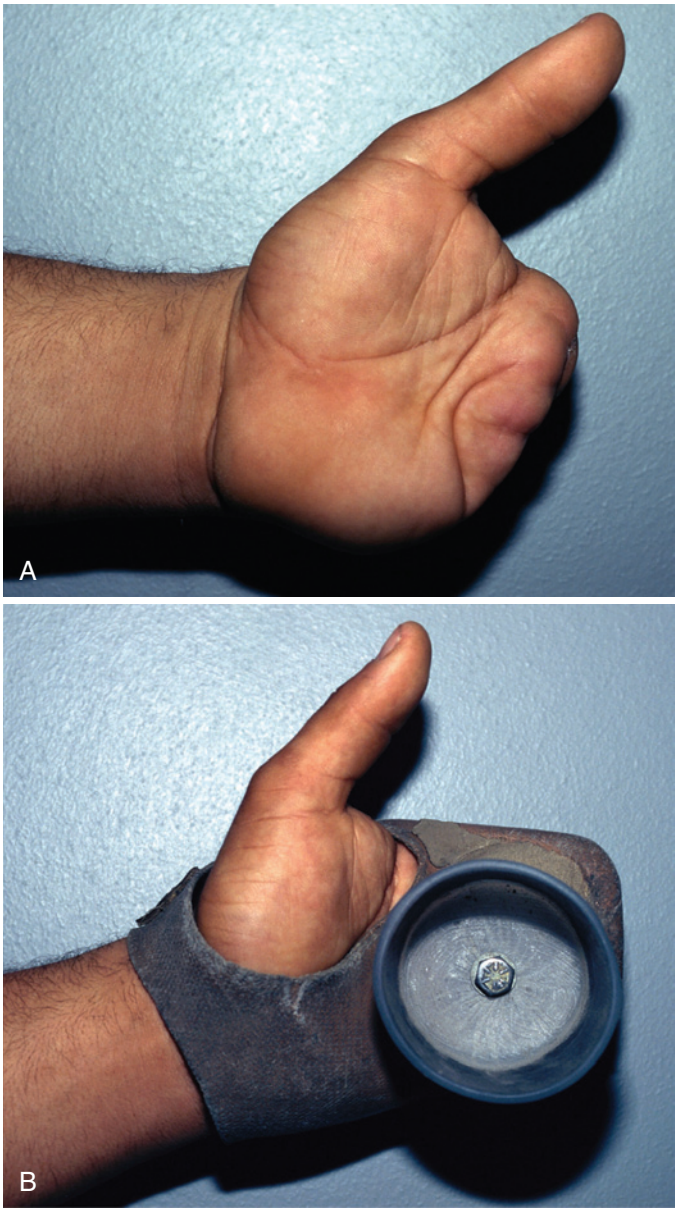


FIGURE 43.7 Sometimes a prosthesis customized to the patient's occupation is the best option, as for this forklift driver.

middle fingers for 20% each, and the ring and small fingers for 10% each. These contributions should be kept in mind when deciding between reconstruction/replantation versus amputation. In the case of mangling injuries, however, these relative contributions do not always apply. For example, with loss of the three central digits, the small finger effectively assumes 50% of hand function.

As discussed previously, surgeons must use their knowledge, experience, and best judgment in an effort to predict a patient's ultimate function with amputation versus reconstruction and with the various reconstructive options. The factors of patient age, health, drug or nicotine use, occupation, and willingness and ability to undergo complex or multistaged reconstructive procedures and rehabilitation must be taken into account. The topics of amputation, replantation, and thumb reconstruction are covered elsewhere in this text, and the reader is referred to these sections for more detailed coverage of the topics.

The thumb is, of course, the most important digit to preserve or reconstruct. The issues related to thumb amputation are discussed in Chapter 48 and vary depending on the level of injury. Interphalangeal (IP) joint motion and the distal phalanx are of relatively lower importance to preserve than multiplanar carpometacarpal (CMC) motion and, to a lesser extent, MP motion.[68] The ability to bring the thumb out of the plane of the hand and into a position of opposition is a key function that must be restored. If the thumb cannot be preserved, consideration should be given to primary pollicization (Case Study 43.2).[54]

The index finger is also important to preserve because of its independent profundus flexion and ability to abduct for precision pinch functions. Without good function and sensibility of the proximal interphalangeal (PIP) joint, however, the index finger is often bypassed in favor of the middle finger because it can be more of a hindrance than help and ray amputation can often improve function by opening the first web space.[30,74,98,108] Amputation at or proximal to the PIP level leaves only the intrinsics for flexion, which is then limited to about 45 degrees. The long and ring fingers are important primarily for grip and grasp functions, although either can take over pinch functions for the radial digits if they are lost. Solitary loss of the ring finger probably results in the least associated functional deficit of all the digits.[98] The small finger, even though it has the least flexion strength, is actually quite important in hand function in that it defines hand width for grip functions, use of tools, and other applications. An important component of this function is the significant CMC motion of the small finger that comes into play with terminal grip.

With amputation at the proximal aspect of the middle phalanx (P2), PIP, or especially the MP level, ray amputation also needs to be considered. Although ray amputation is usually aesthetically preferable to a partial finger amputation, function can suffer. For the index finger, power grip, key pinch, and supination strength are diminished approximately 20%, and pronation strength approximately 50%.[76] There is also a fairly high rate of dysesthesia after ray amputation, thus further arguing against routine ray amputation.

Loss of an isolated digit other than the thumb rarely results in significant compromise of hand function, and as Brown has noted, patient motivation is more important in regaining function than the actual digits lost.[13] Loss of multiple digits, however, is common with mangling injuries and frequently results in significant functional deficits. Maintaining or reconstructing at least the thumb and one opposing digit is a minimum requirement for any type of pinch or grasp. Retaining or reconstructing an additional adjacent digit can nevertheless add significant function by providing lateral stability to the radial digit for power pinch and can allow three-jaw chuck pinch.

Joints

The choice of whether to salvage or fuse a joint is another decision that is often difficult. It is best made by assessing the potential loss of function from a given fusion or set of fusions versus the risk for limited motion, pain, instability, or late arthrosis with reconstruction. Whenever anatomic articular congruity and ligamentous stability can be restored, reconstruction is usually worthwhile. When it cannot be achieved, the potential loss of function needs to be assessed. In general, distal

CASE STUDY 43.2

A 50-year-old male suffered a crush/avulsion injury from industrial machinery to his thumb, index, and middle finger. Initial debridement and index ray amputation were performed (eFigure 43.3).

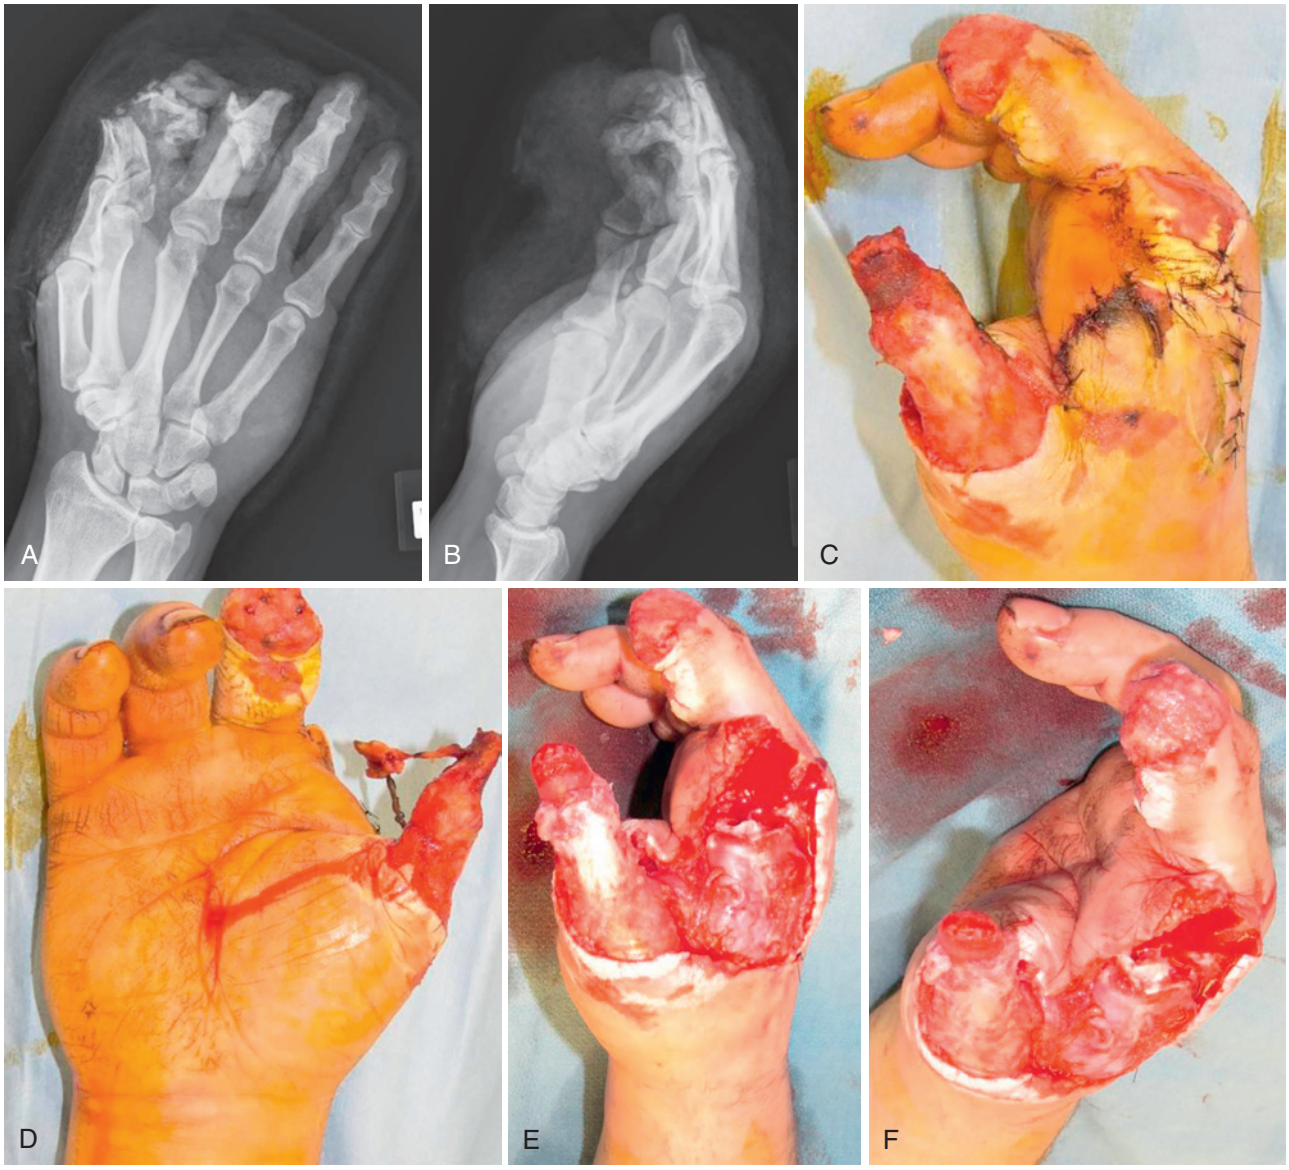
What is the preferred coverage method for this wound (keeping in mind that a toe transfer may be needed for thumb reconstruction)?

a. Pedicled reversed radial forearm fasciocutaneous flap
b. Groin flap
c. Free radial forearm flap
d. Split thickness skin graft

Answer: (b) Groin flap

Rationale: A split thickness skin graft is not appropriate coverage for the exposed thumb skeleton. While a pedicled or free-radial forearm flap would provide coverage, both of these options would alter the radial artery which is the preferred recipient artery for a toe transfer. Therefore, a groin flap is the preferred coverage type.

See postoperative images in eFigure 43.4.



eFIGURE 43.3 Crush/avulsion injury to thumb, index, and middle finger. **A, B,** Radiographs. **C, D,** Clinical photos 48 h after injury (with one debridement). **E, F,** Injury following second debridement.

interphalangeal (DIP) fusions of the digits or IP fusion of the thumb is tolerated well with limited loss of function. PIP joint motion is much more important to preserve. Littler and colleagues described the PIP joint as the "functional locus of finger function."[63]

Not only are fingers with fused PIP joints of little use for grip or grasp, but also they frequently get in the way and are easily injured because they do not follow the normal arc of the other fingers. An additional problem, though less so with the index finger, is the quadriga effect, which can occur when profundus excursion is impaired with arthrodesis. Although delayed arthroplasty can be considered, in the presence of combined injuries involving the joint, nerve, and soft tissue, if the PIP joint cannot be primarily reconstructed, serious consideration should be given to amputation, especially of the ulnar two digits.

The MP joint is perhaps the most important joint in terms of function for the index through small fingers in that it contributes 77% of the total arc of finger flexion.[63] Most activities, however, do not require the full arc of MP motion, and in fact as little as 35 degrees of motion can be acceptable if that arc is within the key functional range and the joint is stable.[6] To that end, stable but markedly limited MP motion, even arthrodesis, is far superior to an unstable, painful MP joint (Figure 43.8).

The decision to perform partial or total wrist fusion is seldom made in the acute setting unless there is extensive, nonreconstructible loss of articular surface. Usually, this decision is deferred until late function and pain can be better assessed, at which time elective arthroplasty or arthrodesis can be performed. Studies have shown that as little as 5 to 10 degrees of flexion and 30 to 35 degrees of extension are needed for most activities of daily living.[16,81] When wrist-level amputation is required, preservation of some wrist motion can be incorporated into mechanical prostheses, and preservation of an intact distal radioulnar joint can significantly improve pronation and supination under loading conditions. The functional benefit of preserving the distal radioulnar joint, although attractive in theory, has never been proved in practice.

Tendons

Preservation and reconstruction of skeletal length and joint motion are of little use without a mobile muscle–tendon unit to move it. Because of its complex balanced "shroud" mechanism and limited excursion, the extensor tendon mechanism, especially over the digits, is susceptible to minor changes in length with repair, as well as adhesion formation and underlying skeletal injury.[29] Intrinsic function is also easily compromised in mangling injuries, especially crush and blast injuries with multiple metacarpal fractures.

Fibrosis and contracture leading to significant disability are common. Because of the overlap in function and transmission through the juncturae tendineae, injuries to the extrinsic extensor tendon tend to be more forgiving, especially if a limited number are involved. Although not ideal, complete loss of the extrinsic extensors with associated reconstruction of dorsal soft tissue coverage and the presence of intact intrinsics is tolerated quite well. In this setting, the ensuing deep cicatrix formation allows adequate MP flexion and extension through scar tenodesis. This, combined with intact IP function, results in good overall hand function.[89]

Preserving or reconstructing flexor tendon function in a mangled hand is obviously important but frequently difficult to achieve. It is often difficult to restore independent superficialis and profundus function, and the pulley systems are frequently ruptured. To prevent bowstringing, the A2 and A4 pulleys must be preserved or reconstructed.[48,61] Given the limited tolerances within the flexor pulley system, it is sometimes best to repair only one tendon, usually the profundus tendon, especially if repairing both tendons would lead to adhesions and limited excursion. Two other complications of

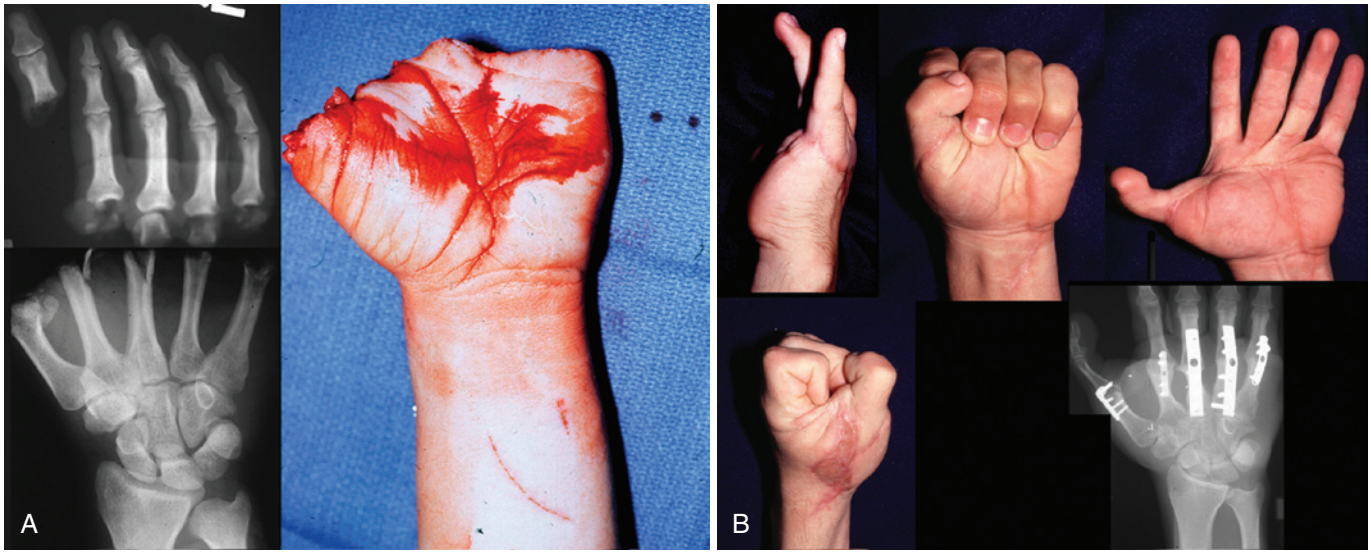

FIGURE 43.8 **A,** Five-digit amputation in an 18-year-old man resulting from a saw accident. **B,** Treatment consisted of primary arthrodesis of the finger metacarpophalangeal joints and replantation of the index, middle, ring, and small fingers. The thumb could not be replanted. Six months after injury, the thumb was reconstructed with a second toe-to-hand transfer. Hand motion is demonstrated a year after the injury.

profundus injury must also be kept in mind and avoided: lumbrical-plus deformity and quadriga.

Lumbrical-plus deformity occurs when a cut and unrepaired profundus retracts, thereby increasing tension on the lumbrical that results in paradoxical extension with digit flexion. This is avoided by either repairing the profundus or, as with amputations, suturing it without tension to the flexor sheath. Quadriga primarily affects the middle through small fingers and is a result of these tendons arising from a common muscle belly. If one profundus becomes adherent in a lengthened position or is repaired with significant shortening, it can prevent full flexion of the remaining digits.

Soft Tissue Coverage and Nerves

Providing durable, stable, pliable soft tissue coverage, with at least a protective sensation in the areas of functional contact, has long been recognized to be the most important factor in determining outcome after mangling injuries.[12,34] Stability of soft tissue coverage is often overlooked in the quest to provide bulk, padding, and durability; it is especially important on the volar aspect of the hand and digits. A bulky, mobile flap subject to shear with a tangential load leads to poor grip function. One can imagine how difficult the simplest of tasks would be if a small water balloon were strapped to one's palm. For this reason, surgeons favor fascia flaps or thin muscle flaps that are skin grafted, as opposed to thick fasciocutaneous or musculocutaneous flaps, especially on potentially friction-dependent, load-bearing surfaces.

Restoring protective sensation (i.e., 7–15-mm two-point discrimination) to the palmar weight-bearing surfaces of the hand is critical. According to the AMA's *Guides to the Evaluation of Permanent Impairment*, greater than 15-mm two-point discrimination is considered functionally insensate.[25] Nerve repair, whether primary or delayed, is an essential component in reconstruction of a mangled hand.

EVOLUTION IN THE TREATMENT OF MANGLING INJURIES

Historically, the primary method of treating mangling injuries has been amputation. Surgeons long ago learned that without effective treatment, devascularized, contaminated, or crushed tissues, along with open fractures, often led to limb- and life-threatening infections; they felt that only with early and thorough debridement plus amputation could such outcomes be avoided. With the advent of antibiotics and advances in anesthesia and surgical care, more aggressive salvage efforts were undertaken. In the 1950s there was a tendency to treat mangling injuries with minimal debridement with the goal of preserving length.

The early enthusiasm for the role of antibiotics for surgical patients was tempered by studies showing failure of antibiotics to significantly alter the rate of postoperative infection.[72] Burke's classic studies finally demonstrated the critical importance of early administration of antibiotics and their significant efficacy when administered before wound inoculation.[20] During the 1970s, the concept of delayed closure to reduce risk of infection was popularized and incorporated into the treatment of mangling upper extremity injuries.[22] In the 1980s, management of mangling injuries became increasingly aggressive and combined thorough debridement with revascularization, early reduction and fixation of fractures, and early vascularized soft tissue coverage with flaps.[5,45]

The identification of and growing experience with reliable axial pedicled flaps and microsurgical free flaps provided a wide range of new opportunities for salvaging mangled extremities (see Chapters 43, 44, and 45). Godina's work showed that with radical debridement and early (i.e., within 72 h) microsurgical soft tissue reconstruction, infection risk, morbidity, and healing time were all dramatically improved.[35] Included in Godina's series and reinforced by other centers was the concept of complete reconstruction in a single emergency setting, including soft tissue reconstruction and free tissue transfer.[62,93] This radical and still controversial approach was viewed as a natural progression in the advances in microvascular surgery used for replantation and the salvage of devascularized tissues (see Chapter 42).

Treatment of the skeletal component of mangling injuries has undergone a parallel evolution over the past several decades. Although the use of external fixation devices remains a mainstay in the treatment of comminuted open fractures, the development of small, strong, low-profile internal fixation devices, when combined with early vascularized soft tissue reconstruction, has revolutionized the treatment of complex open skeletal injuries.[32] Before the advent of modern internal fixation, most complex hand injuries were treated by prolonged immobilization, with the expected results of severe stiffness and tendon adhesions.

Concomitant with the development of early rigid internal fixation was the concept of primary flexor tendon repair and early mobilization popularized by Kleinert and others.[58] Better fracture fixation and early mobilization after tendon repair dramatically improved the outcome of severe hand and upper extremity injuries.

Advances in the treatment of skeletal injuries have prompted independent advances in the repair of vascular and peripheral nerve injuries using microvascular techniques, thereby allowing salvage and reconstruction of mangling injuries that in the past would have certainly resulted in amputation. Taken together, the advances in antibiotics, microsurgery, and skeletal, soft tissue, and nerve reconstruction have dramatically expanded the possibilities of limb salvage. The critical task of the hand surgeon, however, is to know when to use these techniques versus when to choose amputation or partial amputation to achieve the best long-term function for the patient.

RECOMMENDED APPROACH TO TREATMENT

Emergency Treatment

By far the most important aspect of treating a mangling extremity injury is to evaluate the patient and treat other life-threatening injuries before proceeding to evaluation and treatment of the extremity injury. Once the patient has been stabilized and attention can safely be turned to the extremity, the most emergent aspect of treatment is controlling ongoing hemorrhage. This is best done by applying direct pressure to the bleeding area long enough to allow the effects of reflex vasoconstriction and thrombus formation to effectively control the bleeding. Sometimes a compressive dressing held on by an elastic bandage is necessary. In the rare circumstances when

direct pressure is ineffective, it may be necessary to temporarily inflate a proximal blood pressure cuff as a tourniquet until the area of bleeding can be identified and controlled.

It must be kept in mind, however, that tissue distal to the injury may have already been subjected to a period of ischemia and that further complete ischemia will compromise the ability to salvage the limb. Because of the many critical structures running through the extremity, in particular, nerves and arteries, it is important to never blindly clamp bleeding areas and to use clamps only on a specific, well-visualized vessel while being careful to not include any adjacent nerve.

It has been shown that in cases of severe mangling and devascularizing injuries, revascularization before skeletal reconstruction reduces morbidity.[71] If either the brachial artery or both the radial and ulnar arteries are transected or thrombosed, and if extensive skeletal stabilization is going to be required, especially if ischemia has already been present for some time, a vascular shunt should be placed as an initial step.[39,71] This should be done before operative debridement or skeletal fixation to reperfuse the tissues and remove the time pressure so that meticulous debridement and appropriate skeletal fixation and tendon repair can be performed before definitive revascularization.

A standard carotid vascular shunt usually works very well for the brachial, radial, or ulnar arteries. Before inserting the shunt, any thrombus or debris should be removed from the proximal and distal segments with a No. 2 Fogarty catheter to prevent distal embolization after restoration of flow (Figure 43.9). Once the arterial shunt has been connected, it is recommended that the extremity be allowed to bleed so that toxic metabolites do not enter the circulation. In the case of critical ischemia of the upper extremity, 200 cc of bleeding is sufficient to clear the waste products.[78]

As noted earlier, cooling the tissue is the most effective way to prolong the length of time that tissue can be ischemic yet still remain viable. When tissue is amputated, including digits, limbs, or other potentially revascularizable tissue, it should be wrapped in saline-soaked gauze, put in a plastic bag or container, and placed on ice until it can be revascularized. All intact skin bridges should be left intact. There are often critical draining veins within the skin bridge that can provide adequate venous drainage, thereby obviating the need for venous reconstruction at the time of revascularization. In this case, the ischemic digit or limb should simply be wrapped with moist gauze or a moist towel if the patient is not suffering from hypothermia.

Gross skeletal deformity caused by either fracture or dislocation compromises distal circulation and should be reduced, whenever possible. If any flaps of tissue have been traumatically elevated, they should be gently placed back into anatomic position without any tension or kinking to optimize circulation. It is, of course, important to document the results of motor and sensory examination before administering local, regional, or general anesthesia.

With any open wound, the patient's tetanus prophylaxis status should be reviewed and the appropriate prophylaxis given, according to the standard guidelines (Table 43.1).[90] Appropriate intravenous antibiotic prophylaxis should be started at this time. In most instances, a first-generation cephalosporin is adequate because the most common infective organism with open hand injuries is *Staphylococcus aureus*.[27,46,94,95] With agricultural injuries or those that occur at other highly contaminated areas, additional gram-negative coverage should be provided (i.e., an aminoglycoside).

CRITICAL POINTS *Emergency Treatment*

- Evaluate and treat other life-threatening injuries (the trauma "ABCs").
- Control hemorrhage by direct pressure—do not blindly clamp.
- Reduce gross skeletal deformity.
- Administer tetanus prophylaxis and antibiotics.
- For a ischemic major limb, place a temporary vascular shunt.
- Cool devascularized tissue.
- Leave any skin bridges intact.

Operative Treatment

Debridement/Wound Excision

The initial debridement is perhaps the single most important step that determines the functional outcome of mangling injuries. Performing it properly requires experience and judgment. It should therefore not be left to a junior resident to perform. If the initial debridement is inadequate and nonviable tissue is left behind, the result will be infection, further tissue loss, and potential loss of limb or life that might otherwise be prevented. As Pasteur described and as was reinforced by the work of Dellinger and colleagues: "It is the environment, not the bacteria, that determine whether a wound becomes infected."[27] Because there is little in the hand and upper extremity that is not functionally important, some argue for conservative initial debridement so that marginal tissue can "declare itself" over time. We strongly disagree with this approach.

Marginally viable tissue leads to further toxic insult to adjacent tissues, as well as systemic complications. Instead, we favor aggressive debridement of marginally vascularized tissue, especially muscle. The only two exceptions to this approach are (1) if revascularization is going to be performed, final debridement should await definitive revascularization; and (2) in the case of pure skin flaps that are critical for coverage of vital structures, the risk for sepsis by waiting 24 to 48 h for demarcation of viability is small. Nevertheless, if skin does not bleed or oozes only dark blood at the time of initial surgery, it should be debrided. The concept of debridement in the face of mangling injuries should therefore actually be thought of as "wound excision" to create a healthy soft tissue bed for reconstruction.[42]

Unless prolonged muscle ischemia has already occurred, initial debridement is best performed under tourniquet control. This allows safe visualization and preservation of critical structures, specifically major nerves and vessels. Using loupe magnification, all foreign material should be carefully removed, along with clearly devitalized skin, subcutaneous tissue, and muscle. Frayed tendon should be debrided of only loose strands, with any potentially structural portions left intact. Unless clearly destroyed, nerves should be left intact and any foreign material carefully removed. If a major muscle is debrided, one should tag the motor nerve to potentially use later for functional free muscle transfer. The ends of transected major nerves should be tagged with sutures if primary repair is possible or with metal vascular clips if delayed nerve grafting will be necessary; this

FIGURE 43.9 This 24-year-old man sustained a combined complex injury resulting from a rollover motor vehicle crash. In addition to his open fractures were forearm muscle and skin avulsions and transection of the brachial artery. This accident occurred in a rural area, 6 h from the nearest trauma center. The surgeon removed gross debris, reconstructed the artery with a vascular shunt **(A)**, and then transported the patient to our facility. Further treatment consisted of debridement, skeletal fixation, revascularization with vein grafts, and soft tissue reconstruction with a free rectus abdominis muscle flap and split-thickness skin grafts. **B,** These photographs were taken a year after the injury. Forearm rotation is limited to 90 degrees, shared equally by pronation and supination.

TABLE 43.1 Current Guidelines for Tetanus Prophylaxis

General Principles

1. Active immunization against tetanus with tetanus toxoid markedly reduces the incidence of this disease and resulting death.
2. Recommendations for tetanus prophylaxis are based on wound condition, especially its susceptibility to tetanus, and patient's immunization history.
3. Regardless of patient's active immunization status, all wounds should undergo immediate surgical treatment using a meticulous aseptic technique to remove all devitalized tissue and foreign bodies. Consideration should be given to leaving tetanus-prone wounds open. Such care is an essential part of prophylaxis against tetanus.

Warning

4. The only contraindication to tetanus and diphtheria toxoids for a wounded patient is a history of a neurologic or severe hypersensitivity reaction to a previous dose. Local side effects alone do not preclude continued use. If a previous systemic reaction to horse serum is suspected of representing allergic hypersensitivity, immunization should be postponed until appropriate skin testing can be performed. If contraindication to a tetanus toxoid-containing preparation exists, passive immunization against tetanus should be considered for a tetanus-prone wound.

	WOUND CLASSIFICATION	
Clinical Features	**Tetanus-Prone Wounds**	**Nontetanus-Prone Wounds**
Age of wound	>6 h	≤6 h
Configuration	Stellate wound, avulsion	Linear wound, abrasion
Depth	>1 cm	≤1 cm
Mechanism of injury	Missile, crush, burn, frostbite	Sharp surface (e.g., knife, glass)
Signs of infection	Present	Absent
Devitalized tissue		
• Contaminants (e.g., dirt, feces, grass, saliva)	Present	Absent
• Denervated and/or ischemic tissue	Present	Absent

Immunization Schedule

A history of tetanus immunization should be obtained from medical records so that appropriate tetanus prophylaxis can be provided. Individuals with risk factors for inadequate tetanus immunization status (e.g., immigrants, rural or urban poor, elderly without known interval booster shots) should be treated as having unknown status.

	TETANUS-PRONE WOUNDS		NONTETANUS-PRONE WOUNDS	
Adsorbed Tetanus Toxoid History (Doses)	**Tt[a]**	**TIG**	**Tt[a]**	**TIG**
Unknown or <3	Yes	Yes	Yes	No
≥3[b]	No[c]	No	No[d]	No

Disposition

- Each patient should be given an appropriate written record describing the treatment rendered and instructions for follow-up with regard to wound care, drug therapy, immunization status, and potential complications. Arrange for completion of active immunization.
- Every wounded patient should be given a wallet-size card documenting the immunization dosage and date received.

[a]For children younger than 7, diphtheria-pertussis-tetanus (DPT) may be considered.
[b]If only three doses of fluid toxoid have been received previously, a fourth dose, preferably an adsorbed toxoid, should be given.
[c]Yes, if >5 years since the last dose.
[d]Yes, if >10 years since the last dose (more frequent boosters are not needed and can accentuate side effects).
TIG, Tetanus immune globulin (human); *Tt*, tetanus toxoid adsorbed (for adult use).
Modified from Ross SE: *Prophylaxis against tetanus in wound management*, Chicago, 1995, American College of Surgeons Committee on Trauma.

will help in later identification of the nerve ends, either directly or radiographically.

Similarly, the transected ends of major vessels (e.g., the radial, ulnar, anterior interosseous, palmar, or digital arteries) to be repaired should be clamped with spring-loaded microvascular clamps. Smaller branches should be ligated with either suture ties or vascular clips, which we prefer because they are less likely to become a nidus for infection. Nonstructural bone fragments that are not attached to soft tissue should be saved for keying reduction. Attached and potentially viable fragments should be saved, along with structurally important fragments. The remaining bone should undergo curettage to remove contamination and allow anatomic reduction. The wounds should then be irrigated with a gravity-assisted irrigation system if large or with bulb/syringe irrigation if small. The mechanical debridement achieved by scrubbing with a sterile gauze sponge during irrigation is very important.

At this point, the tourniquet should be released and areas of significant bleeding either cauterized or ligated with vascular clips. Any tissues, particularly muscle, that are not pink and bleeding should be debrided down to healthy bleeding tissue. At times it is necessary to reinflate the tourniquet briefly for further debridement. We have not found tissue taken for culture at the time of initial debridement to be of much clinical value.[27]

If the wound is heavily contaminated, or if there are remaining critical areas where viability is not certain, planning for repeat operating room debridement in 24 to 36 h is in order, especially with severe crush injuries.

The debridement phase is when decisions regarding replantation, amputation, partial amputation, or reconstruction must be made, again by looking into the "crystal ball" to predict ultimate function with the various options and relying on the principles described previously for guidance. If amputated tissues have been recovered and on initial inspection are thought to not be appropriate for replantation, they should nevertheless be saved because they could be useful as "spare parts" later in the operation—either as vascularized or nonvascularized grafts: bone, tendon, nerve, or skin.[15] The technical details of various types of amputations are described in Chapter 50.

For the digits, if less than a functional amount of the proximal phalanx remains, we will often perform a ray resection or, in the case of the middle finger, an index-to-middle finger transposition at the time of the initial operation.[43] If the remaining ray will not contribute to function, removal of it can often help in achieving primary soft tissue closure; the skeletal components should be removed, the vascularized soft tissue portions saved, and a "fillet flap" created. This is also the point to pause and plan the reconstruction, both the steps to be performed in the current operation and the type of future operations that may be required. After debridement, reconstruction should then proceed beginning with skeletal reconstruction and working from the base up to the skin.

CRITICAL POINTS *Debridement*

- Excise the wound.
- Perform aggressive debridement of marginally vascularized tissue, especially muscle.
- Save critical structures: nerve, tendon, and arteries.
- Begin with a tourniquet; release and reinflate for further debridement.
- Tag nerves and arteries.
- Save vascularized bone for incorporation; save devascularized bone for keying reduction and then discard.
- Use gravity-assisted lavage with mechanical scrubbing.
- Decide about replantation, amputation, partial amputation, or reconstruction (the "crystal ball").
- Perform amputations as part of debridement; save vascularized soft tissue for coverage/closure.
- Save "spare parts" for later use in primary reconstruction.

Skeletal/Joint Reconstruction

The goal of skeletal reconstruction is to restore length, alignment, and stability, along with anatomically smooth and stable articulations so that the complex flexion and extension units of the forearm and hand can produce the hand's key motor functions outlined previously. This must be achieved while adhering to principles that optimize fracture biology and promote rapid and stable fracture healing. Because the surrounding tissues rapidly become firmer and less pliable in just a matter of days after injury and because tendon gliding and joint motion require early mobilization, the optimal time to achieve anatomic reduction and stable fixation is at the initial operation or, at the very least, within the first week.

Achieving adequately stable fixation to allow early motion is especially important with mangling injuries, when the only chance to overcome the inevitable scar formation around the joints and muscle–tendon units is through early passive and active motion. With the exception of injuries with severe contamination, skeletal fixation is generally best performed during the initial operation. The vascularity of the hand and upper extremity is excellent and allows a far more aggressive fixation approach to be taken than in the lower extremity.

The methods of fixation for humerus, forearm, wrist, hand, and digit fractures and dislocations are adequately covered in other chapters. With open mangling injuries, the wounds often dictate the approach, and every attempt should be made to not create additional, unnecessary soft tissue injury while gaining adequate exposure for fixation. Even with good fracture exposure, intraoperative radiographs or fluoroscopy should always be used to confirm reduction and fixation.

Before proceeding with skeletal fixation, a critical decision must be made as to whether to restore anatomic length or shorten the bone as part of fixation (Case Study 43.3). When concomitant nerve or arterial injury (or both) is present, skeletal shortening can allow debridement and primary repair of nerves or arteries; on the other hand, maintaining length may dictate nerve or vessel grafting with an increased risk for complications from either vascular thrombosis or loss of axonal regeneration across a nerve graft. In the case of severe comminution at the fracture site, shortening can also allow primary bone fixation and thus obviate the need for bone grafting.

Shortening can similarly facilitate tendon repair and soft tissue reconstruction. In general, 1 to 1.5 cm of shortening is tolerated well in the phalanges and metacarpals and up to 4 cm in the forearm without significant loss of function. It must be kept in mind, however, that muscle sarcomeres have a limited capacity to shorten in response to skeletal shortening, and there is a risk for loss of either flexor or extensor function with significant skeletal shortening when tendon shortening is not also part of the repair.[10]

Intraarticular fractures must be assessed to determine whether they are reconstructable or whether primary or secondary fusion is more appropriate. In general, if 50 to 75% of the articular surface remains and is capable of supporting the joint without resulting in bone–bone contact, an attempt should be made at joint salvage. Depressed articular fragments should be elevated and every attempt made to achieve a smooth anatomic surface. If the articular fragments are sufficiently large, small reconstruction screws provide excellent stable fixation.

Frequently, however, multiple Kirschner wires are required for small yet functionally important articular fragments. The mini-condylar plates can be very useful for articular reconstruction.[44,80] If the joint is unstable, an attempt at ligament repair or reconstruction should be made, preferably with adjacent tissue, although sometimes a "spare parts" tendon graft can be used as described in Chapter 6. Joint stabilization can also be facilitated with transarticular Kirschner wires, which are removed after several weeks once the surrounding ligamentous tissues become stable. Carpal fractures and dislocations should be reduced and pinned with multiple Kirschner wires and the ligaments reattached with bone anchors, as described in Chapters 13 and 16.

CASE STUDY 43.3

A 65-year-old man was injured in a motorcycle accident; his left hand was "pinched" off at the metacarpal level by an unknown object (eFigure 43.5).

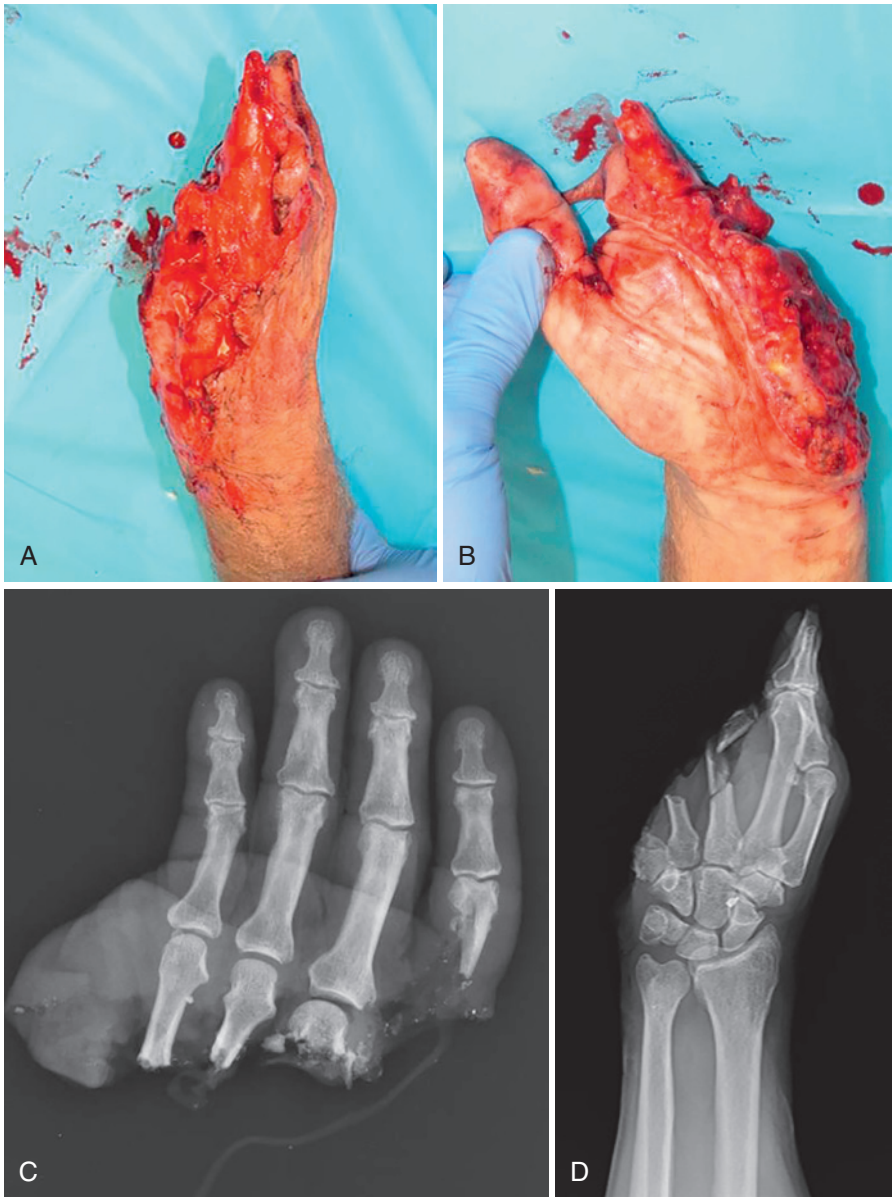
In this patient, a large portion of the proximal index finger stump is degloved, and there is significant soft tissue loss of that ray. Because of this, you elect to perform immediate ray amputation of the index finger. Following debridement and index amputation, the next step in replantation of the remaining part of the hand should be:

a. Arterial anastomosis
b. Nerve coaptations
c. Tendon repairs
d. Skeletal shortening and fixation

Answer: (d) skeletal shortening and fixation.

Rationale: Unlike more proximal amputations or manglings that result in a dysvascular hand, these distal amputations do not require early circulatory establishment as the amputated part does not contain a significant amount of muscle tissue, which is the most sensitive to the duration of ischemia and releases the most toxins when circulation is reestablished. Therefore, skeletal shortening and stabilization should be performed first, thereby allowing a stable "platform" on which one can later perform tendon repair and microsurgical anastomoses/coaptations.

Postoperative images are shown in eFigure 43.6.



eFIGURE 43.5 Hand pinched at metacarpal level. **A, B,** Clinical photos of injury. **C, D,** Radiographs.

eFIGURE 43.6 Injury at metacarpal level following skeletal shortening and fixation. **A, B,** Early postoperative appearance. **C, D,** Follow-up clinical photos demonstrating viable digits and ongoing wound healing. **E, F,** Radiographs with Kirschner wires. **G,** Radiograph showing removal of Kirschner wires; note significant skeletal shortening.

Fractures of the shaft of the radius or ulna (or both) are best treated with 3.5-mm dynamic compression plates. Fractures of the distal end of the ulna or ulnar styloid associated with instability of the distal radioulnar joint should be treated with Kirschner wire and tension band wire reconstruction as described in Chapter 14. Fractures of the distal end of the radius require first an anatomic reconstruction of the articular surface and then frequently either dorsal or volar buttress plating as described in Chapter 15. When metaphyseal comminution or multiple carpal fractures or dislocations are present, the risk of shortening over time is great. External or internal spanning fixation, from the radius to the second or third metacarpal, can provide excellent stable fixation that will allow early motion and does not carry the infection, tendon adhesion, and other risks associated with the use of an external fixator.[19]

An internal spanning fixation is preferable, with a plate that is left in situ for 3 to 4 months, while the metaphysis and articular surface heal completely (Figure 43.10). This plate can be both applied and removed with minimal soft tissue dissection through only a proximal incision of the radius and a distal incision over the metacarpal. In this way, severe metaphyseal comminution can be reconstructed by ligamentotaxis, with the periosteum left intact and the depressing scenario of "a bag of bones" spilling out onto the operating table avoided. We find that a plating system with locking screws works best for this purpose. It can be inserted through a tunnel between the second and fourth dorsal compartments with the use of three to four locking screws on both the radius and metacarpal. Similarly, it can be removed through fairly small proximal and distal incisions without reopening the entire area.

Whenever possible in such cases, the articular surface should be anatomically reduced by indirect techniques under fluoroscopic guidance. Because of the length and narrowness of the plate, some external support in the form of a cast or rigid splint is required while the plate is in place. This approach provides stability and maintains length better than an external fixator does; is much less cumbersome; and has fewer problems related to pain, irritation, and infection of fixator pins.

Specific treatment of carpal, metacarpal, and phalangeal fractures and dislocations is covered in Chapters 7 and 16. Again, the focus with mangling injuries is to provide sufficiently stable fixation to allow early motion. In the carpus, this is usually achieved with cannulated compression screw fixation and, in the metacarpals and phalanges, with miniplate and screw fixation whenever possible. Kirschner wires, nevertheless, still do have a role, especially in reconstructing articular fragments and with fractures around joints where it is not technically possible to perform fixation with plates and screws.

When Kirschner wires are used and are expected to remain in place beyond 4 weeks, we cut them below the skin's surface and plan to remove them in a small operation at a later stage in an attempt to reduce the complications of pin irritation and infection. In the metacarpals and phalanges, achieving accurate rotational correction is, as always, paramount. Kirschner wires can be helpful in providing provisional fixation so that rotational deformities can be evaluated and corrected before definitive fixation. In cases of severe diaphyseal comminution, cerclage wires can hold the "barrel staves" together and prevent collapse. Kirschner wires should be thought of as "internal splints" rather than rigid fixation. Even crossed wire constructs are unstable to horizontal or rotational deformation. Unless numerous crossed wires are used in a single bone, which carries the risk of tendon, ligament, or soft tissue impingement, rigid stability to allow early motion will be difficult to achieve.

One trick that should be kept in mind with Kirschner wires is to use them as both provisional fixation and as a drill for later screw exchange. In this way, the wires can be placed under fluoroscopic guidance and the resulting fixation checked both clinically and radiographically. The individual Kirschner wires can then be replaced with screws with minimal soft tissue exposure. The diameter of a 0.045-inch Kirschner wire is 1.1 mm, which is the core diameter of a 1.5-mm screw. Similarly, the diameter of a 0.062-inch Kirschner wire is 1.5 mm, which is the core diameter of a 2.0-mm screw.

Like Kirschner wires, external fixation still does have a role in mangling injuries. In some cases it is not possible to achieve rigid internal fixation because of comminution or internal fracture anatomy. In such cases the use of an external fixator either across the wrist (Figure 43.11) or across an MP or IP joint is the best option. The mini-external fixator is also very useful in maintaining the first web space after crushing or mangling injuries to prevent the development of an adduction contracture (Figure 43.12). The tendency for development of an adduction contracture in the presence of a mangling or crushing injury is so strong that either a temporary external fixator construct or pinning across the trapeziometacarpal joint is recommended for most cases. Although distraction lengthening techniques could be used for severe, complex upper extremity injuries, the authors have not found this technique to be of much use for the forearm or hand.

When skeletal defects remain, bone grafting needs to be performed. Unlike the lower extremity, the abundant vascularity of the upper extremity often allows primary bone grafting unless there is significant contamination, poor soft tissue coverage, or compromised adjacent tissue vascularity. We have come to favor cancellous allograft in most cases unless autograft is simple to harvest from adjacent bone such as the radius for wrist or hand defects. If the wound, coverage, or both are deemed unsuitable for primary bone grafting, antibiotic-impregnated polymethyl methacrylate beads or spacers can be used to fill the defect until definitive bone grafting is performed, usually after soft tissues have healed. These beads are available commercially or can be made by mixing 1 g of tobramycin and 1 g of vancomycin with the polymethyl methacrylate and forming small beads on a length of No. 1 or No. 2 braided suture. Alternatively, a custom block can be fashioned to fit the defect and secured as part of the fracture fixation. After wound stabilization and maturation, the spacers are replaced with bone graft (Figure 43.13).

Tendon Repair/Reconstruction

After skeletal stabilization, the next step is tendon repair. Unless the ongoing ischemia is critical, performing tendon repair before vascular repair can reduce the chance of disrupting the vascular repair with the maneuvers involved in repairing the tendons. The details of tendon repair and reconstruction are covered in Chapters 5 and 6. We would like to emphasize that the best outcomes after primary tendon repair occur in the setting of sharp lacerations with minimal soft tissue injury, which is rarely the case with mangling injuries. If primary repair can be performed without significant shortening or

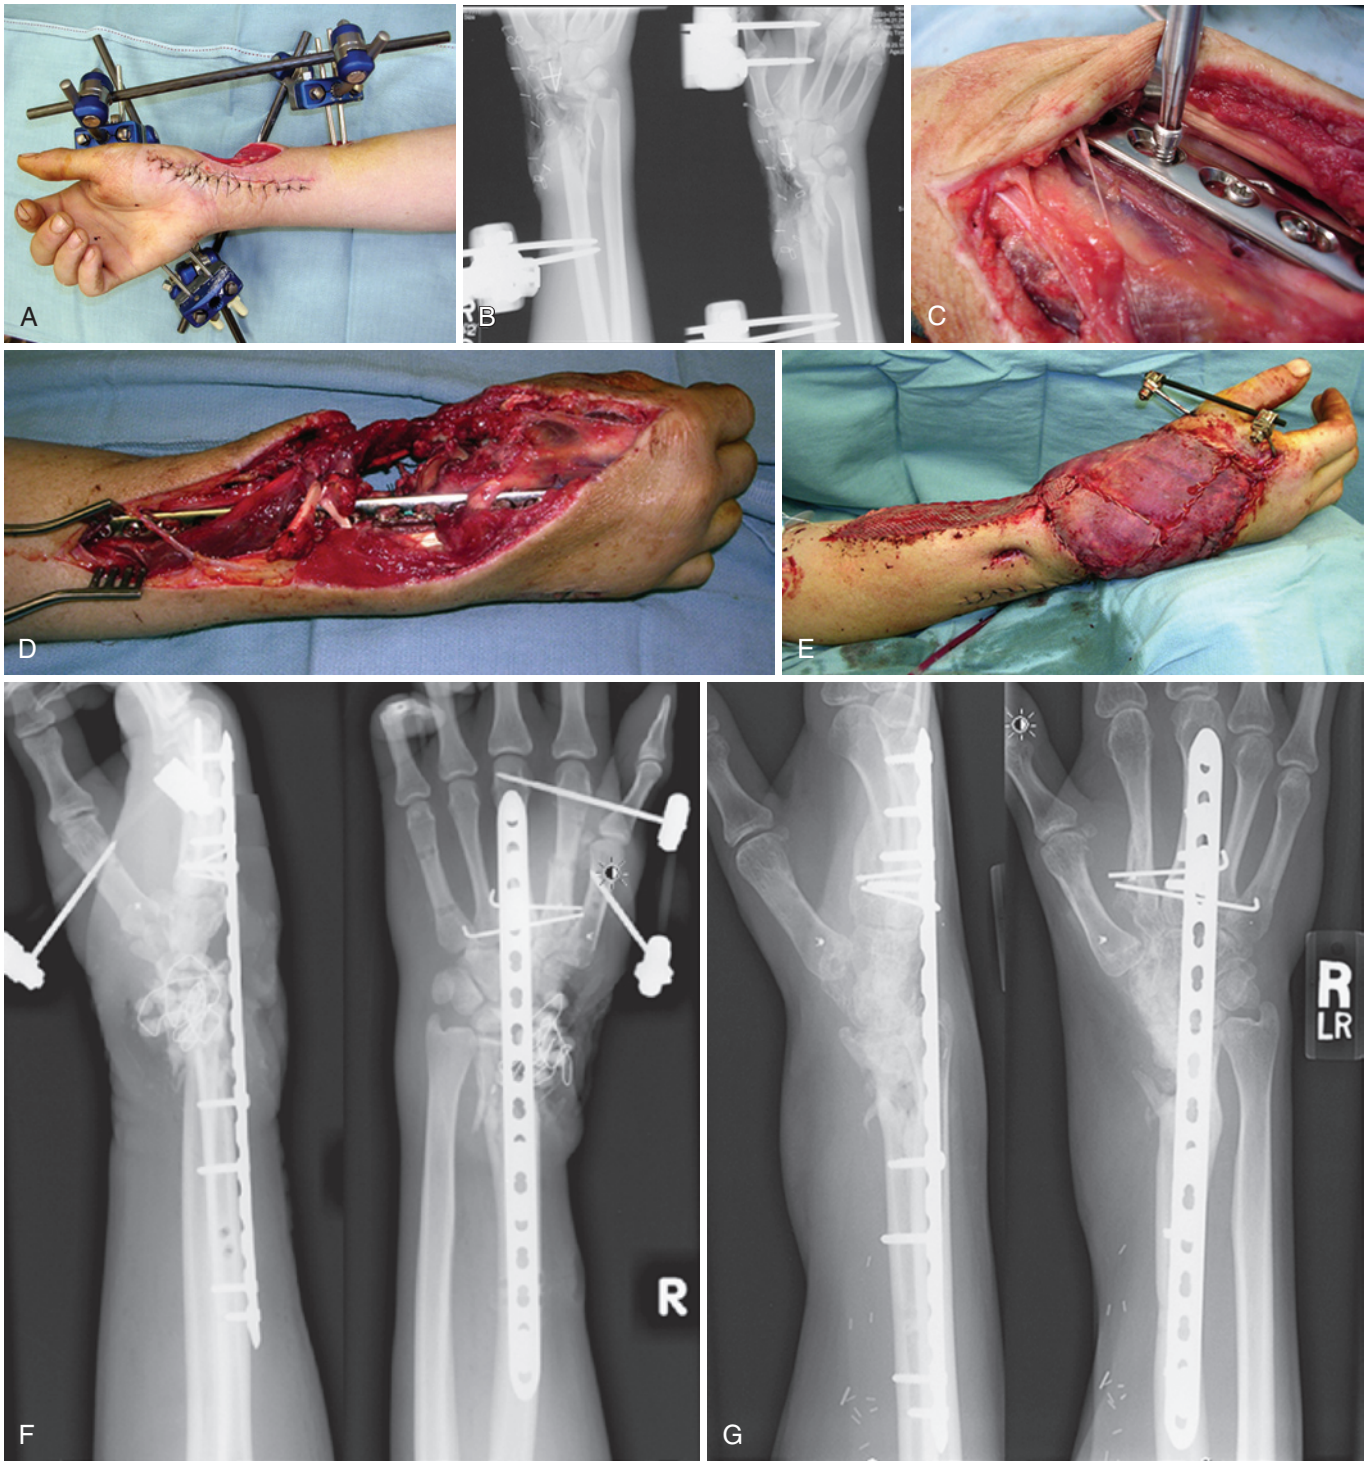


FIGURE 43.10 A rifle injury created this combined complex skeletal and soft tissue injury. **A, B,** Initial treatment consisted of debridement and stabilization with an external fixator before transfer to our facility. **C, D,** Converting the external fixator to a forearm spanning plate with locking screws provided rigid fixation and allowed unimpeded soft tissue reconstruction, including stabilization of the thumb and index carpometacarpal joint dislocations. The bone defect is temporarily filled with polymethyl methacrylate beads impregnated with tobramycin. **E,** The soft tissue defect was reconstructed with the distal three slips of the serratus anterior muscle as a free flap. **F,** Two months after initial reconstruction, the polymethyl methacrylate beads were replaced with allograft cancellous chips milled to fine particles. **G,** Radiographs 6 months after injury demonstrated incorporation of the allograft. The spanning plate was removed 12 to 16 weeks after placement once solid bony healing had occurred.

CRITICAL POINTS *Skeletal Reconstruction*

- Attempt to visualize the fracture with minimal dissection and minimal muscle and periosteal stripping.
- Restore length for optimal function of the muscle–tendon unit or shorten for primary closure and skeletal and nerve repair.
- Perform accurate anatomic reduction with special attention to the articular surfaces.
- Use stable, low-profile, minimally invasive fixation and begin early motion with fracture healing.
- For the radius/ulna, use a 3.5-mm limited-contact dynamic compression (LCDC) plate versus a spanning plate to the second or third metacarpal with locking screws if severe comminution is present.
- For fixation of fractures of the wrist, use compression screws or Kirschner wires, repair or reconstruct ligaments, and stabilize with Kirschner wires.
- For the metacarpals, we prefer miniplate fixation to minimize interference with joints or tendons so that early motion can be achieved.
- Maintain the first web space with an external fixator or thumb CMC pinning.
- For the phalanges, use a miniplate, Kirschner wires, or tension band wiring.
- For skeletal defects, decide between shortening, primary bone grafting, and placement of an antibiotic spacer with delayed bone grafting.

FIGURE 43.11 **A** through **C,** Occasionally it is not possible to achieve rigid internal fixation because of comminution or internal fracture anatomy. In this case, an external fixator across the wrist was used successfully.

FIGURE 43.11, cont'd

FIGURE 43.13 **A,** This injury resulted from a rollover car accident. After debridement, skeletal length was restored with a 3.5-mm plate. **B,** A block of polymethyl methacrylate (PMMA) was incorporated into the distal bone defect (*arrow*). Soft tissue coverage was provided with a split latissimus dorsi free flap and skin grafts. Four months after injury, the PMMA block was replaced with an 8-cm allograft fibula bone graft. **C,** Functional result a year after injury.

contracture, the flexor tendons should be repaired with four core sutures to allow early postoperative motion, as well as epitendinous sutures in zone 2.

With mangling injuries in zone 2, we generally repair both the superficialis and profundus tendons. The exception to this is when repair of both tendons compromises gliding through the A2 pulley and results in limited PIP motion. In this situation, we repair only the profundus tendon. If tendons are transected in mangling injuries, the ends are often frayed and have substance missing. Repair may be possible only with concomitant skeletal shortening or with tendon grafting, either acute or delayed. Acute tendon grafting is possible, but it requires an excellent soft tissue bed, stable skeletal fixation, and an intact pulley system so that an immediate passive or active tendon rehabilitation protocol can be started postoperatively.[93] Usually, however, if primary repair cannot be performed, staged tendon grafting should be planned. At the time of definitive soft tissue closure, Silastic tendon spacers should be placed to allow secondary reconstruction. If the critical A2 or A4 flexor pulleys are disrupted, they should be reconstructed with spare parts, tendon, fascia, or a portion of the extensor retinaculum as described in Chapter 43.

Mangling injuries to the extensor tendons, especially on the digits, present some of the greatest challenges for reconstruction. In the digits the extensor tendon mechanism is a finely tuned, balanced "shroud" mechanism with tight tolerances that reacts poorly to injury or adhesions. The lumbrical and interosseous muscles, which comprise the intrinsic extensor mechanism of the hand, are very susceptible to crushing or mangling injuries. In most circumstances, because scarring plus contracture of these intrinsics after injury is the most significant problem, debridement of crushed, devascularized, and severely injured intrinsics is warranted at the time of the initial operation.

With tendon injuries proximal to flexor zone 2 or extensor zone 5, primary tenodesis or tendon transfer should always be kept in mind. Side-to-side tenodesis of either the profundus flexor or extensor tendons proximal to the MP level can restore excellent function. If the flexor pollicis longus can be repaired only with significant shortening and flexion, transfer of the ring superficialis tendon should be considered. Transfer of the superficialis to other profundus tendons should also be considered in similar circumstances. Any late intrinsic deficiency is best treated by delayed intrinsic tendon transfer. Complete destruction of either the flexor or extensor muscle–tendon unit is best treated by delayed tenodesis, tendon transfer, or free muscle transfer reconstruction as described in Chapters 5, 6, and 51.

Vascular Repair/Reconstruction

Optimal revascularization of a mangled extremity is without question the most important aspect of reconstruction. In most cases, to avoid injury to a fragile vascular reconstruction, definitive vascular reconstruction should be deferred until after debridement and skeletal and tendon reconstruction. If, however, major arterial disruption has occurred and rendered the limb ischemic, a temporary vascular shunt should be placed as an initial step, as described previously (see Figure 43.9) (Case Study 43.4). If possible, it is helpful to dissect out the injured vessels, identify the ends, and place microvascular clamps across the ends while still under tourniquet control. The actual vascular reconstruction can then be performed after the tourniquet is released.

CRITICAL POINTS *Tendon Repair/Reconstruction*

- Debride crushed intrinsic muscles to prevent contracture.
- Use four-core locking sutures plus a fine epitendinous suture if zone 2 is involved.
- Repair both the flexor digitorum superficialis and flexor digitorum profundus unless gliding is compromised, in which case repair just the flexor digitorum profundus.
- Repair/reconstruct the A2 and A4 pulleys.
- For tendon rods use two-stage reconstruction if primary repair is not possible.
- Consider primary tenodesis/tendon transfer.
- For late reconstruction, tendon grafting, tendon transfer, tenolysis, and functional free muscle transfer may be needed.

The most important factor in determining success or failure of the vascular reconstruction is ensuring that the vascular anastomosis is performed with uninjured vessel on both sides of the anastomosis and using careful technique, as described in Chapter 60. With mangling injuries, this usually involves trimming the injured vessels back until healthy, uninjured intima can be seen with magnification. Once this is done, it is frequently difficult to achieve a tension-free primary repair. This situation can be addressed several ways.

Sometimes it is possible to ligate and divide small side branches near the ends to allow sufficient mobilization for primary anastomosis. Occasionally, an adjacent joint can be safely flexed to allow a primary repair, especially if flexion is required for concomitant primary nerve repair. This is certainly the case around the elbow, where flexing can often allow primary vascular repair; however, the extended position may be required for a vein graft, only to have it kink and need to be revised when the elbow is flexed for repair of a tendon or nerve. In many cases, however, a reversed vein graft is required.

Just as it is important to perform the microvascular anastomoses outside the injured zone, if a vein graft is required, it is also important to harvest vein from outside the zone-of-injury. Reasonable places to harvest a vein graft from the upper extremity, only if uninjured, include the dorsum of the hand or the dorsal or volar surface of the forearm. Distant sites include the leg (saphenous) or foot. The dorsal veins of the foot are a good source for vein graft with a reasonable size match for reconstructing the digital vessels in the palm or digits. If the palmar arch needs to be reconstructed, it is sometimes possible to find a venous network on the dorsum of the foot that, when reversed, can provide multiple outflow tracts for the common digital vessels (Figure 43.14).[42]

To reconstruct the brachial, radial, or ulnar arteries, the saphenous, lesser saphenous, or cephalic veins are good choices. For all vein grafts it is important to remember that the grafts must be reversed to retain antegrade flow rather than against the venous valves. In some cases when the brachial/radial-ulnar artery bifurcation must be reconstructed, an antegrade bifurcation of a larger vein can be used and the valves released with a valvulotome (Figure 43.15). It is also important to minimize damage to the vein during harvest and to ensure that all small

CASE STUDY 43.4

The arm of a 32-year-old male is caught in a rebar bending machine. He presents with a dysvascular forearm and hand (eFigure 43.7).

The order of initial surgical steps should be the following:

a. Skeletal stabilization, debridement, revascularization
b. Revascularization, debridement, skeletal stabilization
c. Debridement, revascularization, skeletal stabilization

Answer: (c) Debridement, revascularization, skeletal stabilization

Rationale: The key point in the major upper extremity mangling injuries that involve a dysvascular extremity is to establish *temporary* revascularization via a shunt. Debridement should be done first to remove the heavy contamination and nonviable tissue. Shunting should next be done for the brachial artery. Following establishment of temporary circulation, the skeletal stabilization can proceed in a controlled fashion.

Surgical photos are displayed in eFigure 43.8.

Following debridement, vascular reconstruction, and skeletal stabilization, the patient has a large antecubital fossa defect with exposed vascular graft. The most appropriate soft tissue reconstruction is:

a. Split thickness skin graft
b. Negative pressure would treatment until closure
c. Free tissue transfer
d. Groin flap

Answer: (c) Free tissue transfer

Rationale: A skin graft is not optimal coverage over vascular grafts because of the potential for vascular graft rupture. Negative pressure wound therapy can be used over vascular grafts but should not prolong the time for definitive reconstruction. A groin flap would not reach the antecubital fossa. A free tissue transfer is appropriate as it will allow expeditious and stable one-stage soft tissue reconstruction and will provide durable coverage over vascular grafts, nerves, and the joint.

See eFigure 43.9.

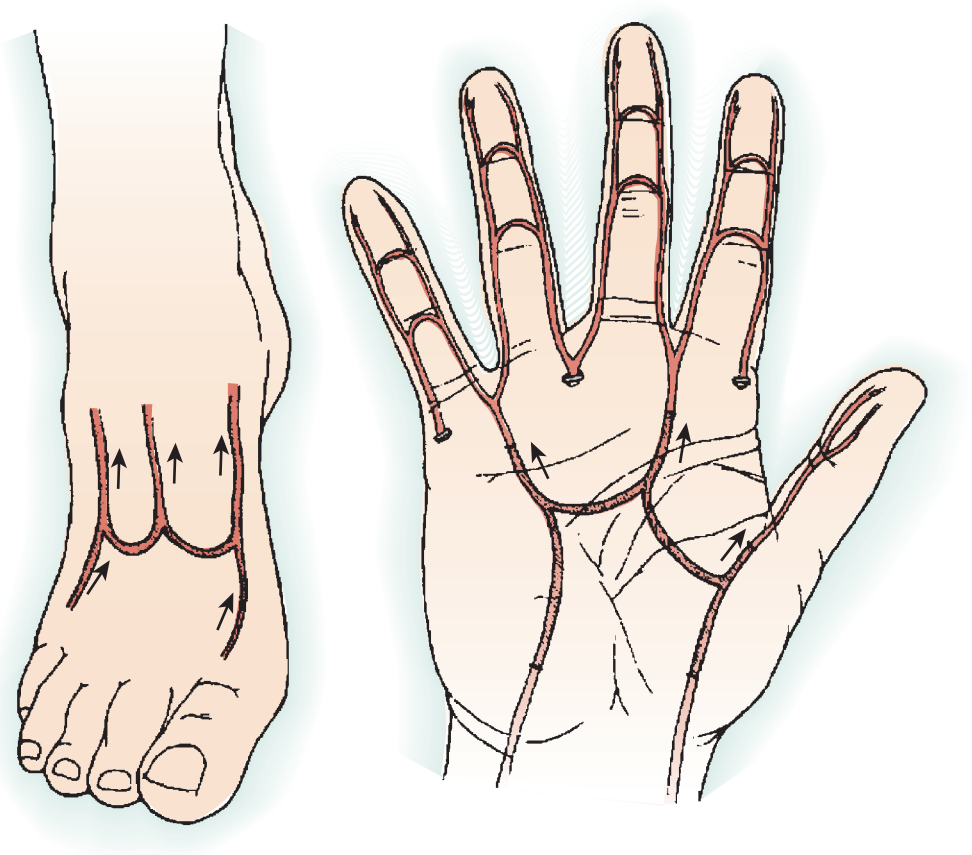

FIGURE 43.14 Venous network on the dorsum of the foot, which when reversed, can provide multiple outflow tracts for the common digital vessels. (Reprinted from Gupta A, Wolff TW: Management of the mangled hand and forearm. *J Am Acad Orthop Surg* 3:226–36, 1995, with permission.)

side branches are ligated either with small hemoclips or with bipolar electrocautery.

Once the vessel ends have been identified, clamped, and trimmed back to healthy tissue, the vessels should be cleared of thrombus proximally and distally. With the major vessels this is usually done with a No. 2 Fogarty catheter or, in the case of digital vessels, by simply milking out the clot and removing it with irrigation and microvascular forceps. The vessels are then irrigated proximally and distally with 10-U/mL heparin in saline solution using a blunt irrigating cannula. If vein graft is to be used, it should first be predilated so that the proper length of vessel can be determined.

One of the most common errors in vein grafting is using too long a piece of vein for the defect, thereby resulting in redundancy, kinking, and thrombosis. Predilation is performed by first reversing the graft and then placing a microvascular clamp on the outflow end of the vessel. The vessel is filled with a heparin–saline solution equivalent to systolic arterial pressure to reproduce the state of the vessel once arterialized. The point of the vein graft that will be used for the proximal anastomosis is cut with microvascular scissors and microvascular anastomosis performed as described in Chapter 60.

With the application of mild tension on both the distal arterial segment and the vein graft to stimulate the state of the vessels under pressure, the point along the vein graft for the distal anastomosis is identified and cut. If a long piece of vein graft is used, it is often helpful to determine the final length by releasing the proximal clamp and allowing the graft to fill with blood under systolic pressure with a distal clamp in place and assume its eventual length. The graft can then be marked and cut to the proper length for the distal anastomosis. The distal anastomosis is performed with double microvascular clamps to take tension off the anastomosis during its creation. The clamps are released and flow established through the anastomoses. Any areas of leakage are addressed with additional sutures at this point and any previously unidentified cut side branches are ligated.

If multiple levels of vascular injury are involved, the proximal reconstruction should be performed first, followed by the more distal ones. In the case of palmar arch or common digital artery injuries, it is not always necessary to reconstruct every common digital vessel because one can adequately perfuse two digits. Reconstructing the common digital artery to the index/middle finger and to the ring/small finger is all that is required, in addition to the thumb, of course. Whether to reconstruct either the radial or the ulnar artery when the other is intact or whether to reconstruct one or both, if both are injured, is a matter of debate.

Some studies have suggested only a 50% patency rate if the other vessel is open and uninjured and that the functional outcome is the same with ligation or repair of a single vessel.[33,52] There is some evidence, however, that with microsurgical repair,

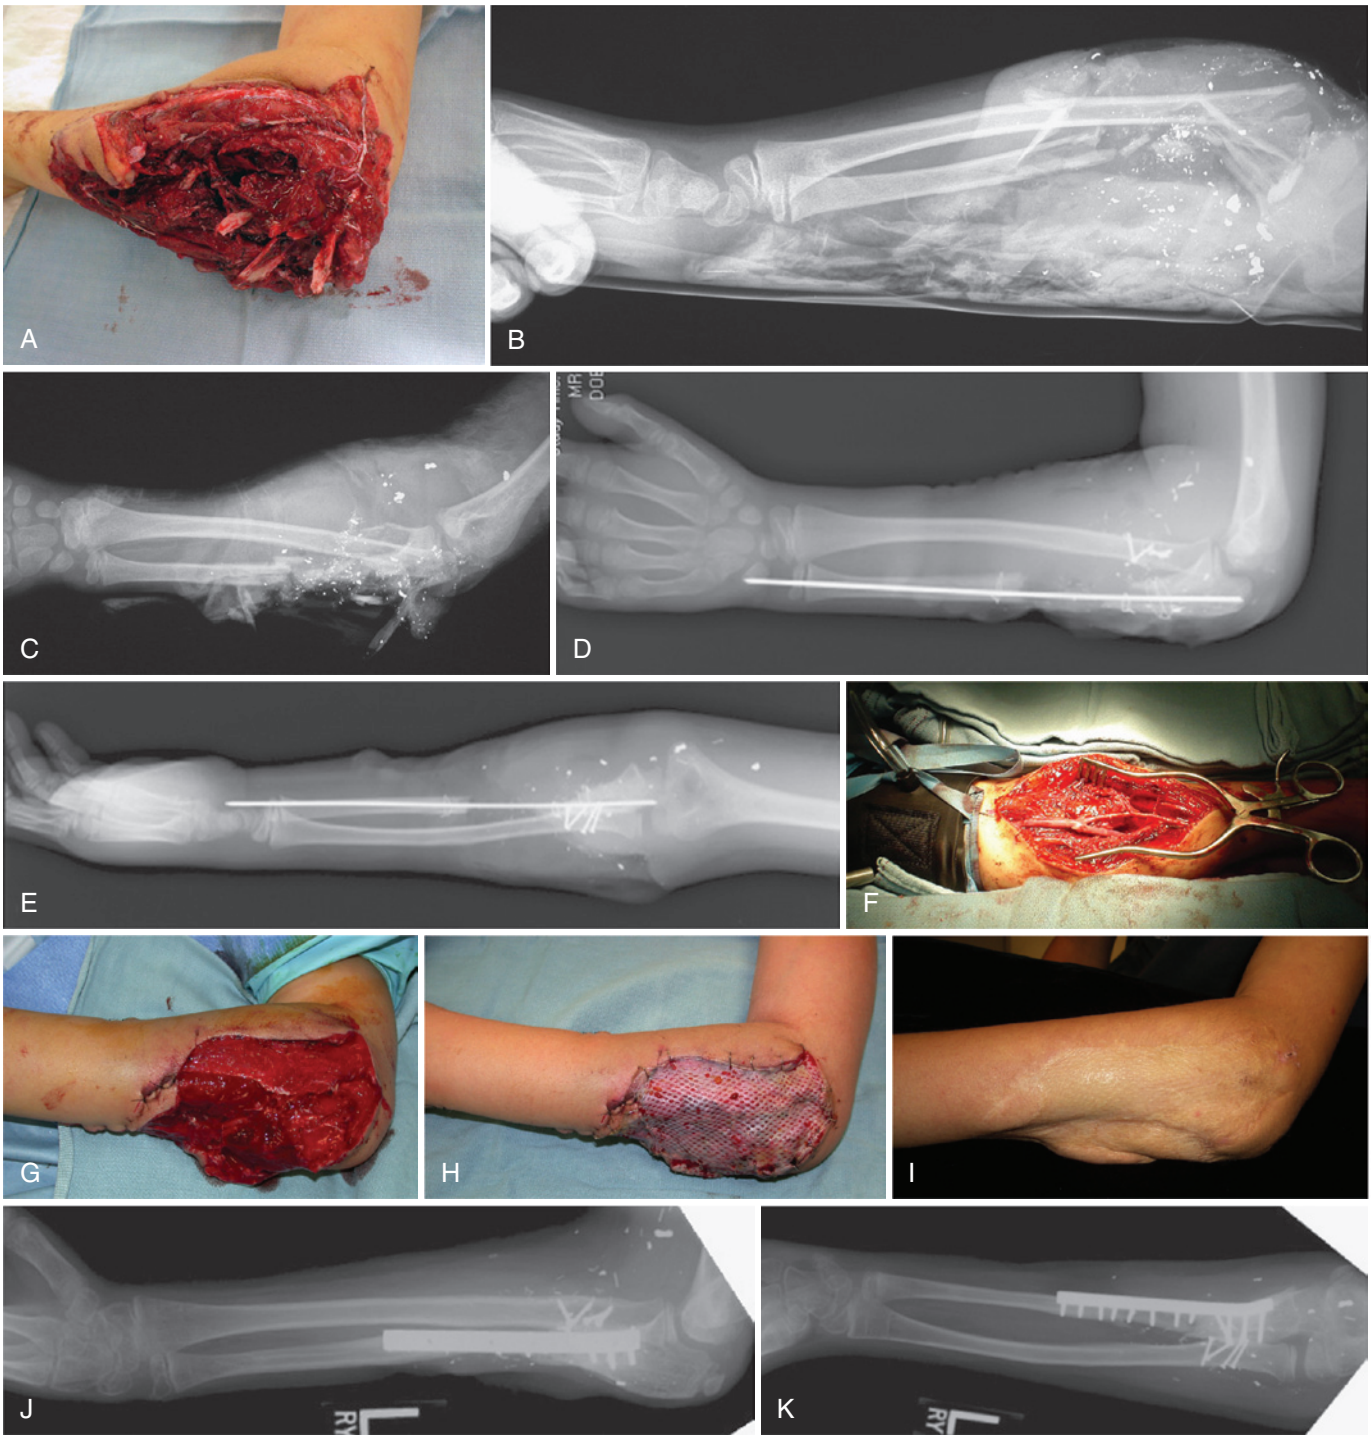

FIGURE 43.15 **A** through **C,** This 10-year-old boy sustained a shotgun wound to his left elbow that resulted in severe soft tissue injury, significant comminuted radius and ulna fractures with bone loss, and devascularization of the forearm with destruction of the brachial/radial-ulnar artery bifurcation. The three major nerves were in continuity, although contused. **D, E,** The wound was thoroughly debrided and provisional fixation achieved with a combination of screws, cerclage wires, and a Steinmann pin through the ulna. **F,** Arterial reconstruction was achieved through a separate anterior approach by using the bifurcation of a large adjacent vein, out of the injury zone, releasing the valves with a valvulotome, and placing it in an antegrade fashion to reconstruct the brachial artery bifurcation. **G, H,** The initially complex wound was treated with negative pressure therapy for a week, which resulted in a wound that could be closed with a simple skin graft. **I,** The resulting soft tissue reconstruction was stable. **J, K,** Skeletal reconstruction was achieved with a combination of an ulna allograft and iliac crest cancellous autograft through a separate approach.

patency rates can be much higher.[91] In the case of most mangling injuries, to maximize flow to all injured tissues through all side branches available and because of the risk for thrombosis in the other vessel, we generally favor reconstructing both the radial and ulnar arteries, if feasible. The same holds true for digital artery injuries.

It is uncommon to require venous reconstruction except in cases in which there is a circumferential or nearly circumferential transection or crush injury to the subcutaneous venous drainage system of either the digit or forearm. In such cases, the same principles that apply to arterial reconstruction also apply to venous reconstruction. Again, the repairs must be performed with an uninjured vessel, and use of a vein graft may be required. Once the arterial and, if necessary, venous reconstructions have been completed, it is important to monitor their patency continuously throughout the remainder of the operation. Should thrombosis occur, it is important to address this quickly before the thrombus propagates distally.

The most common cause of thrombosis in these situations is either technical error in performing the anastomosis or error in judgment with inadequate resection of the damaged vessel. In both cases, reresection of the vessel ends is almost always indicated in revising the anastomosis after thrombectomy. Anticoagulation is generally contraindicated with mangling injuries of the arm and forearm, although it could be considered if injury is confined to the hand or digits. Clinical trials of anticoagulation in microsurgery have failed to demonstrate a consistent benefit.[56,57]

CRITICAL POINTS *Vascular Repair/Reconstruction*

- Perform vascular repair/reconstruction after skeletal and tendon repair unless critical ischemia is present (in which case use a temporary shunt).
- Dissect vessels and use a microvascular clamp under tourniquet control.
- Declot with a Fogarty catheter proximally and distally.
- Trim vessel ends to healthy, uninjured tissue.
- Irrigate and fill with a 10-U/mL heparin solution and then clamp.
- Perform the vascular repair with the microscope, outside the injury zone if possible.
- If there is inadequate length, ligate/divide some side branches, flex the joints, or use a reverse vein graft.
- Perform a vein graft with vein outside the zone-of-injury; predilate and reverse it (valves).
- Repair or reconstruct both the radial and ulnar arteries whenever possible.
- Perform venous reconstruction only if all or nearly all venous outflow is absent.

Nerve Repair/Reconstruction

Nerve repair usually follows skeletal, tendon, and vascular reconstruction in that order because it is less urgent than vascular reconstruction and the delicate techniques involved can easily be compromised by the more aggressive maneuvers involved in skeletal and tendon reconstruction. Again, the details of nerve repair and reconstruction are covered elsewhere (see Chapter 30). As noted previously, it is important to distinguish between neurapraxia, axonotmesis, and neurotmesis in deciding on the appropriate treatment for nerve injury. In nearly all cases involving mangling injuries, if the nerve sheath is in continuity, it is best left alone to see whether function will return later.

In the case of neurotmesis involving the digital nerves or major nerve trunks, primary end-to-end epineural repair should be performed. It is important that the repair be tension-free because a repair under tension leads to nerve ischemia or physical gapping, either of which will impair nerve regeneration. Nerve repair should be performed with the aid of the operating microscope to properly align the major nerve fascicles, to properly place the sutures in the epineurium, and to control the tension when tying the sutures to achieve proper axon-to-axon apposition without bunching. With traumatic nerve transections and especially with crush or avulsion injuries, it is critically important to trim back crushed or injured nerve endings before performing the repair. Again, this is performed with the aid of the operating microscope to determine when soft healthy fascicles have been reached. After trimming, it is sometimes necessary to dissect the nerve proximally and distally, without sacrificing critical side branches, to achieve a tension-free repair.

If primary, tension-free nerve repair cannot be achieved in the acute setting and if the gap is less than 1 to 2 cm, a nerve conduit or decellularized nerve allograft can be used to bridge the gap as described in Chapter 30.[55,66,105] If the remaining gap is longer, however, either delayed nerve grafting or, in the case of a motor–nerve deficit, tendon transfer or nerve transfer should be performed. In nearly all cases, if a functional nerve is to be sacrificed for nerve grafting, we prefer to perform this as a secondary procedure so that healthy nerve endings with soft, viable fascicles can be ensured and the risk of graft loss because of wound contamination and infection is limited.

CRITICAL POINTS *Nerve Repair/Reconstruction*

- Repair or reconstruct nerves as the last step before soft tissue coverage.
- Trim clearly crushed nerve to healthy fascicles.
- Perform epineural repair with the microscope.
- Use the fascicular and surface anatomy for proper alignment.
- Perform a tension-free repair.
- If a nerve gap is present, free the minor branches, flex the joint, use a nerve conduit for a short gap, and use a nerve graft for larger gaps.

Soft Tissue Coverage

Achieving a healed wound with stable, durable coverage and vascularized tissue over critical structures is key. Soft tissue coverage is the last and in many ways the most important step in the treatment of mangling injuries of the upper extremity because it determines the environment in which all other repaired and reconstructed structures will heal and ultimately function. In addition, coverage should be low profile, be supple over mobile areas (e.g., joints and tendons), and have minimal shear characteristics on the volar aspect of the hand and fingers where friction is required for function. Ideally, coverage over the volar tips of the digits should be sensate. Frequently, it is impossible to achieve all these goals with a single reconstruction method, and either some compromise or some combination of methods must be used.

Although achieving early wound closure is desirable to reduce the possibility of infection and optimize healing and

FIGURE 43.16 Use of vascular surgical "vessel loops" in a crisscross fashion with staples along the wound edge to create a "corset" effect that brings the wound together without creating ischemia.

motion, with severe crush or mangling injuries and in particular in the presence of significant contamination, it is often prudent to delay definitive coverage until a stable wound has been achieved. This will sometimes require serial debridements separated by 24 to 48 h. In nearly all cases, however, strive to have definitive coverage by 7 to 10 days even though some smaller, noncritical wound or wounds may remain at that point.

During the intervening period before definitive coverage, it is imperative that the wound and all vital structures remain moist. As swelling develops after injury, there is a clear tendency for wounds to enlarge, thus making closure progressively more difficult. We have found two techniques helpful in controlling this situation. The first involves using rubber bands or vascular surgical "vessel loops" in a crisscross fashion with staples along the wound edge to create a "corset effect" that brings the wound together without creating ischemia (Figure 43.16). This technique also allows a certain degree of limb swelling without creating a compartment syndrome and naturally brings the wound edges together as the swelling diminishes.

The other method uses negative pressure therapy (NPT), an example of which is vacuum-assisted closure (VAC). NPT has a number of salutary effects, including removal of exudate, decrease in edema, closure of dead space, promotion of wound contraction, marsupialization of the wound edges, and promotion of granulation. In essence, it acts as a "mechanical myofibroblast." NPT has revolutionized the approach to soft tissue coverage in complex lower extremity defects in that it allows wounds to contract and granulate to the point where they can be covered with a simple skin graft rather than a complex flap. In the upper extremity, however, because of the importance of maintaining the gliding motion of muscles and tendons, prolonged application of NPT and skin grafting can lead to outcomes inferior to those of early coverage with a supple, vascularized flap.

NPT should never be used to unnecessarily prolong definitive upper extremity soft tissue reconstruction. Nevertheless, it does have an important role in the soft tissue reconstruction of mangled upper extremity injuries. When used judiciously and for limited periods, it can dramatically improve the wound environment and decrease the size requirements for flap coverage.[3,86] The application of NPT has evolved to the current state at which the benefit of immediate soft tissue coverage can be safely postponed. Details on the use of VAC are provided with the device, and because the device can change, the reader is referred to the manufacturer's instructions for details. Trimming the sponge to a size slightly smaller than the wound helps shrink the size of the wound with suction.

Closed NPT should not be used, however, for extremities with severe contamination, infection, or significant bleeding. It should also be used with caution in the setting of vascular repair or reconstruction. Because NPT is a closed system, it is important to change the sponge every 3 to 5 days or more frequently, depending on the level of contamination. In some cases, if the fascial coverage of critical structures is preserved, NPT alone can obliterate dead space and produce a wound that can be skin grafted while preserving vascularized gliding tissue over critical structures (Figure 43.17).

In planning soft tissue reconstruction, it is important to keep in mind the concept of the "reconstructive ladder" as originally described by Mathes and Nahai.[69] This concept implies that the simplest method of coverage appropriate to the situation should be used. We have modified the standard reconstructive ladder to include NPT in the mix. The modified reconstructive ladder generally follows the following progression:

- Primary closure
- Wound contraction ("secondary intention")
- Skin grafting
- NPT
- Flap
- Local
- Distant
- Free

Given the unique functional requirements of the upper extremity, including joint motion and tendon/muscle gliding, the simplest soft tissue reconstruction is not always the most appropriate. The decision often involves making judgments regarding the ultimate functional goals and balancing them with the complexity of the reconstruction required to achieve the goals. If the area in question has exposed "white structures" (i.e., tendon, nerve, bone, or ligament/joint), some form of a vascularized soft tissue reconstruction will be required. If, however, critical functional structures are not involved, a simpler form of reconstruction can be used.

Gottlieb and Krieger have made the point that merely using the simplest reconstruction and moving "up the ladder" when that fails is not appropriate, but rather, riding the "reconstructive *elevator*" up to the most appropriate treatment for the particular condition is what is required.[37] The essential principle is to not merely use the simplest technique possible but to use the simplest technique that will achieve optimum form and function. Do not be afraid to choose a complex reconstruction if it will provide the best result but not every wound requires a free flap.

Whenever possible, primary closure or delayed primary closure (5–7 days after injury) should be performed. In doing so, it is critically important to close the wound loosely so that tension does not lead to ischemia of edges with subsequent dehiscence or ischemia of the underlying structures because of increased compartmental pressure. It is far better to have small gaps that heal secondarily than to have a large dehiscence or, even worse, to induce necrosis in marginally vascularized skin that would otherwise survive, especially in the case of traumatically elevated flaps.

In these situations it is always best to simply lay the skin down and at most tack it in place loosely rather than stretch it

FIGURE 43.17 **A,** A complex crush injury resulted in a severe combined injury that included skin, muscle, and bone. **B,** Complete excisional debridement was performed with removal of all nonviable soft tissue; a "see-through" wound was left that would otherwise require a large flap **(C)**. By preserving and using the forearm fascia, this complex wound could be transformed, with the aid of negative pressure therapy **(D)**, into a wound that could be skin-grafted **(E)** while preserving vascularized gliding tissue over critical structures **(F, G)**.

back to its original position, thereby creating ischemia and necrosis in a large area of the flap, resulting in a defect much greater than one that would be left by simply laying the flap down (Figure 43.18). If the wound edges cannot be closed primarily, it is certainly reasonable to allow the wound to close secondarily by wound contraction if the remaining defect is less than 1 to 2 cm and if there are no vital structures or motion areas (e.g., joints or web spaces) left exposed. Many fingertip injuries and amputations heal best with wound contraction to bring the adjacent, sensate skin together to provide coverage, as opposed to insensate grafts or flaps.

For larger noncritical defects, a skin graft may be required. Skin grafts can consist of autograft (from the patient), allograft (from a human skin bank), or xenograft (usually porcine skin). A xenograft is used primarily as a "biologic dressing" and usually does not revascularize. Allograft can revascularize and "take"; however, it will be rejected after the first week or so. It is useful in promoting vascular ingrowth into a wound bed and preparing the bed for later autografting. If an allograft takes, one can be fairly confident that an autograft will do well and that the wound bed is healthy. Autografts can be either full or split thickness.

Split grafts, because they are thinner and more easily revascularized from the bed, will take better than full-thickness grafts, are more resistant to infection, and will do better in a marginal wound bed. Full-thickness grafts will contract less, be more durable and flexible, and have better sensation. They are therefore preferred for areas prone to shear and load such as the fingertips, palm, web spaces, and areas over joints. Split grafts can be either meshed or unmeshed. Meshed grafts will have fewer problems with seroma, hematoma, and infection and will therefore take better. Their appearance is not as aesthetically pleasing, however. In all cases maintaining contact between the graft and the bed is imperative for inosculation (i.e., ingrowth of vessels into already existing vascular channels) and neovascularization (i.e., new vessel formation) to occur.

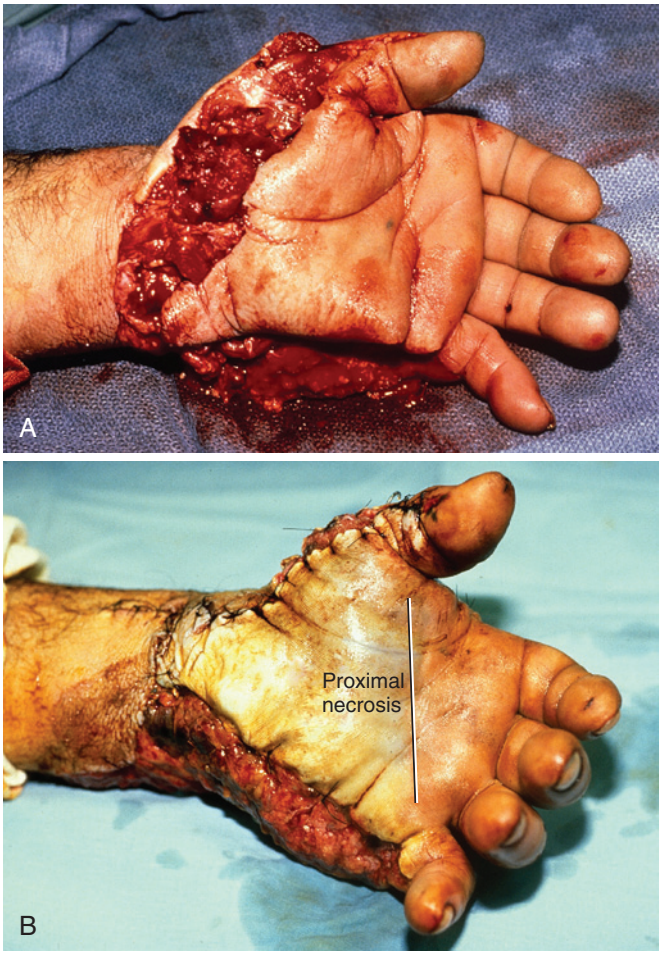

FIGURE 43.18 **A, B,** With traumatically elevated flaps, "lay it, don't stretch it." It is always best to simply lay the skin down and at most tack it in place loosely rather than stretch it back to its original position, thereby creating ischemia and necrosis of a large area of the flap as shown in this case.

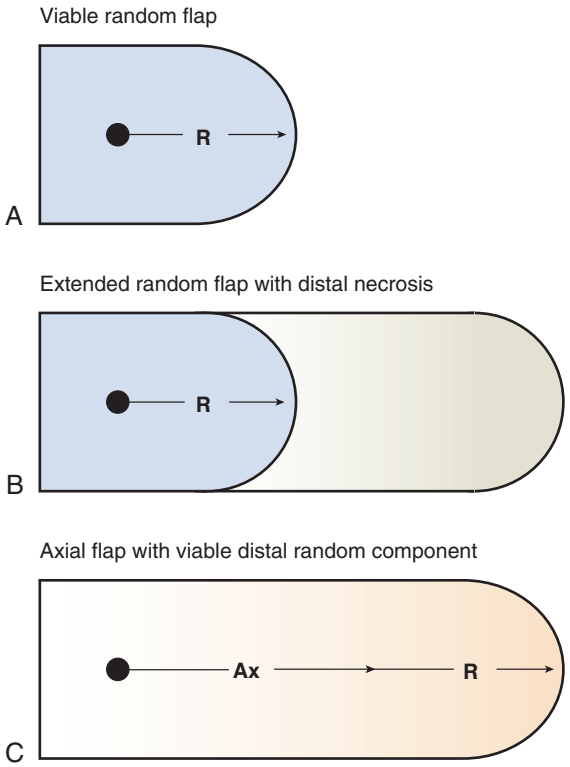

FIGURE 43.19 The importance of axial perfusion of a flap is illustrated. **A,** Reliable perfused area of a flap based on purely random perfusion (R) from the vascular pedicle (*black circle*). **B,** Random flap designed beyond the limits of reliable random perfusion (R), which results in distal flap necrosis. **C,** Benefit of designing a flap based on an axial pedicle. The length of reliable flap perfusion includes the same length of reliable random perfusion (R) plus the length of the axial pedicle (Ax). (Reprinted from Vedder NB: Flap physiology. In Mathes SJ, Hentz VR, editors: *Textbook of plastic surgery*, Philadelphia, 2005, Elsevier, © 2003 Nicholas B. Vedder.)

During the first 24 to 36 h the graft must survive on diffusion, sometimes referred to as "serum imbibition," but without revascularization after that point, the graft will not survive. Anything that disturbs the revascularization process, such as hematoma, infection, or shear, will prevent proper engraftment. The best way to achieve successful engraftment is with a moist, compressive dressing or bolster over the graft to provide both pressure and immobilization. We prefer a first layer of fine-mesh gauze, followed by a layer of gauze soaked in mafenide (Sulfamylon) solution, which has the added benefit of decreasing the local bacterial level and thereby promoting graft take. For split grafts in the extremities, NPT is very effective at optimizing graft–bed contact and graft take.

Donor sites for split grafts include the lateral aspect of the thigh, hip, buttock, scalp, or trunk. The medial aspect of the thigh should be avoided because the skin is much thinner and a full-thickness wound can develop from harvesting skin there. Generally, adults' skin should be harvested at a 0.0010- to 0.0012-inch thickness. Full-thickness skin can be harvested from an elliptic excision in the groin crease, the abdomen, or the hypothenar aspect of the hand, which provides thick, glabrous skin. The volar wrist crease can also be used; however, we avoid it because the resulting scar may be mistaken for a self-inflicted laceration.

For complex wounds, including those with exposed "white structures," wounds over joints or web spaces, or those at risk of compromising function because of scarring or contracture, vascularized soft tissue (i.e., a flap) is required. A flap is simply tissue that contains its own blood supply, as opposed to a graft, which requires revascularization from the bed. Because they remain viable, flaps tend to stay soft and supple while providing vascularity to otherwise devascularized areas. Flaps are mainly classified according to their vascular supply as either random or axial. Flaps that are based on an axial nutrient vascular system will be much more reliable than flaps that are not. Random flaps are those not based on a dominant nutrient vascular system but instead are supplied by flow through the subdermal or subfascial plexus (or both).

As a result, random flaps are much less reliable than axial flaps, and their length is limited to a short distance from the pedicle origin. The portion of an axial flap that extends beyond the axial vessel is random in nature (Figure 43.19). An axial flap that is transplanted from its origin and then connected to a new blood supply elsewhere in the body microsurgically is a free flap. Flaps can then be further classified on the basis of the tissue that they contain (e.g., cutaneous, fascial, fasciocutaneous, muscle, musculocutaneous, osteomusculocutaneous).

In general, random flaps have little role in the reconstruction of mangling injuries to the hand and upper extremities. The exception is the treatment of fingertip or small digit injuries or the treatment of small defects over critical structures such as the median nerve at the wrist or an exposed vascular repair. In most situations, robust and reliable axial flaps from outside the zone-of-injury are required. The various flap choices and the technical details of their transfer are clearly described in Chapters 44 and 45. We will therefore simply point out some of the "workhorse" flaps that are regularly relied on for various areas of the hand and upper extremity in the setting of mangling injuries.

Fingers, Hand, and Wrist. A number of local random and axial flaps are described in Chapters 44 and 45; they are suitable for covering fingertip and finger defects, as well as digit amputation stumps.[34,88] The Moberg advancement flap, cross-finger flap, flag flap, and other axial intrinsic flaps are suitable for isolated digit defects. For severely crushed digits, removing the crushed skeletal component and converting them to a fillet flap can often provide the necessary vascularized tissue for covering critical defects. If multiple digits are involved, sometimes using the Millard "crane principle" and burying the digits in abdominal fat for 2 weeks and then removing them can result in enough vascularized soft tissue coverage to allow skin grafting. This approach is primarily applicable for dorsal defects and not palmar ones with exposed flexor tendon or digital nerves.

For larger defects, a regional or distant axial flap is required. The tubed groin flap is a reliable axial flap that can cover a large defect; it is certainly an upper extremity workhorse flap. In addition to being large and reliable, it contains a thick fatty layer that allows the tendon to glide beneath it and forms an excellent foundation for secondary reconstructions, including tenolysis, tendon transfers, and toe-to-hand transfers. The disadvantage is that unless it is performed as a free flap, which is technically very difficult because of the small pedicle vessel size, it requires that the hand be attached to the groin for at least 2 weeks, which is both awkward and makes effective hand therapy difficult.

The other disadvantage is that it is very thick and bulky and usually requires multiple staged defatting procedures. It can nevertheless produce excellent results (Figure 43.20). Some

FIGURE 43.20 **A** through **G,** Reconstruction of a multidigit degloving injury with a tubed groin flap, including staged syndactyly release.

FIGURE 43.21 **A,** Right hand and forearm of a male in his sixties injured in a log splitter. **B,** Dorsal hand wound following debridement, now with exposed extensor tendons. **C,** Periumbilical perforator flap attached to dorsal hand. **D,** Healed dorsal hand wound.

patients may have had prior groin surgery or pelvic trauma, thereby presenting a contraindication for the groin flap. In this situation, the periumbilical perforator flap as described by O'Shaughnessy is a useful alternative.[79] This flap is based, as the name suggests, on axial vessel(s) near the umbilicus, and a large piece of tissue can be obtained for coverage (Figure 43.21). It does have similar disadvantages to the groin flap in that it requires a second surgery for division and can be bulky.

The other upper extremity workhorse flap is the radial forearm one based on the radial artery and perforating vessels coming up in the septum between the brachioradialis and flexor carpi radialis. Preservation of these perforators during dissection is critical, and dissection must always focus on staying deep, below the artery and its veins. If it is transferred based on reversed flow through the radial artery from the ipsilateral arm, it has the advantage of confining the surgical defect to that one extremity. It is, of course, critical to first confirm that the remaining ulnar artery and the palmar arch are intact by performing an Allen test with a Doppler probe preoperatively. The disadvantage of this flap is that the donor site on the forearm and the palmar arch must not be significantly involved in the zone-of-injury.

When it is taken as a fasciocutaneous flap, unless the cutaneous component is very small, the morbidity of the forearm donor site can be significant, both functionally and aesthetically (Figure 43.22). It is very important to design the flap on the proximal volar aspect of the forearm to allow direct closure over the flexor tendons and skin graft the donor site only over proximal muscle. Because it, like the groin flap, is a fasciocutaneous flap, its bulk can often hinder function and requires defatting. This can also be a significant problem on the palmar aspect of the hand and digits, where firm attachment of the skin to the base is required for grasping and friction-based functions.

For these reasons, we usually transfer the radial forearm flap as a fascia-only flap with skin grafting on the fascia and leave the thick skin and fat layer in the forearm. This provides well-vascularized gliding coverage that is both thin and functional (Figure 43.23). It provides excellent resurfacing for both palmar and dorsal hand and digit defects and can even reach the tips of the fingers (Figure 43.24). The forearm donor defect is then simply a linear scar. The entire width of the forearm fascia can be taken on the radial artery, but even so, there is significant contraction and shrinkage when the flap is finally transferred. If the flap is harvested as fascia only, it is very important to leave the network of small fascial vessels on the surface, as well as a thin stippling of fat, when dissecting the forearm skin and subcutaneous tissue off of the fascia. Even though the flap will usually survive from reversed flow through both the artery and veins, it is beneficial, whenever possible, to microsurgically anastomose an effluent vein from the tip of the flap to a dorsal hand vein. The other reversed-flow flap of the forearm to consider is the posterior interosseous flap, which can also be taken as either a fasciocutaneous or a fascia-only plus skin graft flap. In our experience, this is a much less reliable flap, especially for a mangled extremity.

If a larger piece of fascia is required than can be harvested with the radial forearm flap, the anterolateral thigh fascia free flap, based on the descending branch of the lateral circumflex femoral artery, is an excellent choice (Figure 43.25). It is, of course, transferred as a free flap, usually end-to-side into either the radial or the ulnar artery or end-to-end into the princeps pollicis artery and carries the attendant microsurgical risks. It, too, can be taken as a fasciocutaneous free flap, but the bulk is usually detrimental in the hand and wrist; if used for reconstructing the forearm or elbow region, however, it can provide durable, supple coverage. If harvested as a suprafascial

FIGURE 43.22 **A, B,** The radial forearm fasciocutaneous flap can provide good vascularized coverage of critical defects, although when harvested with the skin, subcutaneous tissue, and fascia, it is usually too bulky for reconstruction of either the palmar or dorsal surfaces of the hand and leaves a morbid "shark bite" defect in the forearm with a skin graft on tendon. For this reason, we now prefer a fascia-only flap with a skin graft for hand and wrist reconstruction. *STSG*, Split-thickness skin graft.

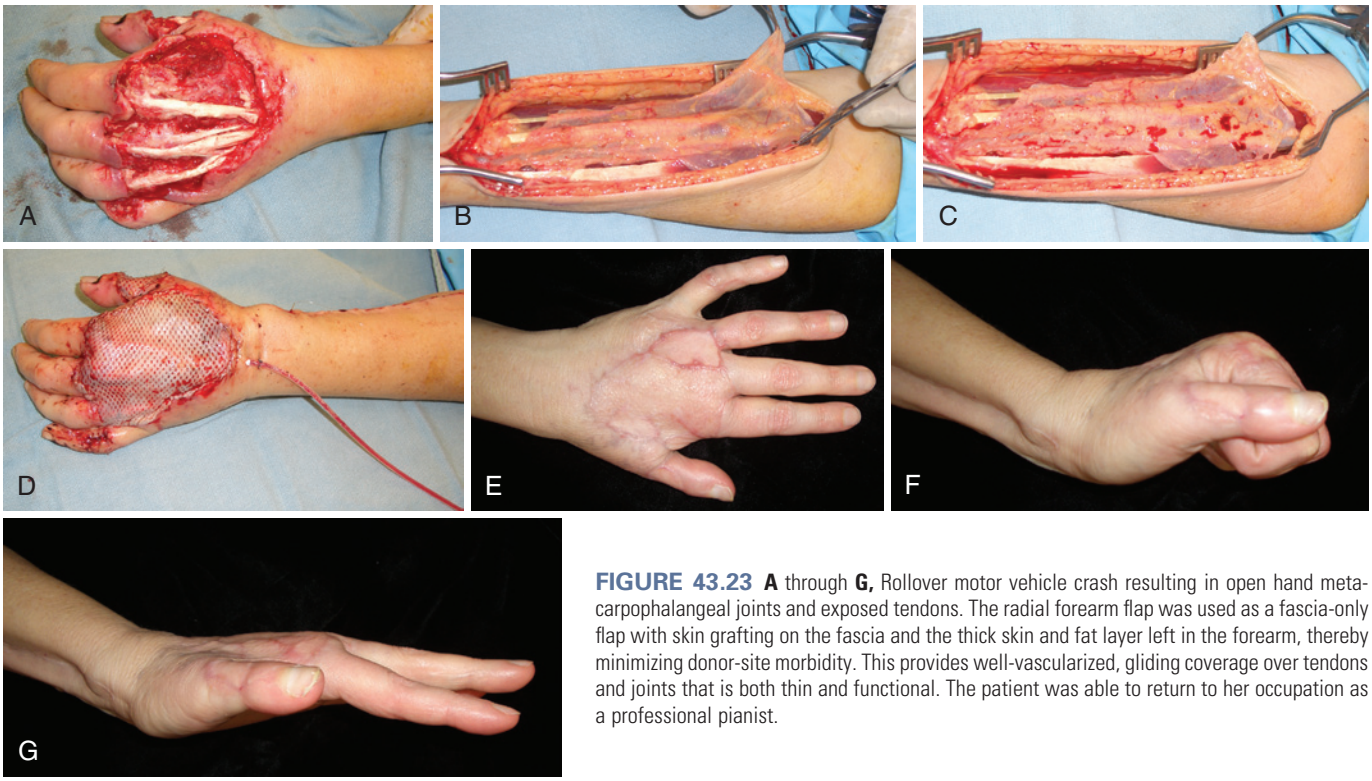

FIGURE 43.23 **A** through **G,** Rollover motor vehicle crash resulting in open hand metacarpophalangeal joints and exposed tendons. The radial forearm flap was used as a fascia-only flap with skin grafting on the fascia and the thick skin and fat layer left in the forearm, thereby minimizing donor-site morbidity. This provides well-vascularized, gliding coverage over tendons and joints that is both thin and functional. The patient was able to return to her occupation as a professional pianist.

FIGURE 43.24 A through **H,** The radial forearm flap as a fascia-only flap with skin grafting can even reach the fingertips, as in this case with these severe deep-contact burns and exposed interphalangeal joints.

perforator free flap, it can be quite thin. In addition, with the thigh fascia preserved, the donor defect is easier to close primarily (Figure 43.26).[60]

The lateral arm free flap, either as a fascia plus skin graft or as a fasciocutaneous flap, can provide more tissue than the radial forearm flap and can be harvested from the zone-of-injury. Like the radial forearm flap, surgery can be confined to one extremity, yet it relies on microsurgery, and the donor defect, even if it can be closed primarily, is very noticeable (Figure 43.27).

Forearm. Forearm defects requiring vascularized coverage generally need a fairly large flap. Although a groin flap can be used, a free flap is usually more appropriate. Many defects can be reconstructed with a free gracilis muscle flap, especially if the muscle fascia is scored, which allows the flap to be spread 8 to 10 cm and also results in a thinner contour (Figure 43.28). For larger defects, generally the latissimus muscle free flap is used. Again, to reduce bulk and minimize donor site morbidity, we use muscle-only flap with a skin graft rather than a fasciocutaneous flap. Even though it is muscle and not fat, it provides good coverage for tendon and joint gliding and is easily reelevated for secondary procedures. If a large cutaneous flap is desired specifically for the purpose of tendon gliding, either an anterolateral thigh suprafascial perforator flap, as described earlier, or a scapular or parascapular fasciocutaneous flap can be used (Figure 43.29). When the defect includes major muscle groups of the forearm (e.g., the flexor or extensor compartments), it is sometimes possible to achieve both coverage and motor reconstruction in a single stage by using an innervated functional free muscle transfer (Figure 43.30).

Elbow and Arm. For defects around the antecubital area, such as exposed vascular or nerve reconstructions, the proximally based brachioradialis muscle flap is an excellent choice with minimal donor morbidity (Figure 43.31). For larger defects around the elbow and even extending to the proximal third of the forearm, the latissimus dorsi muscle can be transferred as a pedicle flap and be skin grafted. By detaching its insertion from the humerus, significant additional length can be achieved; however, it is important to ensure that the proximal pedicle is not stretched or kinked. Although tunneling the flap subcutaneously down the arm has been described, we think that the risk of vascular compromise favors opening the posterior of the arm and skin grafting over the muscle, which can later be revised (Figure 43.32).

Composite flaps and spare parts surgery can also play a role in the soft tissue reconstruction of mangling injuries. Even though an amputated part or segment of tissue may be deemed not replantable or functional, portions of it may still be useful in reconstruction. Any residual nonfunctional proximal phalanx of the index finger can, for example, be transposed

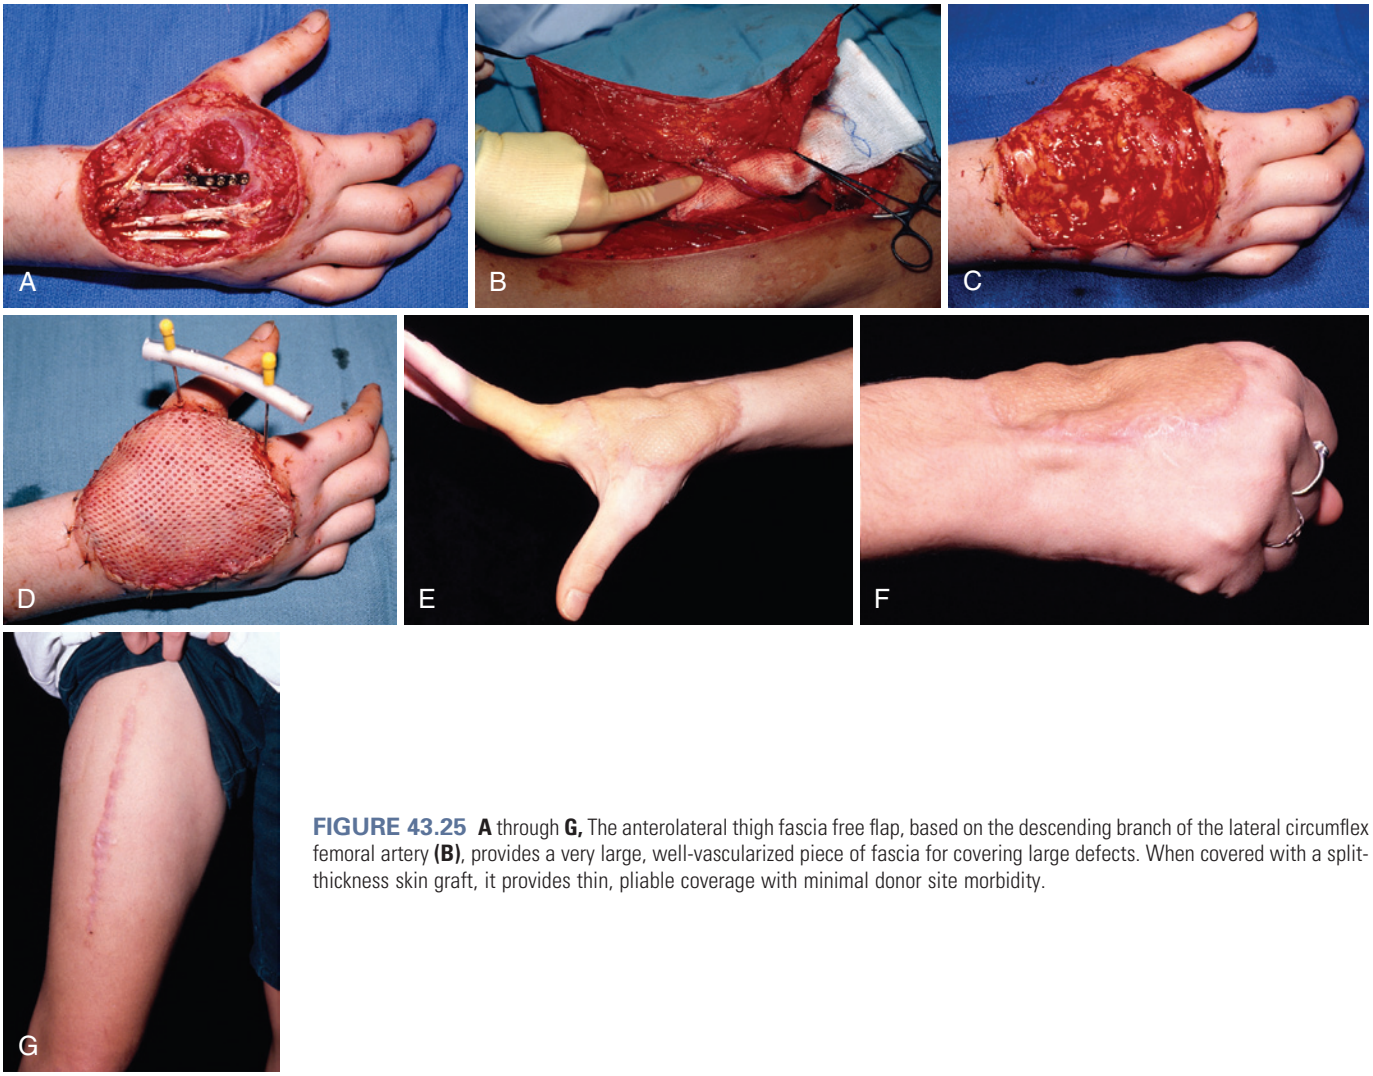

FIGURE 43.25 **A** through **G,** The anterolateral thigh fascia free flap, based on the descending branch of the lateral circumflex femoral artery **(B)**, provides a very large, well-vascularized piece of fascia for covering large defects. When covered with a split-thickness skin graft, it provides thin, pliable coverage with minimal donor site morbidity.

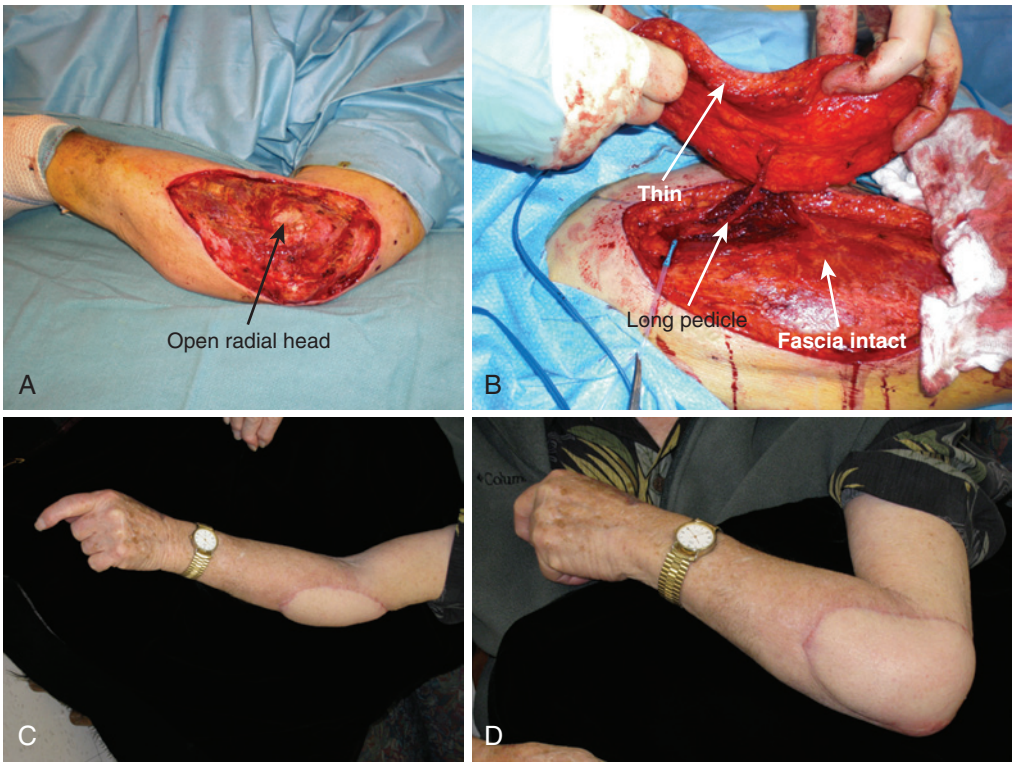

FIGURE 43.26 **A** through **D,** A large soft tissue defect of the elbow region with exposed radial head. The anterolateral thigh flap, when harvested as a suprafascial skin flap, can be quite thin and provides a soft, supple reconstruction with excellent contour while minimizing the donor defect and improving the ability to achieve primary closure.

FIGURE 43.27 **A, B,** A severe mangling injury of the hand and wrist reconstructed with a lateral arm fasciocutaneous free flap. Note the significant donor defect associated with a large lateral arm flap.

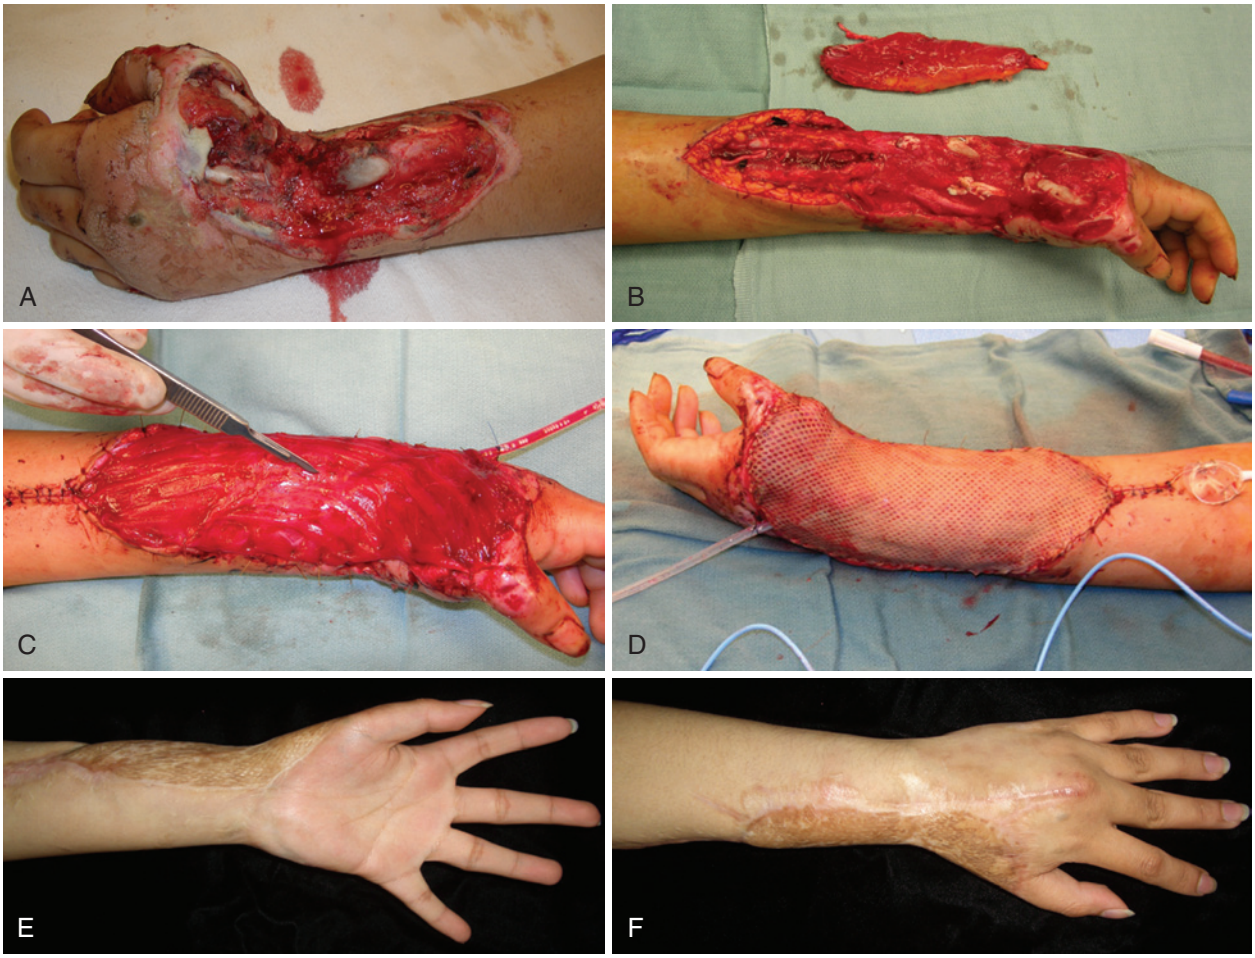

FIGURE 43.28 **A,** Large complex wound of the wrist with exposed metacarpal and radius fracture fixation and loss of the thumb extensors. The free gracilis muscle leaves a minimal donor defect, and although initially small and narrow **(B)**, it can cover a large area if the fascia is multiply scored longitudinally and the muscle gently stretched after insetting it proximally after microvascular anastomoses **(C, D)**. **E, F,** The resulting contour is excellent, and secondary extensor tendon reconstruction can be achieved with a tendon transfer.

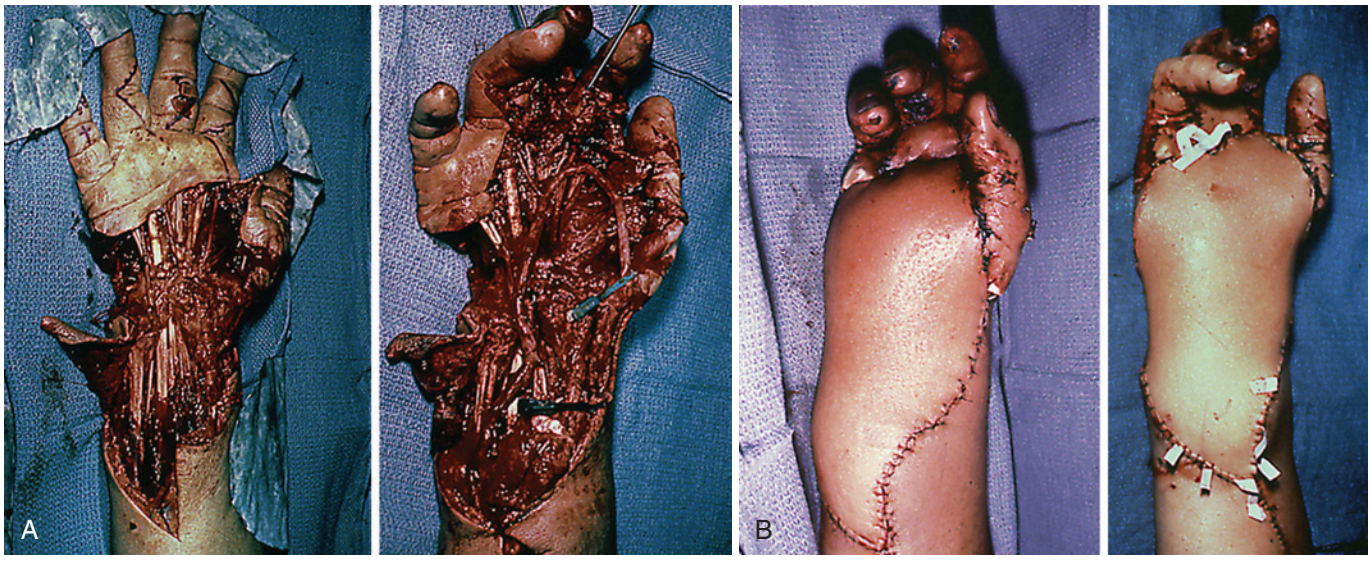

FIGURE 43.29 **A,** This farmer's hand was caught in a fertilizer spreader. Reconstruction consisted of debridement, skeletal stabilization, and soft tissue coverage with a scapular free flap. Note the significant bulk associated with a fasciocutaneous flap **(B)**, which often requires later debulking.

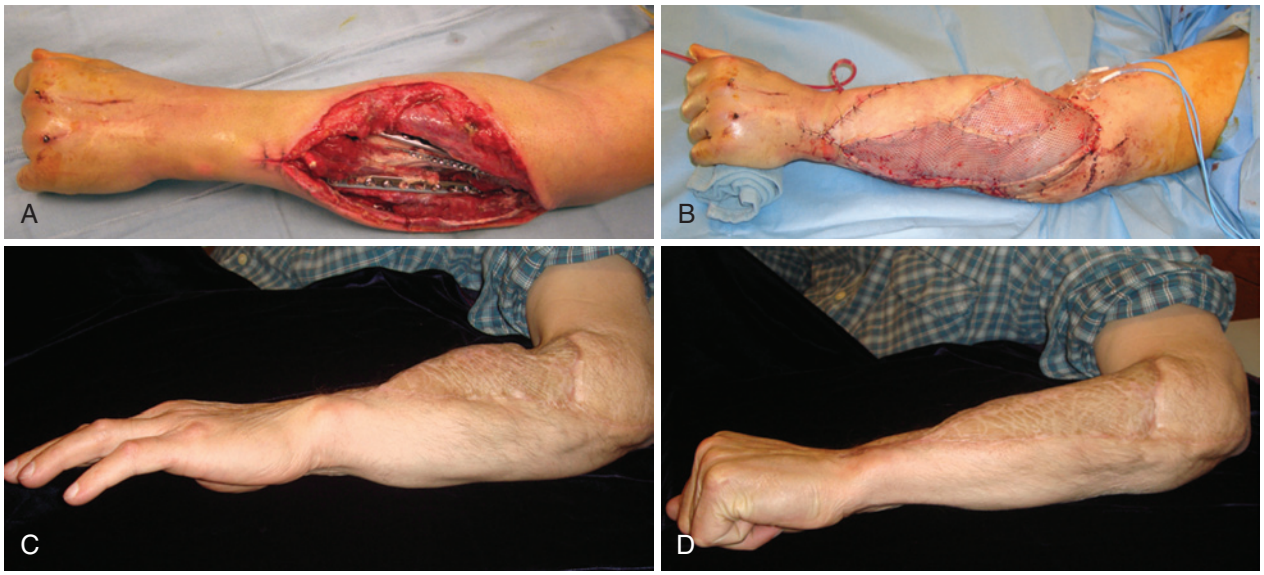

FIGURE 43.30 **A,** After sustaining an explosive injury, this forearm defect included the muscles innervated by the posterior interosseus nerve. **B,** An innervated free gracilis transfer provides both soft tissue coverage and functional motor reconstruction. **C, D,** One year after reconstruction, active finger extension was achieved.

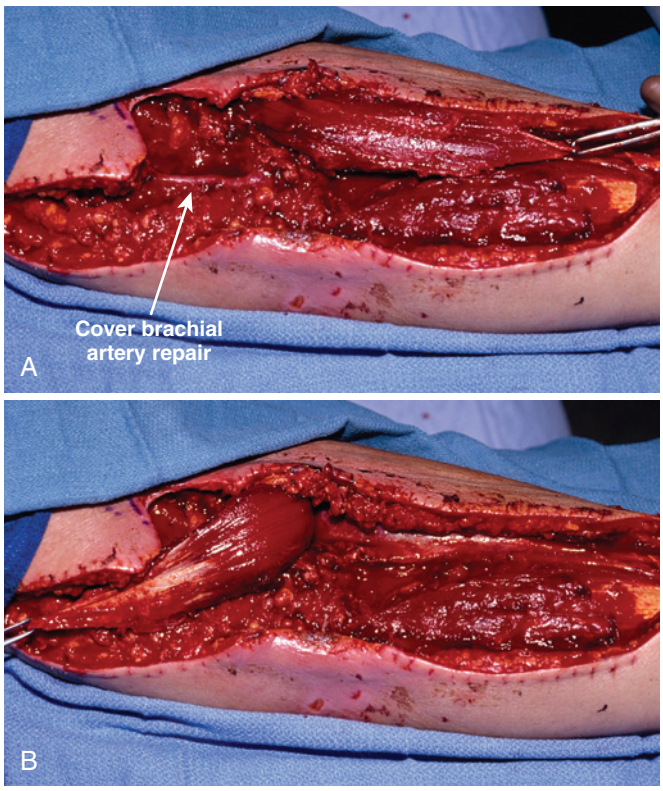

FIGURE 43.31 **A, B,** For defects around the antecubital area, such as exposed vascular or nerve reconstructions, the proximally based brachioradialis muscle flap is an excellent choice with minimal donor morbidity.

to provide additional, sensate length to an injured thumb (Figure 43.33).

The palmar skin of the hand, based on either the radial or ulnar artery, along with either the median or ulnar nerve and its branches, can be used as a vascularized, sensate pedicled flap or free tissue transfer. Spare parts surgery may be one of the very few indications for an "emergency" free flap in the setting of a mangling injury (reviewed by Neumeister and Brown[77]). Similarly, skin or skin and radius bone, based on the radial artery, can be used as a composite flap either as a reversed-flow pedicled flap or as a free tissue transfer. In addition, before discarding amputated tissue, it should always be evaluated for potential use as free graft tissue, either defatted skin, nerve, bone, or tendon.

POSTOPERATIVE MANAGEMENT/ REHABILITATION

Early institution of an appropriate and well-planned therapy and rehabilitation program is critical to achieve an optimal functional outcome. As mentioned previously, injured tissues rapidly become less pliable in just a matter of days after injury; thus, optimizing tendon gliding and joint motion require early, protected mobilization.[23] Edema formation can significantly limit joint mobility, which, if uncorrected, can result in permanent joint contractures. The hand should always be splinted postoperatively in the "safe" position: the MP joints flexed to prevent shortening of the MP collateral ligaments, which can lead to MP extension contracture and the IP joints in extension (Figure 43.34).

Whenever possible, initial skeletal and tendon reconstruction should be performed in a stable enough fashion to allow early mobilization. Conversion to a thermoplastic splint within the first several days after injury can facilitate both wound care and hand therapy. With most mangling injuries, immediate active motion after tendon repair is usually contraindicated, although passive motion can be started immediately. With nerve injuries, blocking splints can be fashioned to prevent tension across the repair while allowing motion in the direction of the nerve. Hypersensitivity is very common after crush and mangling injuries and should be treated by early desensitization therapy.

If a skin graft is used, it is important to prevent motion or shearing beneath the graft for the first 5 to 7 days to allow

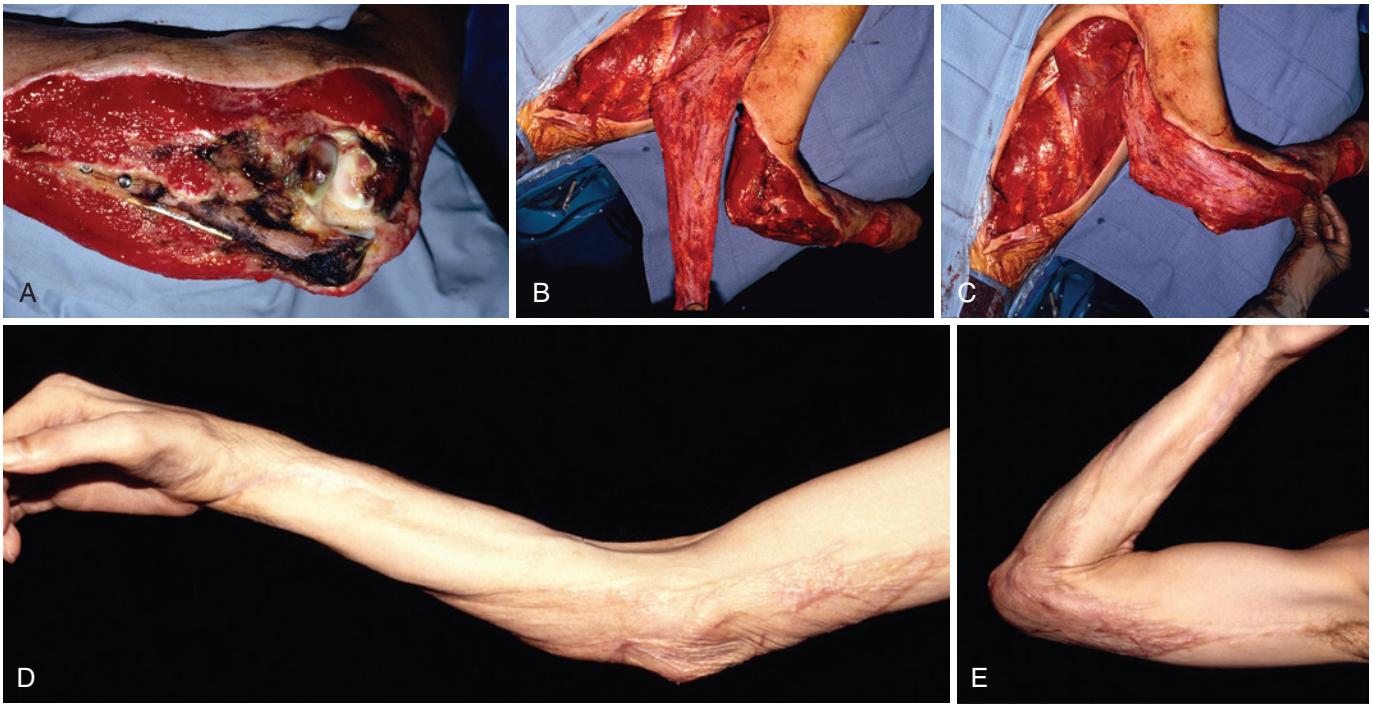

FIGURE 43.32 **A** through **E,** After thorough debridement, the pedicled latissimus dorsi muscle flap can cover large defects around the elbow and even extend to the proximal third of the forearm. By detaching the humeral insertion, significant additional length can be achieved. Then the muscle is skin grafted.

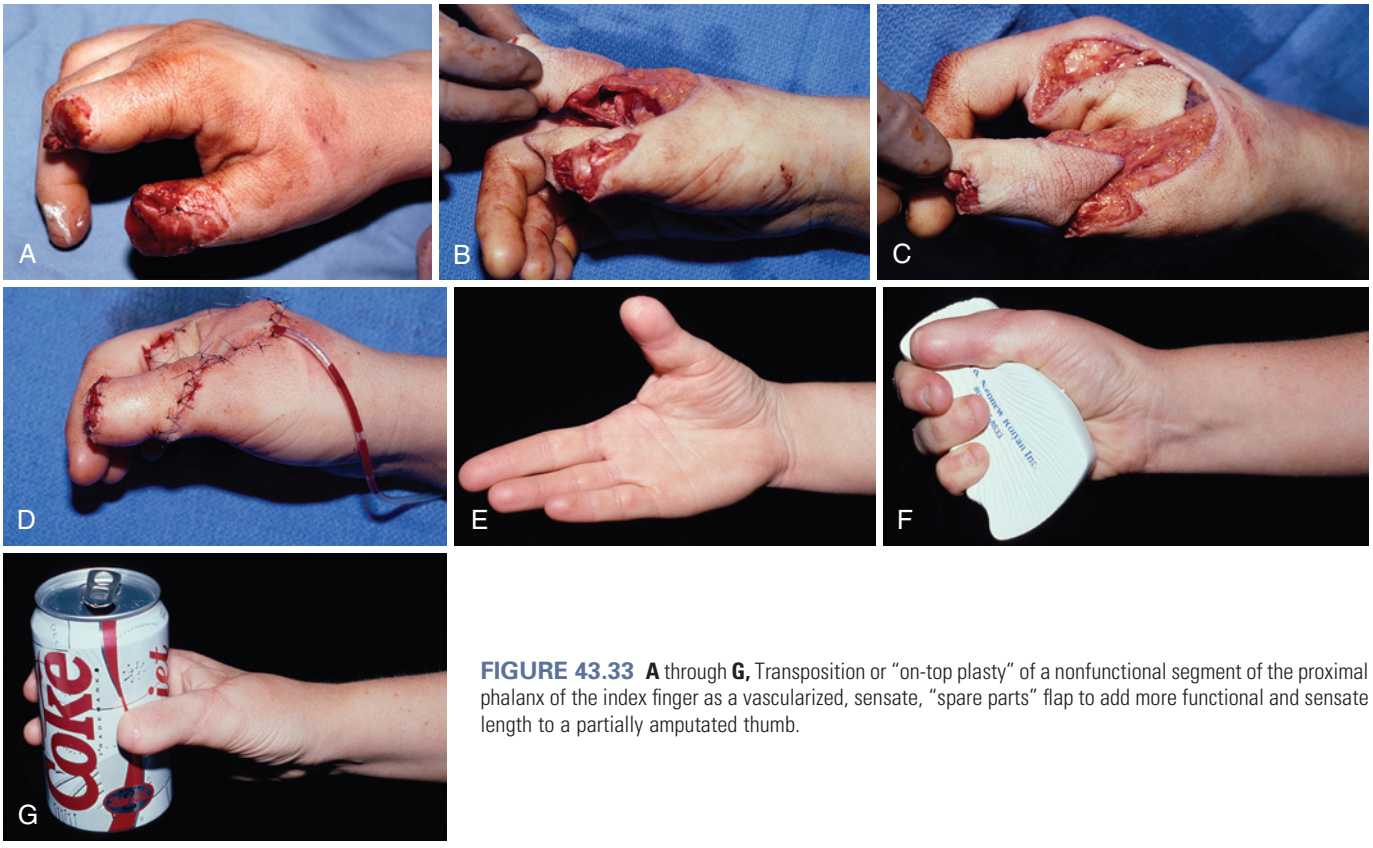

FIGURE 43.33 **A** through **G,** Transposition or "on-top plasty" of a nonfunctional segment of the proximal phalanx of the index finger as a vascularized, sensate, "spare parts" flap to add more functional and sensate length to a partially amputated thumb.

CRITICAL POINTS *Soft Tissue Coverage*

- Coverage over joints and tendons should be adequately vascularized, low profile, and supple.
- Coverage over volar pressure-bearing surfaces should be sensate and have minimal shear characteristics.
- Delay definitive coverage until the wound is stable; repeat debridements if needed.
- Provide definitive coverage by 5 to 10 days; keep the wound moist in the interim.
- Control the size of the wound: vessel loop weave versus NPT.
- Recognize that NPT is contraindicated if infection or bleeding is present.
- Cover "white structures" (i.e., tendon, nerve, bone, or ligament/joint); vascularized soft tissue (flap) is required.
- Do not stretch traumatically elevated flaps to their original position; simply lay them in place.
- For a larger, noncritical defect, use a split-thickness skin graft; use a full-thickness skin graft if area is small, if subject to pressure/shear, or if motion is critical.
- For complex wounds with exposed white structures, use a flap.
- Axial flaps are preferable; include fascia if possible, and consider a fascia-only flap plus a split-thickness skin graft.
- For the fingers, hand, or wrist, use a Moberg, cross-finger, intrinsic, crane, radial forearm, or groin flap.
- For a radial forearm flap, consider a fascia-only plus a split-thickness skin graft; stay deep during dissection and create an effluent venous anastomosis.
- For a groin flap, include sartorius fascia to prevent kinking of the pedicle, protect the lateral femoral cutaneous nerve, delay for 2 weeks, divide/inset at 3 weeks, perform multiple thinning stages, and continue motion to decrease stiffness.
- For the forearm, use a groin, gracilis-free, latissimus-free, lateral arm-free, anterolateral thigh fascia, or suprafascial perforator free flap.
- For the elbow or arm, use a brachioradialis (antecubital defect), latissimus pedicled or free, or suprafascial anterolateral thigh free perforator flap.

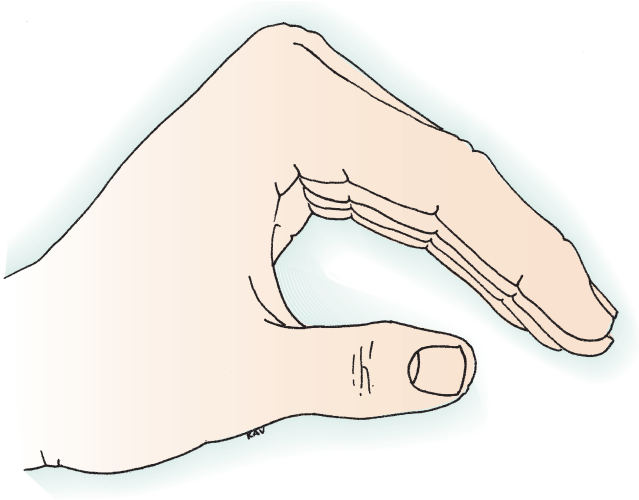

FIGURE 43.34 The hand should always be splinted postoperatively in the "safe" position, with the metacarpophalangeal (MP) joints flexed to prevent shortening of the MP collateral ligaments and subsequent MP extension contracture, and with the interphalangeal joints in extension.

inosculation and take of the graft. Otherwise, liberal washing and soaking of wounds is preferable rather than keeping them wrapped in occlusive dressings where pus can accumulate and an infection can result. The exception to this is NPT, which effectively removes serum and exudate. It should be changed every several days, however.

CRITICAL POINTS *Postoperative Management/ Rehabilitation*

- Splint the wrist in a neutral extended position with MP flexion and IP extension (to minimize contractures and optimize function).
- Prevent early shear of skin grafts/flaps.
- Begin early motion to optimize gliding/motion.
- Control edema.
- Perform desensitization.
- Use goal-based therapy.
- Do not overlook psychosocial issues as well as therapy.

SECONDARY PROCEDURES

Mangling injuries often require secondary reconstructive procedures to achieve optimal form, function, or both. Planning for these secondary reconstructive procedures is best done at the time of the initial operation, again "looking into the crystal ball" and having a vision for the future function of the extremity.[92] The goal of secondary procedures is to improve motion, sensibility, and durability. Some of these procedures have been mentioned previously, including bone grafting, nerve grafting, joint replacement, tenolysis, and release of contractures. Successful secondary reconstruction is predicated on good soft tissue coverage.

In general, secondary procedures should be delayed until the soft tissues have matured and softened, which often takes 3 to 6 months. The exception, however, is bone or nerve grafting, which should be performed early. Some secondary procedures require postoperative immobilization and should be performed first, whereas others require mobilization postoperatively and should therefore be performed at a separate stage. All secondary procedures require stable, soft, and well-vascularized soft tissue coverage; this may require secondary flap reconstruction. In rare cases, tissue expansion techniques can be used.[65] Experience shows, however, that tissue expansion in upper extremity reconstruction is associated with an extremely high complication rate.

If bone grafting is not performed at the initial operation, we perform it as soon as the wounds have healed and crusts have fallen off to minimize the risk for infection, generally at 4 to 6 weeks. As mentioned previously, we favor cancellous allograft in most cases unless autograft is simple to harvest from adjacent bone (e.g., radius for wrist or hand defects). In cases in which tissue vascularity is questionable or with nonunion, cancellous autograft, usually from the iliac crest, is indicated. For defects larger than 6 cm, vascularized bone grafting is indicated. Possible sources for such grafts and techniques are clearly described in Chapter 46 and include fibula, iliac crest, rib, and second metatarsal.

Our preference is a free fibula graft because of its length, minimal morbidity, ease of dissection, and large peroneal vascular pedicle. Structural allograft can also be considered, but

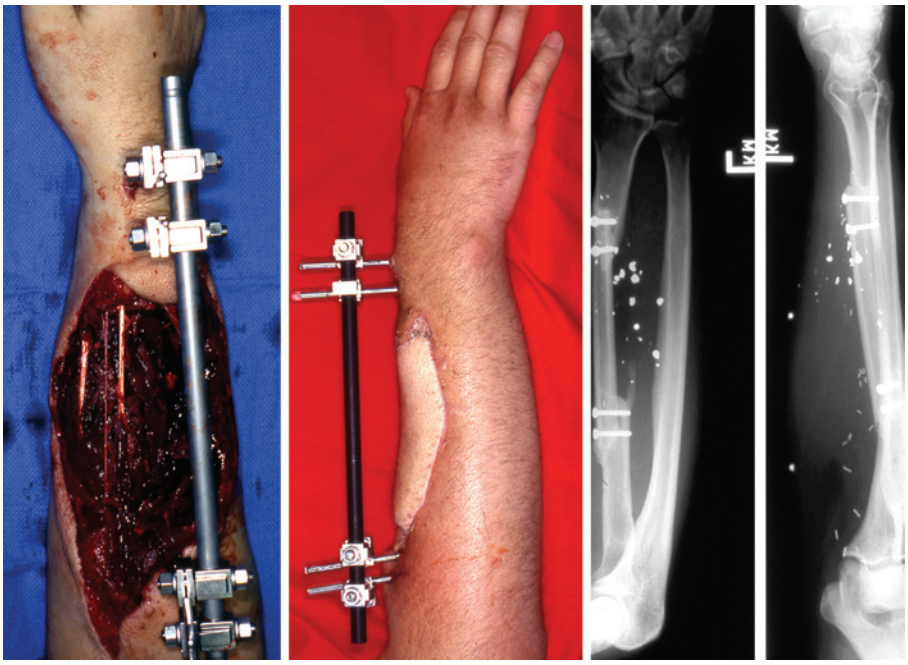

FIGURE 43.35 A close-range gunshot wound resulted in loss of 12 cm of radius, the radial artery, the superficial branch of the radial nerve, and the skin defect shown here. After debridement, the radius was stabilized with an external fixator and the bone and skin defects were reconstructed with an osteocutaneous fibular graft. The radiographs on the right were taken 4 months after reconstruction.

only as a secondary procedure in a mature, well-vascularized tissue bed. With all bone grafting, ensuring adequate soft tissue coverage and tissue vascularity, as well as good postoperative immobilization, is key to achieving bony union (Figure 43.35; see also Figures 43.10 and 43.13).

Corrective osteotomies for functionally significant malunion and the treatment of nonunion should be performed in the initial series of secondary procedures. They usually involve either metacarpal or phalangeal osteotomies to correct digit crossover, distal radius osteotomy to correct dorsal tilt or shortening, or ulnar-shortening osteotomy to correct ulnar impingement.

Nerve grafting for the purpose of restoring motor function should also be performed early because the degree of functional return is inversely related to the delay from the time of injury.[97] Nerve grafting to restore sensory function, however, can be delayed. Again, the techniques for nerve grafting are adequately described in Chapter 30. When nerve grafting is not feasible, a decision must be made as to whether some other form of a sensory or motor reconstruction is required. Again, this depends on the patient's functional needs and a balance between these needs and what can reasonably be expected with additional procedures. For motor reconstruction, tendon transfers should be considered. The indicators and techniques for these are described in Chapters 5 and 6.

When inadequate motor units remain to allow tendon transfer for basic functions, such as composite flexion or extension, functional free muscle transfer using the innervated gracilis muscle should be considered. This is covered in Chapter 51. In areas critical for sensation, specifically the ulnar tip of the radial digit (usually the thumb) and the ulnar tip of the primary opposing ulnar digit (usually the index or middle finger), sensory reconstruction may be required. If sensation is absent and cannot be reconstructed by nerve grafting because of the lack of sensory organelles in the restored soft tissue coverage, transfer of vascularized, innervated glabrous skin can prevent recurrent ulceration and improve tactile-dependent hand function.

The most common indication for sensory reconstruction is when the digit is resurfaced or reconstructed with flap tissue (e.g., a radial forearm or groin flap). If the middle or ring fingers are uninjured, the ulnar pulp can be transferred based on the ulnar digital nerve, artery, and periarterial veins and the donor defect covered with a full-thickness skin graft. Critical to this procedure is ensuring that sufficient perivascular tissue is taken along with the pedicle to allow adequate venous drainage, as well as ensuring that the palmar arch and distal arterial system are intact (Figure 43.36). If pedicled neurovascular island transfer is not possible, a free tissue transfer of the lateral great toe pulp, along with the lateral digital nerve and vessels, can be performed. The technique and dissection are similar to the toe wraparound procedure described in Chapter 47; however, in this case a small 1.5- to 2-cm piece of glabrous skin can be used to allow primary closure of the donor defect (Figure 43.37).

Amputation neuromas are a common and severely disabling complication after a mangling injury. Neuromas are differentiated from normal hypersensitivity after injury by the fact that a symptomatic neuroma is well localized to the nerve stump and does not improve with desensitization therapy, whereas hypersensitivity should improve with desensitization. Treatment involves resecting the neuroma and burying the nerve stump in well-padded, vascularized soft tissue where it will not be subject to pressure irritation.

When the MP or IP joints are destroyed as a result of a mangling injury or when attempts at their initial reconstruction

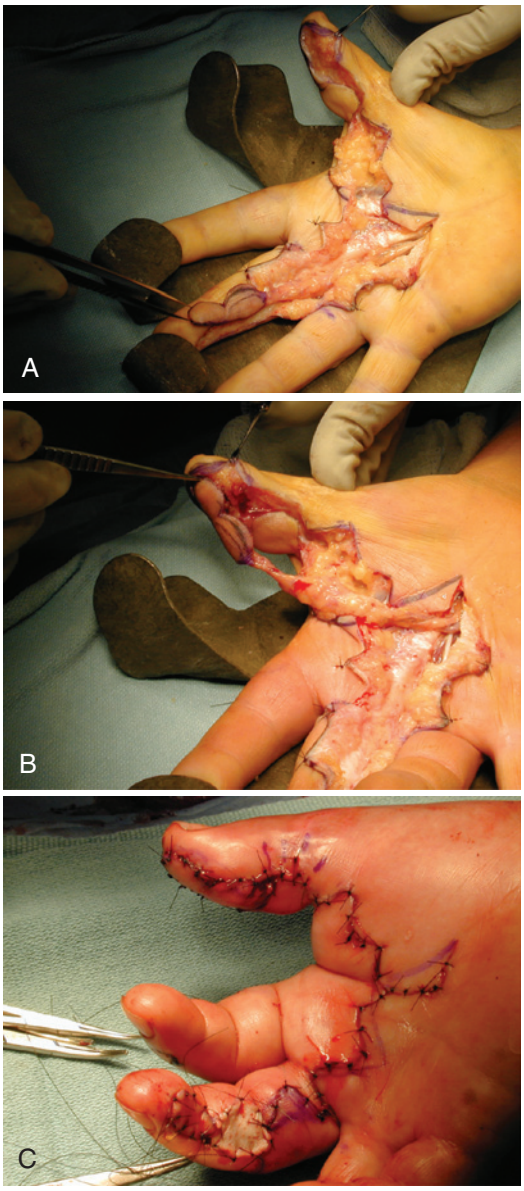

FIGURE 43.36 **A** through **C,** Neurovascular island flap from the ulnar side of the middle finger to the volar surface of the thumb to restore thumb sensation after replantation of an avulsed thumb that had no reconstructible digital nerves. It is critical to ensure that adequate perivascular tissue is taken along with the pedicle to allow venous drainage.

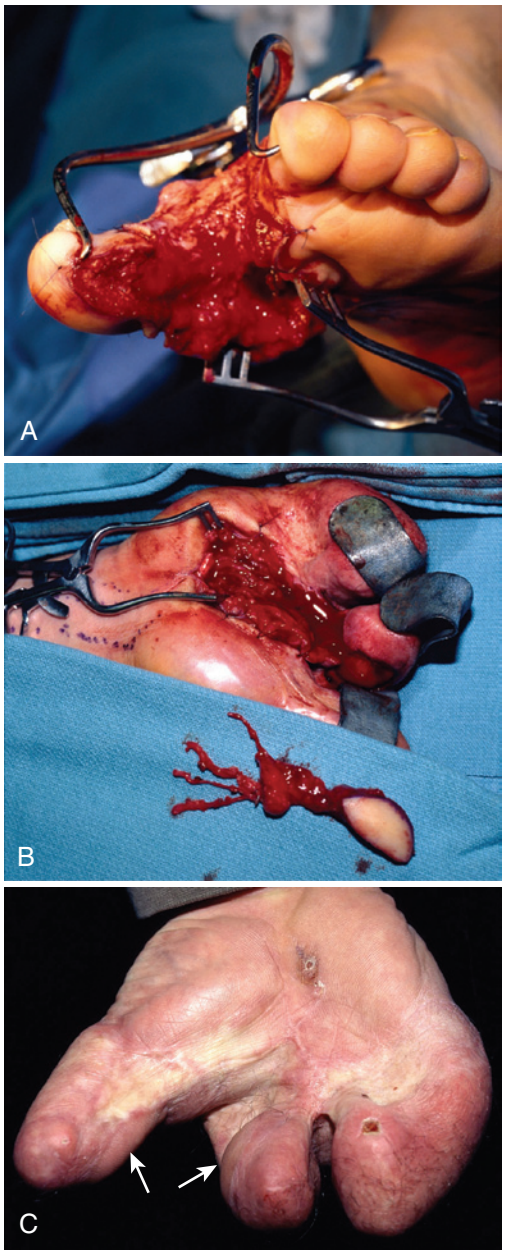

FIGURE 43.37 **A** through **C,** If a pedicled neurovascular island transfer is not possible, a free tissue transfer of the lateral great-toe pulp, along with the lateral digital nerve and vessels, can provide sensate tissue for critical areas of contact. In this case, functional, sensate pinch is achieved between the residual thumb and middle finger with bilateral lateral great-toe pulp neurosensory free flaps (*arrows*).

result in posttraumatic arthrosis, the usual treatment is either arthrodesis or amputation. In rare circumstances, however, when the soft tissue coverage is soft, supple, and well vascularized, arthroplasty can be considered. The indications and procedural details for arthrodesis and arthroplasty are covered in Chapter 12. Posttraumatic arthrosis of the radiocarpal joint, in contrast, especially in patients who use their hands actively, is best treated by wrist arthrodesis, as described in Chapter 12.

Tenolysis, capsulotomy, and contracture release play important roles in secondary reconstruction after a mangling injury.[53,99] Differentiating joint contracture from tendon adhesion is sometimes difficult, and they often occur in concert. Although the lack of active motion relative to available passive motion is a reflection of tendon adhesions, sometimes what appears to be joint contracture with a clear block to passive motion can also be the result of tendon adhesions. Both need to be addressed at the time of secondary surgery. If release will result in a coverage defect that will require either a skin graft or flap reconstruction (if vital structures are left exposed), postoperative immobilization will be required; therefore, the release should be incorporated into the early set of reconstructive procedures. Common areas of contracture after mangling injuries include the MP, IP, and wrist joints, as well as the thumb's CMC joint. For the CMC joint, it is very important to both treat the skin contracture in the underlying adductor muscle contracture and immobilize the joint in both radial and palmar abduction

with either buried Kirschner wires across the CMC joint or a mini-external fixator for a period of at least 6 weeks.

Tenolysis and capsulotomy require early postoperative active and passive mobilization and should therefore be performed only at a separate stage after completing any secondary procedures that require postoperative immobilization and after the overlying soft tissues have matured and softened. There is no fixed time that dictates how long one should wait before performing these procedures; instead, the timing should be dictated solely by the character of the soft tissues. If both flexor and extensor tenolysis and joint releases are required, it is best to begin with the dorsal side first, with aggressive postoperative active and full passive flexion and extension being performed. Release of flexion contractures and flexor tenolysis can then be done at a second stage, again followed by aggressive active and passive flexion and extension and immediate postoperative mobilization. Attempting to address both the dorsal and volar problems in one stage carries a significant risk of disabling postoperative edema, pain that prevents adequate mobilization, recurrent stiffness, and risk of vascular compromise, especially in the digits.

CRITICAL POINTS *Secondary Procedures*

- Procedures requiring immobilization (do first):
  - Bone grafting
  - Corrective osteotomies
  - Joint reconstruction
  - Nerve grafting
  - Sensory reconstruction
  - Tendon transfers
  - Functional muscle transfer
  - Soft tissue reconstruction
  - Toe transfer
- Procedures requiring mobilization (do second):
  - Tenolysis
  - Capsulotomy
  - Contracture releases

COMPLICATIONS

Complications encountered in reconstruction of a mangled extremity are the same as those encountered in the various component parts of the reconstruction: skeletal, vascular, nerve, tendon, and soft tissue. Complications specific to the mangled extremity revolve mostly around failure to recognize and properly address the extent of the zone of tissue injury. Failure to adequately debride devitalized tissue, especially deep muscle, can have devastating consequences, including myoglobinemia, hyperkalemia, necrotizing soft tissue infection, limb loss, generalized sepsis, and death. For this reason, a "second-look" debridement 24 to 48 h after the initial injury, as well as sometimes even a third debridement, is important. Tissue that may not initially appear devitalized can become so as a result of the inflammatory response to injury during this period.

Thrombosis of a vascular reconstruction is another complication that may be related to failure to recognize the zone-of-injury. If soft tissue infection develops, it is important to provide wide, open drainage and debridement to arrest the progression. Even though coverage issues can become a problem, they can always be dealt with later. Osteomyelitis is a challenging complication after a mangling injury and can be due to either inadequate bony debridement at the time of the initial injury, inadequate vascularized soft tissue coverage, percutaneous fixation devices, or fracture motion due to inadequate osteosynthesis. Treatment involves complete debridement of the devitalized, infected bone down to healthy, bleeding bone, along with vascularized soft tissue coverage. Frequently, a temporary spacer consisting of antibiotic-impregnated methyl methacrylate can be placed after debridement and coverage to allow delayed bone grafting.

Other common complications include hypertrophic scarring, joint contractures, tendon adhesions, neuromas, and soft tissue ulcerations, all of which are addressed in the previous section on secondary procedures. In the end, one must recognize that these are very high-risk cases, that complications are not infrequent, and that they need to be anticipated, identified quickly, and treated appropriately before a "snowball effect" develops and leads to a poor outcome.

EXPECTED OUTCOMES

"Expected" outcomes after a mangling injury are very difficult to quantify because no two injuries are the same in terms of their magnitude, location, or involved structures. Although quantitative outcome measurements, such as active range of motion, grip strength, pinch strength, sensibility, and others, are all important components, the most important outcome measure is the degree to which the patient incorporates the reconstructed extremity into daily activities and is able to resume a normal life.[24,47] Important contributors to this outcome include not only biomechanical and sensibility factors but also appearance and psychological factors associated with the mangling injury and the degree to which the patient is able to adjust to its altered function and appearance. Very often the degree of the injury and the functional loss do not correlate with the psychological impact on the patient.

Sometimes injury to a single digit can be more devastating to a patient than a mangling injury involving the entire forearm. Posttraumatic stress disorder has been described for patients after mangling injuries of the upper extremity (reviewed elsewhere[40,73]). This is particularly a problem in work-related injuries, where merely revisiting the site of injury can elicit severe symptoms and be a significant impediment to returning to the job. Enlisting the assistance of rehabilitation psychologists early after an injury is very important when signs of emotional stress are noted. Often more extensive psychological or psychiatric evaluation is needed, and patients may benefit from antidepressant or anxiolytic therapy.

Of all the factors that contribute to the outcome of a mangling injury, the nature and degree of the soft tissue injury have the most impact. The success of skeletal, nerve, tendon, and joint reconstruction all depends on the overlying soft tissue injury and the quality of its reconstruction, as does the final appearance. For this reason, it is critically important to make soft tissue reconstruction a high-priority item in both the initial treatment and secondary reconstruction of mangling injuries.[64]

As noted previously, the success of any reconstruction must be judged against the results of amputation with or without a

prosthetic. A wide array of outcome scores exist for major extremity trauma.[28,31,51,87] There are also a number of outcome scores specifically designed to address the upper extremity, including the Hand Injury Severity Score (HISS); Hand Function Score (HFS); Disabilities of Arm, Shoulder, and Hand (DASH); and the Michigan Hand Questionnaire (MHQ).[21,22,37,104] Although outcome studies of lower-extremity salvage have shown equivocal benefit for complex reconstruction versus amputation and a prosthesis,[8,9] it has long been thought that because of the complex mechanical and sensory functions of the hand, nearly any sensate function is preferable to a prosthesis.[11,18,38,84] This has not been definitively shown, however. As mentioned at the outset of this chapter, no scoring system exists that reliably predicts outcome in a way that allows it to be used as the sole discriminator in choosing salvage versus amputation in the upper extremity. Experience and clinical judgment are still key.

CONCLUSION

Treatment of mangling injuries to the upper extremity is among the most challenging facets of hand surgery. Achieving good outcomes requires intimate knowledge and expertise in all aspects of hand surgery and the ability to evaluate, synthesize, and prioritize a wide variety of treatment options in developing a comprehensive treatment plan that may require multiple staged procedures and rehabilitation protocols over a period of many months. Because the initial operation sets the stage for all that will follow, it is important at that point to be able to look into the crystal ball many months into the future and envision the patient's overall function with various treatment choices to formulate a comprehensive reconstructive plan that achieves both short- and long-term objectives.

Critical aspects of successful reconstruction include complete debridement of devitalized tissue, restoration of good vascularity; early rigid skeletal fixation while minimizing additional tissue injury; and most important, stable, vascularized soft tissue coverage. The important goals of treatment are to preserve life, preserve viable tissue, preserve function, and reconstruct and restore function of the extremity to allow the patient to incorporate the reconstructed extremity into daily life and resume normal activities. Achieving these goals for a patient with a mangling injury is the ultimate challenge for the multidisciplinary reconstructive hand surgeon. It is a true test of one's mastery of the "art" of hand surgery.

Nonmicrosurgical Coverage of the Upper Extremity

William C. Pederson

Acknowledgment: This section on skin grafts was originally a chapter written by Dr. Earl Browne, and much of his writing remains.

SKIN GRAFTING

The skin is the largest organ of the body and serves a number of vital functions. It functions as a semipermeable membrane and a barrier to toxic material and microbes, but it also contributes to homeostasis through temperature regulation and sensibility. This latter function—perception of stimuli—is most important in the hand, especially on the palmar surfaces of the fingers.

All skin is composed of a thick layer of dermis covered by epidermis. The epidermis constitutes only about 5% of the thickness of the skin, and the thickness varies considerably depending on the area of the body.[3] The skin on the palm and back is quite thick, whereas the skin of the inner arms and thighs is relatively thin. The quality of skin depends to a great extent on the epidermal appendages contained in the dermis, which also vary a great deal from area to area. This is especially true for the skin of the palmar and plantar areas, which contains no hair or sebaceous glands but is the almost exclusive domain of the Meissner and Vater-Pacini sensory end organs.[9] It is reasonable to think of the epidermis as the barrier and the dermis as the functional portion of the skin.
