One must also consider the hand as an organ and think of the skin as an envelope enclosing a multitude of tendons, nerves, vessels, bones, and joints. For the hand to function properly, this skin envelope must be elastic and nonadherent, contain as many of the appropriate appendages as possible, and be large enough to allow freedom of motion. The palm skin must also be thick enough to withstand the pressure and friction caused by grasp and pinch.

When considering the replacement of hand skin, as is done in skin grafting, one must keep these principles in mind. It is convenient to divide the hand into dorsal and volar surfaces, each having different basic requisites. Dorsal skin must be thinner, more elastic, and loose enough to not restrict flexion and must serve as a barrier to cover tendons and joints. Volar skin must be thicker and tougher while still being loose and elastic enough to allow motion, but above all it must retain its function of sensibility. It is often possible to adequately replace dorsal skin by grafting while this may not be possible with volar skin.

General Considerations in Skin Grafting

Histologic Findings of Skin

Figures 44.1 and 44.2 depict the major differences between dorsal and palmar hand skin. Common to both is the irregularity of the border between the basal layer of the epidermis and the dermis, at the juncture of which are located the dermal papillae and the epidermal rete ridges. Both also contain intraepidermal nerve endings terminating in Merkel cell/neurite complexes and sweat ducts extending out from glands located in the base of the dermis and subcutaneous fat. A network of blood vessels and sensory and autonomic nerve fibers in the dermis is shared by all skin.

Figure 44.1 depicts dorsal hand skin, which is similar to skin found anywhere else on the body. The basal layer of the epidermis is continuous with the hair sheaths and sebaceous glands. Hair follicles lie at different depths and are surrounded by a network of fine nerve endings.

Figure 44.2 depicts the palmar hand skin. The papillae and ridges are deeper and the keratin layer is considerably thicker than in dorsal hand skin. Most significant, however, are the absence of pilosebaceous structures and the presence of specialized encapsulated nerve endings. Meissner corpuscles are present in dermal papillae, and Vater-Pacini corpuscles are present in the deep dermis. These latter structures are also found along nerve trunks, joints, and other areas but exist in the skin almost exclusively in digits and the genital area.

Substitution by Skin Grafts

Because it is similar to the skin of most other areas, dorsal hand skin can usually be adequately replaced by a skin graft. No matter how thick the graft is, however, palmar skin cannot always be fully substituted by ordinary grafts because the special dermal neural mechanoreceptors will be absent. Only glabrous skin will provide these, and, unfortunately, not much of this type of skin is available for grafting.

When a split-thickness graft is removed, healing of the donor area occurs by epithelialization from hair follicles and very little dermal regeneration occurs. The deeper the graft, the better the quality of the skin, but the less there is left behind at the donor site to aid in healing. Also, a deeper graft increases the chance of reinnervation of Merkel complexes and restoration of sensibility in the recipient site.[106] Thick nonglabrous grafts will transfer hair follicles, however, and result in unwanted hair growth if placed on palmar surfaces.[112] In addition to poor

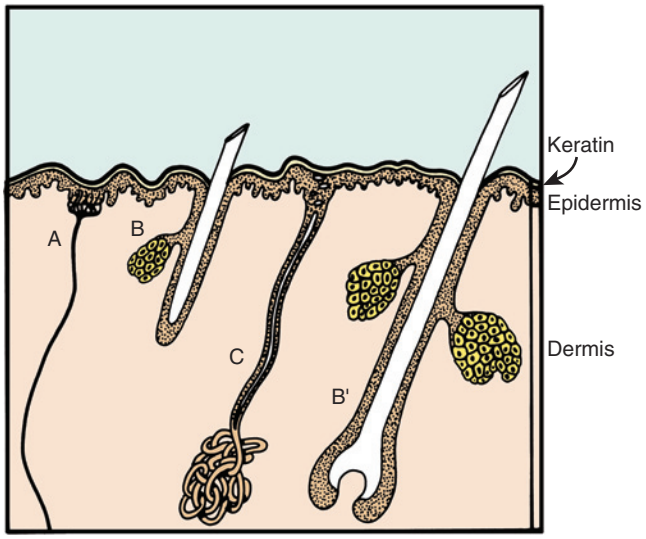

FIGURE 44.1 Dorsal hand skin is similar to skin of the rest of the body in that it has hair and sebaceous glands. **A,** Merkel's cell/neurite complex. **B** and **B′,** Hair follicle and sebaceous apparatus. **C,** Sweat gland.

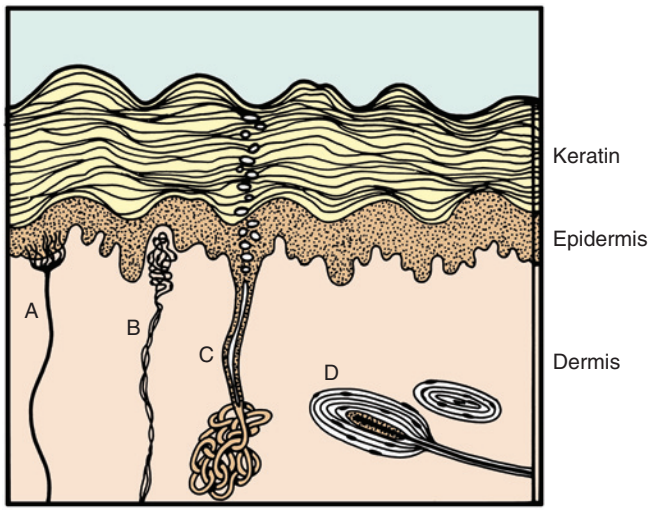

FIGURE 44.2 Palmar hand skin. There are no pilosebaceous structures present. Meissner and pacinian corpuscles exist almost exclusively here. **A,** Meikel cell/neurite complex. **B,** Meissner corpuscle. **C,** Sweat gland. **D,** Vater-Pacini corpuscle.

return of sensibility, grafts on palmar areas do not provide the vascularized subcutaneous tissue necessary to cover tendons and nerves. In general, palmar grafts should be considered a compromise and are usually only indicated in release of flexion contractures in areas not requiring critical sensibility.

Response to Injury

Any injury that results in the loss of a full-thickness segment of skin initiates the process of wound contraction. Although beneficial in helping to minimize defects in other parts of the body, this process of gradual shrinking of the wound edges can be disastrous in hand wounds (Figure 44.3). It appears that fibroblasts migrate into the base of the wound and differentiate into so-called myofibroblasts.[4] These cells have the ability to contract, and the network of these cells and collagen fibers that

FIGURE 44.3 The end result of scar contracture due to severe burn to the hand.

forms in the base of the wound is responsible for pulling the wound edges together. It has been shown that contraction can be temporarily halted by treatment of the wound with smooth muscle relaxants.[74] Once the contraction process has begun, it is not altered to any extent by split-thickness skin grafting.[25]

In a series of experiments by Stone and Madden, wounds in animals were treated with immediate grafting, delayed grafting, and immediate and delayed grafting with splinting.[103] They concluded that immediate grafting with split-thickness skin did not significantly affect wound contraction. However, immediate grafting and splinting with a compressive dressing for 7 days did significantly inhibit wound contraction. On the other hand, delayed grafting had no effect on wound contraction no matter what adjunctive therapy was used. Splinting, although effective with immediate grafting, was ineffective in preventing contraction when used with delayed grafts.

It is generally believed that the condition of the wound is the main determinant in the result of skin grafting. Even full-thickness skin grafts can be found to contract if wound contraction has already begun. Rudolph has found that the application of split-thickness skin does not seem to have as much effect on the differentiation of fibroblasts into myofibroblasts as does a full-thickness graft.[92] He has shown in animal experiments that wounds mature much more rapidly after the application of full-thickness grafts than after split-thickness grafts. The amount of actin and fibronectin found in rat wounds that were allowed to heal secondarily was compared in wounds with split-thickness grafts and those with full-thickness grafts. The thicker the graft, the less matrix protein present, which correlated well with the extent of wound contraction that occurred.[111]

This is important in considering the source of a graft for palmar wounds. The Shriners Burn Institute has compared the results of split-thickness and full-thickness grafts for coverage of deep palmar burns. Normal range of motion was found in over half of the full-thickness group, and only a fourth needed reconstructive procedures. In contrast, normal range of motion was present in only a fourth of the split-thickness group, and two thirds required reconstructive procedures.[97]

Effect of Infection on Wound Healing

A great deal of bacteria is normally present on the skin. It has been estimated that about 1000 organisms per gram of tissue are normally present in hair follicles, crevices, and recesses of the skin. This number of organisms does not seem to have a negative effect on wound healing.[53] However, when contamination of the wound takes place, much higher levels are present. Surface bacteria, which can easily be removed, do not appear to be important in skin grafting if the wound is carefully prepared before surgery. On the other hand, penetration of the bed of the wound is of great significance.[44] It has been established that 10,000 organisms per gram of tissue is a fairly critical level of contamination.[58] Wounds that contain fewer organisms than this do not commonly become infected. In a series of skin grafts applied to contaminated wounds, Krizek and colleagues[53] have shown that no matter what technique was used to prepare the bed of the wound for grafting, a bacterial count of greater than 10,000 organisms resulted in a successful skin graft take of only 19%. If the count was less than 10,000 organisms, however, there was a 94% successful take.

Vascularity of the Wound

After application of a skin graft to the wound, the graft first survives in a precarious fashion, apparently nourished by transudate from the wound. This has been referred to as "plasmatic circulation."[18] It is imperative that the graft become vascularized for ultimate survival, however, and anything that acts as a barrier to this process will cause loss of the graft. The most potent of all barriers is blood, and hematoma will kill a graft even in the absence of infection.

The actual process of vascularization is not altogether clear, but it is certain that this process must begin within a few days if the graft is to survive. It appears that the most important process is the ingrowth of capillary buds into the skin graft from the edges of the wound and, more importantly, from the bed of the wound.[5] For this process to take place, there must be a vascularized bed containing the necessary fine network of capillaries from which budding will take place. Grafts will not take on denuded bone or tendon, and skin grafts are not satisfactory coverage for vital structures.

Timing of Grafting

From the previous discussion, it is obvious that the ideal time for grafting the wound is as soon as it is clean enough and after the fine network of vessels has been established. In this way, contamination of the wound and establishment of a large milieu of myofibroblasts are avoided. In general, immediate débridement and grafting are often possible, and no more than 2 or 3 days should be allowed to pass for the purpose of establishment of a good bed. The principle of allowing a healthy bed of granulation to develop is no longer considered correct, and it should be replaced with the concept of early grafting. The vacuum-assisted wound closure device may be helpful in promoting granulations in severe wounds and may aid in obtaining granulations over tendons and bone,[37] but its use in the hand should be limited to avoid the marked scarring often caused by the device and increasing stiffness.

Bacterial Content Determination. If it appears that the wound may be infected, determination of the bacterial content is necessary. Rather than rely on a wound swab to determine the presence of bacteria, which may yield a false-positive result, it is important to know whether the bed of the wound has become colonized with pathogenic bacteria. A useful method of determining this is by performing a wound biopsy. To do so, the surface of the wound is cleaned to prevent contamination, and a segment of tissue weighing about 1 g is removed. This can be done conveniently with a punch biopsy. A colony-count culture can be obtained from the biopsy material, or a more rapid determination can be made by crushing the tissue and examining it microscopically. It has been said that bacterial presence greater than 1 per high-power field roughly corresponds to a critical level of 10,000 organisms.[58]

Temporary Storage of Skin Grafts. At times the wound may not seem to be ideal to receive a graft because of infection, bleeding, or poor vascularity. It may be convenient to remove skin from the donor site at the time of surgery for wound preparation to avoid another round of anesthesia and operation. In this way, the skin can be stored while the wound is being prepared by dressing changes or periodic bedside débridement to reach an ideal state.

There are very convenient methods for storing such skin grafts if they are removed. One is simply to replace the skin on the donor site from which it was removed. The graft will begin to "take" and will remain well nourished and viable. If this technique is used, it is necessary to remove the graft before significant tensile strength has occurred, which is usually before about 5 or 6 days after harvest. This may be done by injecting a solution of saline and local anesthetic between the graft and the donor site, and the graft can be placed on the recipient site at the bedside.[98]

Another technique is to store the skin graft in tissue culture medium during this interval. A common practice is to wrap the skin graft in a saline-soaked sponge and store it in the refrigerator. This is effective for a few days, but seldom can the graft remain viable for more than a week. It has been shown that by storing the graft in tissue culture medium with various additives, the viability of the graft can be markedly prolonged. Hurst and associates have demonstrated that the use of McCoy 5-A medium containing amino acids and vitamins can allow skin grafts to be stored successfully for up to 30 days.[40] The method of preparing the medium and storage of the grafts is described in detail in their article. This is an excellent method for 10 days to 2 weeks, but after that time the quality of the skin does not seem to be as good as the quality of a freshly harvested graft.

Types of Grafts

The two primary types of skin graft are split-thickness and full-thickness grafts. While other differences were discussed earlier, the main clinical difference in these grafts is in the way in which they are harvested. Split-thickness skin grafts are harvested with a knife or dermatome, and only the superficial layer of the skin is taken. The donor site of a split-thickness graft will heal on its own from propagation of epithelial cells from the deeper skin appendages (hair follicles and sweat glands). Full-thickness grafts are harvested with an incision with a knife and involve taking the entire layer of skin down to the subcutaneous fat. These donor sites must be closed as with an incision; otherwise the patient is left with a wound.

The standard thickness for harvesting split-thickness skin grafts is in the range of 0.015-inch thick. Split-thickness skin

grafts may be taken as either "thin" grafts (0.008 to 0.010 inch) or "thick" grafts (0.016 to 0.020 inch). Thicker split grafts have the theoretical advantage of potentially less contraction, because they contain more dermis. The downside of these types of grafts is that the donor site may have difficulty healing, and this can lead to worse scarring. One prospective study of the differences between standard and "thick" split grafts in the hand found no advantages in terms of range of motion, appearance, or patient satisfaction.[67]

Although it is true that full-thickness grafts afford better protection, hold up better, establish better sensibility, contain more epidermal appendages, and contract less than split-thickness grafts, thick grafts are not always desirable. There are several disadvantages to thick grafts. Full-thickness grafts do not take as readily as split grafts. A full-thickness graft requires a much better bed on which to be placed, and the graft is more prone to infection.

In addition, the availability of skin must be considered. It is not always possible to sacrifice enough skin to afford the luxury of full-thickness grafting, and split-thickness grafts must often be substituted. In general, full-thickness grafts should be used only in situations in which the quality of the skin and the tendency to less contracture are crucial. As a rule, these conditions are necessary only on palmar skin grafts, and the greater level of return of sensibility is an added bonus under these circumstances. Full-thickness grafts have recently been shown to be superior to split-thickness grafts in coverage of palmar wounds extending onto the digits in a large series of children with burns.[13] Dorsal wounds can generally be treated very adequately with intermediate split-thickness grafts.

Skin Substitutes

There have been many attempts in recent years to develop skin substitutes. Autogenous epithelial cells have been cultured and placed on a variety of collagen matrices and used as skin grafts. These have been of great value in the treatment of massive burns, but the take of the graft is not equal to that of standard autografts and the quality is not predictable.[6,117] Cultured epithelial autografts remain extremely expensive and afford very poor coverage, particularly in the hand.

Work continues on the goal of providing skin coverage without the need for a donor site, particularly in terms of reconstruction of the dermal layer.[21,116] Several products now exist that provide a collagen matrix to act as a layer of dermis when placed on a vascularized wound.[27,113] The primary problem with these dermal substitutes is that they generally have to be applied 1 or 2 weeks before coverage with a split-thickness graft to allow for revascularization of the collagen matrix, thus necessitating two operations. Some authors have noted no statistically significant long-term difference in elasticity, scar contracture, and patient satisfaction in patients treated with dermal substitutes plus split-thickness skin grafts versus split-thickness skin grafts alone in the management of donor sites from radial forearm free flaps.[116] It should be noted that the time necessary for rehabilitation of the hand was significantly longer with the dermal substitutes, as the hand had to be immobilized while the dermal autograft became vascularized.

Recent reports have noted that dermal substitutes have few complications when utilized in the upper extremity and obviate the morbidity of a full-thickness skin graft donor site. One fairly large study found that placement of dermal substitute after contracture release was as effective as full-thickness grafting.[30] Other reports of smaller series of patients have shown the utility of this approach to avoid the need for a full-thickness graft in burns and wounds of the upper extremity.[27,49,113] Skin elasticity in patients managed with dermal substitutes and split-thickness skin grafts has been found to be close to normal in objective testing.[79] The issue remains, however, that the application of dermal substitutes in the hand necessitates a period of immobilization while the dermis becomes revascularized, and then a potential second period of immobilization while the split-graft heals. Coupled with the fact that the morbidity of most full-thickness skin graft donor sites is minimal, the utility of these materials in the hand remains in question in my mind.

Skin Thickness

When determining the thickness of a graft to be removed, the skin thickness of the donor area must be considered. Epidermis and dermis vary according to age and sex, as well as location. It is said that the epidermis ranges from 20 to 1400 μm in thickness and the dermis from 400 to 2500 μm.[3] When considering donor sites, however, there is only a practical range of 25 to 80 μm of epidermis and 500 to 1800 μm of dermis. In relation to dermatome settings, these values translate to 0.001 to 0.003 inch of epidermis and 0.020 to 0.070 inch of dermis.

In general, the epidermis is quite thin in infants and reaches a maximum thickness at puberty; it then becomes thinner with age until it is almost as thin in old age as it was during childhood. There is very little difference in epidermal thickness between sexes. The dermis, however, remains relatively thin in youth; it reaches its maximum thickness at about the fourth decade and subsequently becomes thin again in old age. There is a marked difference between sexes, with male dermis being significantly thicker than female dermis.

The skin of the trunk and dorsal and lateral surfaces of the extremities is the thickest. Skin thickness may range from 0.020 to 0.025 inch in a small child to 0.100 inch on the anterior of the abdomen in an adult man. In general, most donor sites cannot be expected to be much thicker than about 0.060 inch in a man and about 0.040 inch in a woman.

Split-Thickness Grafting

Choice of Donor Sites

Removal of a skin graft is a morbid procedure. Although regeneration of the epidermis will occur, it appears that loss of the dermis is irretrievable.[95] The thicker the skin graft, the poorer the quality of the donor site after healing. Therefore, the thickness of the desired graft must, to a certain extent, determine the location of the donor site. The thicker portions of the body, such as the posterolateral aspects of the trunk and thighs, afford the best chance of good healing when a thick graft is desired. The thinner areas, such as the inner aspect of the thigh, are generally unsuitable for donor sites (unless they are absolutely necessary) because of the poor quality of healing of the donor site and the tendency of the skin graft to become hyperpigmented in its new area. So that morbidity and subsequent scarring are prevented, a reasonable guideline for graft thickness is offered in Table 44.1.

The optimal thickness for split-thickness grafts is 0.015 inch in thickness. Thinner grafts of 0.010 to 0.012 inch may be best

TABLE 44.1 Guidelines for Appropriate Thickness of Skin Grafts

Patient	Thickness of Graft
Infants	Never over 0.008 inch
Prepubertal children	If >0.010 inch necessary, remove from lower abdomen or buttocks
Adult males	0.015 inch from thighs, 0.018 inch from abdomen or buttocks
Adult females	Try never to use inner thigh; if >0.015 inch, use lower abdomen
Elderly adults	Treat like children's skin

for wounds where graft survival is at risk. Split grafts greater than 0.018 inch are seldom indicated because of donor site morbidity. If thicker skin is desired, it is best to use a full-thickness graft.

If possible, a graft should be taken from an area that is easy to care for during the healing process. No one likes to have to lie or sit on a donor site, and donor areas that cross intertriginous areas are very unsuitable because of the constant cracking and subsequent drainage with motion of the area. In women and children, it is desirable to remove the graft from the lateral aspect of the upper thigh or buttocks or perhaps the lower portion of the abdomen. These donor sites can be covered by a bathing suit or some other article of clothing. It is important to remember that the thicker the skin graft, the larger the number of hair follicles that are transferred in the graft; thus whenever possible, a relatively hairless area should be selected as a donor site for the hand.[112]

Harvesting Skin Grafts

A very small piece of skin can be removed with a No. 10 knife blade by dissecting superficially just under the surface of the skin. It is convenient to make a very shallow incision in skin that has been distended with intradermal lidocaine before beginning the tangential dissection. In this way the appropriate depth and width of the graft can be selected. The blade is then placed into the depth of the incision, and with a back-and-forth sawing action, parallel to the skin, the desired size of graft can be removed. It is possible to remove a reasonably uniform piece of skin up to about the size of a dime with this technique, but the procedure is difficult for a surgeon without some experience.

A much more satisfactory method of taking a small skin graft is with the Weck-Goulian knife set. There are a number of depth gauges available that can be fitted over the blade (Figure 44.4). These gauges vary in thickness from 0.004 to 0.030 inch. By placing the gauge next to the skin, the appropriate depth and angle of cut are automatically established. Because this instrument tends to take a rather thick graft, I prefer to use the 0.010 guard, avoiding excessive thickness. A strip of skin 2 cm or so in width can easily be removed, and with practice a long strip can be taken. This instrument has the advantage of removing a strip of skin of relatively uniform thickness.

Although it is very convenient to remove a split-thickness skin graft from the upper inner aspect of the forearm because it is in the operative field, this is, in practice, a very poor

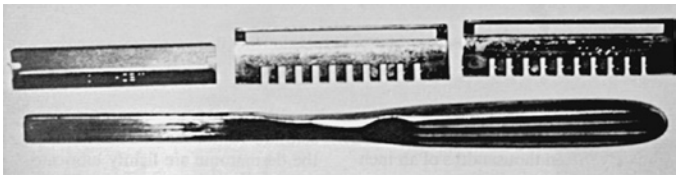

FIGURE 44.4 The Weck-Goulian skin graft knife set before assembly. Depth gauges of many thicknesses make it possible to remove a graft of uniform thickness.

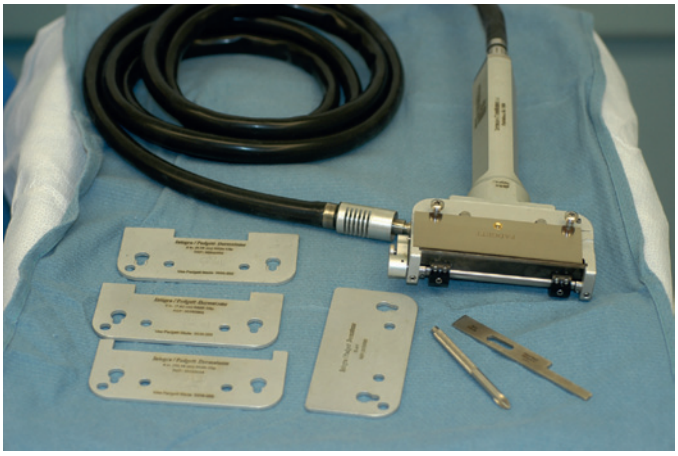

FIGURE 44.5 The Padgett gas-turbine driven dermatome. Guards are shown on the lower left with variable openings to control the width of the graft. The blade is seen loaded on the device.

procedure. The skin of the forearm is relatively thin in this area, and often the scar will become hypertrophic. These scars are very obvious to both patients and casual observers, and often women will complain more of the donor site scar than the recipient area scar. It is preferable to remove these grafts from areas of thicker skin, where the scar will not be so readily apparent.

Dermatomes

Padgett Dermatome. The Padgett dermatome is a motorized dermatome (via electricity or nitrogen turbine) and uses a disposable blade that cuts with a very rapid back-and-forth motion. There is a depth gauge on the side of this instrument with which the surgeon can set the desired depth of the graft. Variable-sized plates determine the width of the graft taken (Figure 44.5). After determination of the desired width, the blade is fitted on the machine and the appropriate plate placed over the two screws and screwed down tightly. To put the blade on, it is necessary to first slip the base of the blade under the two projecting metal pieces and snap it down so that the hole in the blade fits onto the projection of the drive shaft. The appropriate graft thickness is selected by moving the blade up and down by using the depth gauge on the side of the machine. The depth of the graft taken is also determined by the pressure applied to the device on the skin and the angle of attack of the blade against the skin.

The skin is surgically prepped and cleansed with saline before taking the graft. The skin should be lubricated so that the dermatome will slide easily and not skip. Either mineral oil or a surgical soap solution can be used for this purpose and is placed both on the skin and on the flat surface of the instrument

that is in contact with the skin. The dermatome is placed flat on the donor site, and traction is held behind the dermatome. It is not necessary to stretch the skin in the direction in which the dermatome will be advanced. It is easy to remove a piece of skin with this dermatome, and very minimal pressure should be exerted on the donor area. A common mistake is to dig the edges of the dermatome into the skin and press too hard, which creates an improper cutting angle. As the dermatome is advanced, the skin may be lifted up to check the thickness, if desired. This is not necessary, however, and in general, a very uniform piece of skin is removed with the Padgett dermatome. This is probably the best instrument to use to take a skin graft if one is not experienced in this area.

Zimmer Air Dermatome. A similar instrument has been produced by Zimmer and is used in the same fashion as the Padgett dermatome. A special disposable blade is made to fit the dermatome and snaps easily onto the reciprocating post. The width gauges are fitted in place and screwed down in the same fashion. The thickness of the graft is adjusted by a gauge on the side of the instrument in the same fashion as the Padgett dermatome, and the technique of skin harvest is identical. One must be careful in the setup of this instrument, however, because it has been reported (and I have personal experience) that this dermatome can cut down to muscle and cause serious injury if it has not been properly set up with the proper blade by the operating room personnel.[66]

Meshed Grafting

At times the condition of the wound cannot be made optimal for grafting. The risk of infection or hematoma may be so great that the chance of survival of a sheet of autograft would be small. In these instances, it is often wise to use a piece of skin that has been "meshed" so that many perforations are present through which blood or exudate can escape. An instrument has been devised that will automatically make these perforations. The skin can be expanded so that the interstices allow drainage and rapidly become epithelialized (Figure 44.6). This method of grafting has wide application in the treatment of burns and large wounds.[64]

It must be remembered, however, that only the portion of the wound that has skin applied to it is being grafted and the interstices of the mesh are left open and allowed to epithelialize. The quality of the graft will not be as good as that of a sheet of skin, and the tendency toward contraction and poor cosmetic results is greater. If meshed grafts of this nature are placed over flexion creases, joint contractures are likely to occur. These factors can be limited somewhat by compression, and it is imperative to treat wounds grafted in this fashion with long-term compression, such as can be obtained by use of a custom-fitted pressure glove.

FIGURE 44.6 A meshed split-thickness graft placed over an innervated gracilis muscle to the forearm.

CRITICAL POINTS *Split-Thickness Skin Grafting*

Indications
- Simple wound with good underlying soft tissue bed
- Marginal wound with plan for more complex reconstruction at a later time

Preoperative Evaluation
- Inspection of wound (for adequate vascularity); possibly, quantitative wound cultures

Pearls
- Avoid a graft that is too thick.
- Small grafts may be taken with a freehand knife or Weck dermatome.
- Mesh or "pie-crust" graft to avoid fluid collection underneath

Technical Points
- Recipient site should be very clean and débrided back to viable tissue everywhere.
- Avoid air or fluid pockets underneath graft (mesh or pie-crust graft).
- Graft must be held in place well to avoid moving against the wound bed.
- Avoid removing the dressing for at least:
  - Three days if there is a question of wound cleanliness
  - Five to 7 days if the wound is very clean
- Place a bolster for graft in a concave surface.

Pitfalls
- Early infection (usually *Streptococcus* or *Pseudomonas*) that destroys the graft
- Early motion that keeps the graft from adhering

Postoperative Care
- Immobilize for at least 2 weeks.
- Change the dressing if signs of drainage, etc., are present.
- Avoid any shearing force on the graft for a minimum of 3 weeks.

Expected Outcomes
- Skin graft will not match surrounding skin in terms of color and texture.
- Split-thickness skin graft should afford stable coverage.
- Donor site morbidity is minimal over the long term; however, donor site scarring can be conspicuous.

Although they were not specifically evaluating hand grafts, el Hadidy and colleagues evaluated the results of meshed versus nonmeshed grafts in burns.[25] As expected, the results of either graft in late excision were significantly worse than the results in early excision, but the meshed grafts contracted more in both groups. In addition, there was a difference in the amount of growth that occurred in the two groups. With early excision, nonmeshed grafts grew back to a size of 91% as compared with 78.5% in the meshed group.

Meshed grafts are often placed on a wound without the graft "expanded," which prevents collection of fluid under the graft

but avoids the necessity for skin to grow over the open interstices. Whereas using a meshed graft in this way inevitably leads to more scarring than using a nonmeshed graft, the functional differences are usually minimal. The advantages of meshing a graft usually outweigh the disadvantages. Nonetheless, split-thickness skin grafts are usually reserved for coverage of the dorsum of the hand, whether meshed or not. When the dorsum of the hand is covered with a muscular or fascial flap, it is certainly acceptable to place an expanded meshed split-thickness graft over the flap. It is sometimes convenient to use a mesh graft as a "temporary" biologic dressing, however, until a later resurfacing procedure can be done as part of the reconstruction.

Preparation of a Meshed Graft. After the graft is taken, it is spread out onto the surface of a plastic carrier, which is provided with the dermatome (Figure 44.7). The "dermacarrier" plastic board has angled troughs cut into it that dictate how much the graft will expand. The various boards are marked and allow expansion from 1.5:1 to 9:1, but sizes larger than 1.5:1 have very large holes that are not practical for hand surgery. Grafts thicker than 0.015 inch in thickness will not feed well into the meshing machine, and thus grafts thicker than this do not mesh well. After the graft has been carefully spread out onto the surface of the carrier, it is fed into the lower end of the machine and run through the mesh by using the hand crank.

It is absolutely critical that the card be fed through the mesher with the grooved side up, however. If the skin is inadvertently placed on the wrong side of the mesh card and passed through the dermatome, the result will be multiple small strands of "linguini" that are unusable.

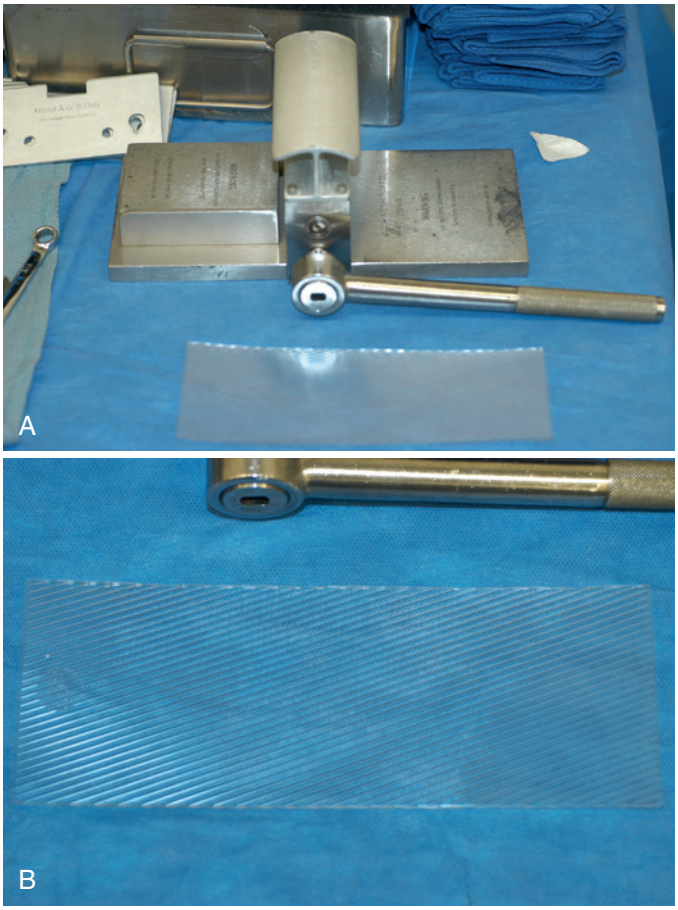

FIGURE 44.7 A, The mesher device with a "dermacarrier" board in front. **B,** Note oblique troughs in board that control size of mesh of graft.

Full-Thickness Grafts

Full-thickness grafts transfer all the skin appendages and nerve endings except the sweat glands located in the subcutaneous tissue and some of the Vater-Pacini corpuscles of the palmar and plantar skin. This thickness is an advantage for the restoration of sensibility and quality of coverage. These grafts must always be taken from relatively hairless areas to minimize subsequent hair growth in the recipient area. Good donor sites for this type of skin are in the lower and lateral abdominal areas. It is possible to obtain good-quality, relatively hairless skin here, and the area is loose enough to allow a large piece of skin to be removed with no subsequent defect after wound closure. Smaller pieces can be removed from the extremity being operated on, and this is often very convenient inasmuch as the area has been prepared along with the operative site. The medial upper arm offers a good choice for full-thickness grafts from the upper extremity, and large pieces of skin may be taken in older patients. If skin is harvested from the posteromedial aspect of the arm, the scar is usually not objectionable. The volar wrist crease and antecubital fossa are often described as good choices for full-thickness skin grafts, but these areas should be avoided owing to potential scarring. Scars on the volar wrist crease can also be interpreted as a sign of a prior suicide attempt. For coverage of the palmar surface of the fingers, glabrous full-thickness grafts may be taken from the hypothenar eminence. A fairly large graft can be taken from this area with minimal scarring and morbidity. In instances in which sensibility is critical, such as in the fingertips, a fairly large piece of "fingerprint" skin can be obtained from the hypothenar area (Figure 44.8). Small glabrous full-thickness grafts can also be taken from the lateral surface of the great toe. Glabrous full-thickness grafts have the added advantage of transferring skin of a more similar nature, that is, skin containing Meissner corpuscles, thereby potentially restoring better sensibility.

Most full-thickness grafts will be placed on the palmar aspect of the hand; however, the surgeon must remember that there is a marked difference in pigmentation of the palmar skin in black patients, and nonglabrous donor sites should be avoided if possible. In dark-skinned patients, full-thickness grafts for placement on the palmar fingers or in the palm should be taken from the hypothenar area of the hand or from the previously mentioned foot donor sites.

Technique of Obtaining a Full-Thickness Graft

After the appropriate size has been determined, an area for harvest of the full-thickness graft is marked. I prefer to infiltrate underneath this area with plain lidocaine or marcaine, which will elevate the skin somewhat and make harvesting easier (as well as provide some anesthesia in the postoperative period). Local anesthetic with epinephrine should be avoided as this has been reported to cause spasm in the capillary bed of the graft and lead to poor "take" of the graft. An ovoid of skin is excised from the predetermined area with the axis in the direction of minimal tension. The wound is closed in standard fashion. Most donor sites for hand coverage will be small, and primary closure can be performed easily without undermining of the edges.

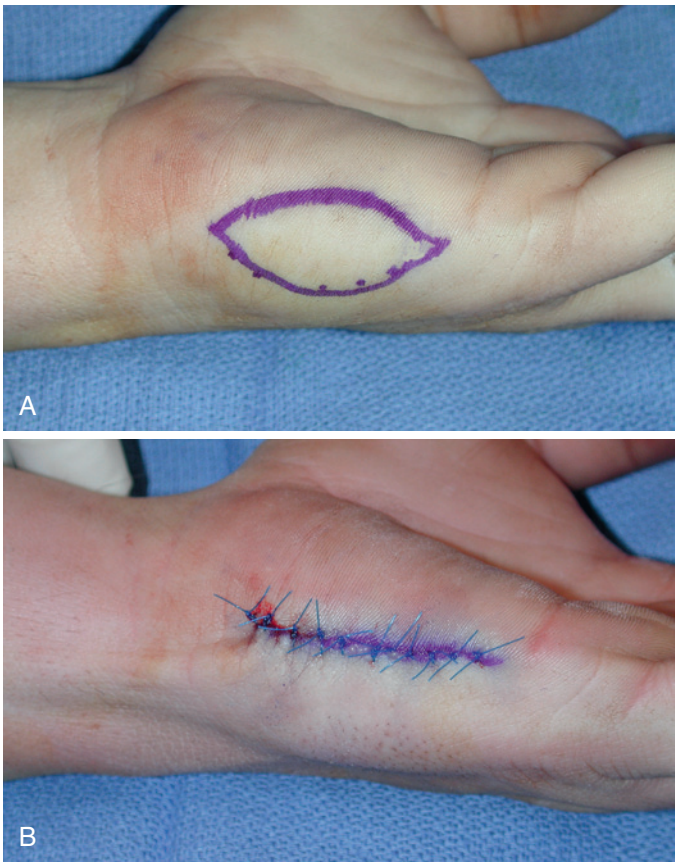

FIGURE 44.8 **A,** Full-thickness skin graft donor site marked on hypothenar area of hand. **B,** Donor site after primary closure, which can usually be performed easily.

Because there will be a moderate amount of tension on the edges, it is probably best to close the wound with buried subdermal sutures and a subcuticular suture to minimize the cross-hatching that might occur with ordinary cutaneous sutures. The wound can be dressed with sterile skin closure strips only.

It is necessary to remove all fat and subcutaneous tissue from the undersurface of the graft because they will otherwise act as a barrier and prevent vascularization. If desired, this can be done at the time of removal of the graft by very carefully excising only the skin and lifting it off its bed of subcutaneous tissue by dissecting sharply with a scalpel in the subdermal plane. The graft can be rolled over a finger as it is taken, and, with appropriate tension, most of the underlying subcutaneous fat can be removed. Once the graft is excised, the remaining subcutaneous tissue is removed. This is easily done by draping the graft around the surgeon's nondominant index finger while holding tension with the ends of the graft in the other fingers. The remaining fatty tissue is removed with a small curved pair of scissors. The normal tendency is to remove portions of the dermis as well, which can actually lead to creating a "thick" split-thickness graft and lead to more contracture. The final result in terms of quality of the graft will be better if the subdermal areolar tissue is left with the graft. The fat can also be removed by placing small mosquito hemostats on the very tips at each end of the graft and draping the skin over a finger or the thumb while keeping tension on both hemostats. If some tension is maintained, it is very easy to snip away the fat in this fashion.

CRITICAL POINTS *Full-Thickness Skin Grafts*

Indications
- Wounds with very good bed in an area where better coverage is desired
- Management of scar contraction in palmar surface

Preoperative Evaluation
- Wound bed vascularity
- Lack of infection in wound bed

Pearls
- Avoid grafts from wrist crease and antecubital fossa.
- Graft from medial upper arm or groin.
- Do not "defat" graft so much that it becomes a split-thickness graft.

Technical Points
- Place lidocaine (without epinephrine) under the skin to be taken first.
- Defat the skin graft as you elevate it.
- Take an ellipse that can be closed primarily at the donor site.
- Suture the graft into the defect exactly, trimming as necessary.
- Avoid straight suture lines along web spaces.
- Use a "tie-over" bolster for almost all full-thickness grafts.
- Leave in place with the extremity immobilized for at least 2 weeks.

Pitfalls
- Infection under grafts
- Motion of graft before revascularization
- Defatting graft too much and making it into a split-thickness graft

Postoperative Care
- Bolster and immobilize the graft for at least 2 weeks.
- Begin motion carefully.
- Consider compression garment/silicone sheeting early to prevent hypertrophy.

Expected Outcomes
- The full-thickness graft should have nearly normal texture and elasticity.
- The color of the full-thickness graft may match the recipient area; however, it may be darkly pigmented if a poor donor site is chosen.
- The donor site morbidity should be minimal because the scar will be a simple straight scar.

Choice of Graft

As previously indicated, a thicker graft contracts less, holds up better, and regains better sensibility than a thinner one. In general, split-thickness grafts should not be used on palmar surfaces of the hand unless there is no other choice or the coverage is considered to be temporary, with secondary resurfacing to be performed at a later date. If split-thickness grafts are to be used, they should be relatively thick and long-term compression with an elastic glove should be used.

Full-thickness grafts are seldom indicated on the dorsal surface of the hand. The need for coverage is not as critical on the dorsum, and split-thickness grafts are generally satisfactory. In addition, the convexity of the dorsum and the subsequent greater tension on the wound edges with motion in the postoperative period appear to allow split grafts to be used with less contraction than would be the case on the concave palmar aspect. The general rule is that a sheet of graft of good-quality skin approximately 0.015 inch thick, if placed on a well-vascularized bed early in the evolution of the wound, will heal

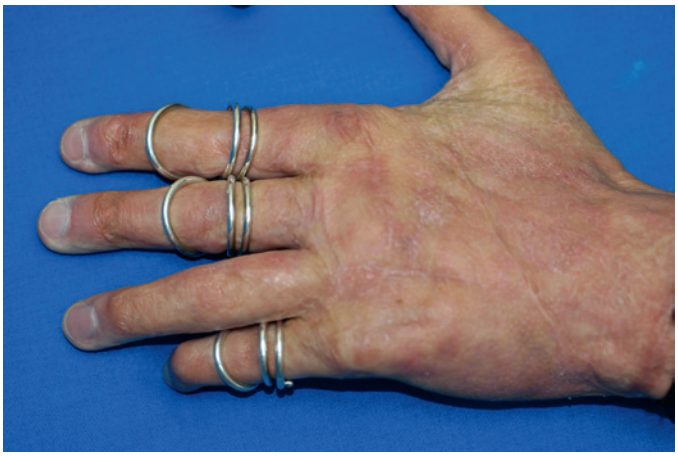

FIGURE 44.9 Hand of a patient who suffered burns of the hands and was treated with excision and primary split-thickness sheet grafting. Note quality of dorsal hand skin after placement of sheet graft.

so well that it is difficult for a casual observer to know that a graft has been done (Figure 44.9). If the bed is not ideal, it makes no difference what kind of graft is used, because the result will always be less than satisfactory. Large areas of bare tendon, bone denuded of periosteum, and nerves and vessels bowstringing in the wound should never be covered with a graft; in such instances, coverage should be obtained by the use of a flap (see later in this chapter). Very small areas of exposed tendon can sometimes be covered successfully with a full-thickness graft if the surrounding bed is good. This is due to the presence of the capillary bed in a full-thickness graft, which will allow vascularization of small areas of graft that are not over areas with adequate vascularity (assuming that the rest of the graft becomes vascularized).

Negative Pressure Wound Therapy

Negative pressure wound management (most usually the VAC device) has become a popular and effective treatment for open wounds.[39,109] It can be used as the sole method for wound closure in certain large wounds of the torso and extremities and has been found to be quite effective as a method of wound management. It has been shown experimentally to increase wound vascularity (possibly as an effect of the polyurethane sponge) and cell proliferation.[80,96] This technique can be easily used in the outpatient setting, and in fact makes it much easier for the patient to manage the wound in this setting. The primary downside of negative pressure wound management is the cost, as the equipment and use of home-health services are quite expensive. Some surgeons question whether this technique is superior to other methods of wound management because high-level evidence studies on it are few.[35,39] Nonetheless, it has some application in the hand and upper extremity. It can be used to prepare a wound bed for skin grafting because it promotes the growth of granulation tissue. It can actually promote granulations over nonvascularized bone and tendon in some instances, but this takes a somewhat lengthy application of the technique. Although it can occasionally be used to great benefit in the arm and forearm, it must be used with care in the hand in my opinion. It is certainly useful as a temporizing measure to manage a wound after or between débridements when preparing the wound for graft or flap coverage. It has been successfully applied to the management of digital pulp defects[2] and is also useful as a dressing if a dermal substitute is being used for wound closure.[57] There has been a report of using the VAC device as a "glove" in hand wounds and allowing motion during healing[78]; however, our experience has been that prolonged application of negative pressure therapy to the hand often leads to marked stiffness. VAC can be used as a very effective bolster for skin grafts (see below); however, it remains a very expensive option in this regard.

Filling the Defect With the Graft

In general, a graft on a convex surface can be placed on the wound with normal tension and held in place in whatever fashion is desired. The convexity will tend to hold the graft in place; by securing the graft to the edges of the defect, the tendency toward shearing will be minimal. One must always remember that the secret to grafting is the amount of dermis that is placed into the wound and that it is a mistake to stretch a graft too tightly for compression of the wound. This will result in thinning of the dermis by stretching, with less net dermis being grafted, which will lead to a poorer result. The graft itself will not cause pressure on the bed inasmuch as any amount of fluid will easily lift the graft up no matter how tightly it is stretched. Compression must come from external dressings. Any blood present under the graft should be irrigated out with saline.

Sheets of skin placed on the hand, whether split thickness or full thickness, should be carefully tailored to the defect. If the margin of the skin graft lies in a line that is likely to cause a scar contracture (particularly in the palm), darts should be made in the hand skin along this line and the graft fitted into these. These small darts break up the scar and can prevent a linear scar contracture from occurring later on (Figure 44.10).

Grafts on the dorsum of the hand may be held in place with sutures or skin staples. Meshed split-thickness grafts are usually easiest to hold down with metal skin staples. After closure is completed, the graft is covered with a compressive dressing and

splint. Meshed grafts should be kept moist and are usually covered with some type of nonadherent gauze that is then covered with moistened gauze. The gauze is soaked with a solution of antibiotic saline that is used for irrigation in the operating room. Many types of nonadherent dressings exist, and most contain some type of petroleum solution that is not water soluble.

Grafts placed on a concave surface must always be held securely in place. They will have a natural tendency to "tent" over the wound and float up off the wound as serum collects under them. One excellent method of preventing this is the use of a bolster or tie-over dressing. In this technique, grafts are placed into the concavity and sutured around the edges with strands of suture that are left long. After the completion of suturing, the graft is covered with some type of nonstick gauze and the concavity filled with wet cotton. The ends of the sutures are tied over the dressing to make a package that will hold the graft in place and prevent shearing, minimize serous accumulation, and optimally cause some pressure on the base of the wound (Figure 44.11). This is an especially good dressing for a full-thickness graft. This bolster dressing can be used anywhere desired, but its use is difficult on a convex surface because the sutures tend to pull the graft up from the edges of the defect. If it is believed that the graft needs to be examined early, rather than tying the sutures, they can be temporarily secured. One way of doing this is by passing the long ends of the thread through a shortened, disposable syringe cylinder and holding them in place in proper tension by then placing the piston back into the syringe cylinder. This allows the threads to be loosened and the dressing removed, replaced, and secured again by the syringe.

FIGURE 44.11 **A,** Finger after scar release and full-thickness skin graft to volar surface. Note irregular contour of graft to avoid scar contracture. **B,** Cotton bolster tied over graft.

A piece of soft foam also can be used as a skin graft dressing. A piece of nonadherent gauze is placed over the graft, a piece of foam is cut large enough to cover the gauze, and the foam is simply stapled down to the skin defect edges. This holds the graft and dressing in place without other sutures or dressings, provides compression and protection from shearing, and is quick and cost effective.

With full-thickness grafts in the hand, we prefer to tailor the graft to fit the defect exactly and then suture the margins in place with running 4-0 chromic sutures. The subgraft area is irrigated with a mixture of thrombin solution and antibiotic solution that is forced out by manual pressure on the graft. A bolster of nonadherent gauze covered with wet cotton balls is placed over the graft and held in place with several polypropylene sutures placed in the surrounding skin and tied over the cotton.

Many surgeons now use vacuum sponge devices to bolster skin grafts.[22] This technique has the advantage of removing exudates from the wound and is very effective in terms of holding the graft down while it is becoming revascularized. This technique has limited application in skin grafts in the hand, with the exception of large wounds.

Postoperative Care

There are two schools of thought in caring for skin grafts. Some surgeons like to look at the grafts within 24 hours so that if a hematoma is present, it can be evacuated. The other group says that doing this might disturb a graft that is getting along well and that a hematoma could be stirred up at that time. In addition, it is almost never possible to put on as good a dressing as the one put on at the time of surgery.

If it is anticipated that hematoma or seroma collection might be a problem, the dressing should be removed at 24 hours and the wound inspected periodically. If fluid collects under the graft, it should be evacuated by stabbing the graft with a No. 11 knife blade and gently rolling the graft with a cotton-tipped applicator to remove the fluid. Care should be taken to roll and not rub, because rubbing can cause shearing of the graft from the bed.

If there is really no reason to suspect that either of these problems will arise, the wound can be monitored just as any other wound would be. As long as there is no drainage, foul smell, fever, or other cause for concern, the splint and dressing can be left undisturbed for 7 to 10 days. After that, the dressing can be removed; and if healing appears to be satisfactory, early guarded motion may begin.

It must be remembered that a skin graft is just like any other wound; that is, there is very little tensile strength present until enough collagen deposition has occurred to cause the wound to be strong. Therefore, even though the graft may be well vascularized at this stage, it will be very prone to injury from shearing forces for another 10 days. If blisters develop, motion should be stopped and the graft adequately protected for a few more days.

Small areas of graft loss of several millimeters in diameter will generally fill in satisfactorily without excessive scarring, especially if compression with a support garment is used. Larger areas of loss should be débrided and regrafted. After the "take" is judged to be satisfactory, the grafts should be kept lubricated with a moisturizing lotion or cream.

Because an open wound continues to contract even after it is covered by a skin graft, there is always the concern of scar contracture limiting motion. The elastic compression garment has been the standard of aftercare of grafts to minimize this effect.[115] The principle of this technique is to provide sufficient compression to exceed capillary pressure to the graft and thus inhibit fibroblasts. To facilitate even pressure, a silicone insert is generally placed over the graft or scar under an elastic glove for the hand. More recently, it has been found that the use of silicone alone will inhibit scar formation, and the effect of mechanical pressure may not be the causative factor.[110] One of the easiest to use is silicone sheeting. Sil-K silicone sheeting (Degania Silicone, Israel) is one of the most applicable types for grafted skin. It is a thin, pliable membrane that can be cut to size and simply taped over the scar. This product, as opposed to gel, stays relatively clean and can be washed and used over and over again. The patient should use this material as much as possible, at the least sleeping every night with it taped in place. If use of silicone sheeting is begun shortly after the skin graft has been judged to have taken well, significant reduction in scarring can be achieved.

Care of the Donor Site

Full-thickness sites require no special care and should be treated like any other wound. Split-thickness grafting, however, is a moderately morbid event, and the patient should be told before grafting that the donor site will probably cause a great deal more discomfort than the grafted area.

A donor site is just like a skinned knee. The sooner it dries out and forms a scab, the quicker it will become asymptomatic. This obviously is a factor of depth inasmuch as a thinner graft will heal much more rapidly than a thick graft. If a thin scab forms on the surface of the donor site, it will generally separate in about 14 days.

There are many of ways of treating donor sites that involve the application of every known kind of dressing or medication. The longer it takes for the wound to become dry and the thicker the resultant eschar, however, the more morbidity the patient will suffer. Whatever technique leads to rapid drying of the donor site will usually result in the best healing. The "old" technique of leaving the donor site totally open probably works the best but can be quite painful in the immediate postoperative period. Many surgeons use an occlusive adherent plastic dressing to cover the split-graft donor site, but this technique suffers from fluid collection under the plastic and an increased risk of infection at the donor site. This approach has the advantage of decreasing pain in the postoperative period, but the benefits are outweighed by the potential problems.

The donor site is covered immediately with a single layer of fine-mesh gauze, which is sprayed with thrombin solution. This is covered with a warm, moistened sponge, which is left until the operation is over. At this time the sponge is removed, with the fine-mesh gauze left in place. There will usually be no further bleeding at this point unless the fine-mesh gauze is removed. The local area is cleansed, and an appropriately sized occlusive plastic dressing placed. The plastic is removed at 2 to 3 days and the fine-mesh gauze left in place to dry onto the wound. This area is dried out by the nursing staff or patient with a bare-bulb light or hair dryer. This approach makes use of the benefit of decreased pain at the donor site from the occlusive dressing for the first couple of days but allows the donor site to dry out before infection can become established. Once the donor site is dry, there is usually very little further pain. The scab formed with the fine-mesh gauze will usually separate in 2 to 3 weeks.

Outpatient Surgery

Traditionally, skin grafts have been done as inpatient procedures, with the patient kept at bed rest to protect the graft from bleeding and shear effect. In this new era of managed care, this will no longer be possible, so ways to perform quicker and less expensive surgery, preferably under local anesthesia, will be desirable.

One approach is to use lateral femoral cutaneous nerve block for anesthesia of the donor site. This nerve passes under the inguinal ligament and provides sensibility to most of the lateral side of the thigh, the perfect donor site. Enough skin can easily be obtained with this block to surface the entire dorsum of the hand. There is some variability in the course of the nerve, but with practice it can almost always be blocked. The usual landmark is two fingertips inferior and two fingertips medial to the anterior superior iliac spine in the average adult. About 10 mL or so of anesthetic should be injected in a fanlike fashion while making sure to place half of it deep to the underlying fascia lata. No infiltration of the skin of the thigh is necessary, which makes harvesting of a large graft much less morbid. Also, if a longer-lasting anesthetic agent is used, the patient has no trouble getting up and walking out.

Although the Unna boot dressing was developed to heal leg ulcers by compression and the drying action of the paste, those same properties make it an ideal support for skin grafts. The Medicopaste bandage (Graham Field, Inc., Hauppauge, NY) can be rolled right over a skin graft to keep it compressed in a bacteriostatic environment. The dressing can be left on for a long time to maintain compression and is, of course, ideal for a graft on an edematous leg because it allows early mobilization. Sanford and Gore, however, have reported the use of this dressing to facilitate outpatient skin grafting of hands.[94] Sixteen burned hands were treated by outpatient débridement, skin grafting, and Unna boot dressing. When the patients returned on the fifth postoperative day, there was 95% "take" of all grafts, with no infections. This allowed the shifting of fairly extensive débridement and skin grafting to the outpatient setting.

Acknowledgment: This section was originally written by Dr. Graham Lister, and much of his contribution remains because of his ability to convey concepts in a clear manner. We also thank Danny Smith, formerly of Louisville and now of Salt Lake City, and Grace von Drasek Ascher, medical illustrator of Louisville Hand Surgery, for their hours of work on the figures in this section of the chapter. LOCAL AND REGIONAL FLAP COVERAGE OF THE HAND

Because scarring limits the motion that is essential for function in many areas of the upper extremity, every effort must be made to achieve primary wound healing to avoid healing by secondary intention, which involves significant scar formation. Skin defects that are the result of injury or surgery should be closed directly or covered with imported skin. In certain situations, free skin grafts will suffice. In others, free grafts may not "take" or may, by their necessary adhesion to underlying tissue, be unsuitable. "Take" of a skin graft requires that the bed on which it is placed have a blood supply adequate to revascularize the free graft. This blood supply is not present when bare bone, cartilage, or tendon is exposed in the wound. "Take" requires firm adhesion of the graft. This is not acceptable when further surgery is planned beneath the new skin cover (e.g., when tendon grafts will be necessary after an avulsion injury of the dorsum of the hand). It is also not suitable where the firm adhesion of the graft prevents mobility of the skin envelope over underlying structures (e.g., where a graft on a fingertip is adherent to bone). Shear forces applied in daily use will cause intermittent avascularity of the skin and eventual breakdown. A similar mechanism of breakdown may occur when grafts have been placed over the convex aspect of joints. Flexion renders the graft taut and avascular; this situation, along with normal trauma, results in ulceration. To a degree that is inversely proportional to its content of dermis, a free skin graft will contract during the first 6 months after its application; the extent of contraction depends on the location. Thus, on the dorsum of the hand, which is subjected to repeated stretching by normal use, less contracture occurs than on the flexion aspect of a joint. In the latter location, only full-thickness grafts with perfect "take" are suitable. In any circumstances in which free grafts do not provide the best skin, flap coverage is indicated.

Types of Flaps

A *flap* is skin with a varying amount of underlying tissue that is used to cover a defect and that receives its blood supply from a source other than the tissue on which it is laid. The part of the flap that provides the blood supply is termed the *pedicle.* A *graft* is a piece of tissue that does not have an intrinsic blood supply and must be revascularized by the underlying tissue bed. Table 44.2 lists the various flaps discussed in this chapter.

TABLE 44.2 Types of Flaps

Type of Flap	Random Flaps	Axial Flaps
Local	Transposition	Axial flag
		FDMA
		SDMA
	Rhomboid	Reversed dorsal metacarpal
		"V-Y" (Moberg) advancement
		Rectangular advancement
Regional		Cross-finger
		Neurovascular island
		Fillet
		Scapular
		Forearm
		Reversed posterior interosseous artery
		Latissimus
Distant		Groin

FDMA, First dorsal metacarpal artery; *SDMA,* second dorsal metacarpal artery.

Random-Pattern Flaps

The manner in which the skin receives its blood supply has been studied by many anatomists. Lamberty and Cormack[55] described angiotomes in the upper limb, these being areas of skin with a known single arterial supply. The constancy of these arteries has been confirmed by Doppler studies in patients and volunteers. Taylor et al[105] studied the venosomes and reported that venous territories correspond closely to recognized areas of arterial supply. The blood supply of a flap may come not from a single arteriovenous pedicle but from the many minute vessels of the subdermal or subcutaneous plexus. Such a flap is termed a *random-pattern flap.* Although the shape of a random-pattern flap need not be quadrilateral, it is usually conceived as such, and it is raised by incising three of the four sides. The fourth constitutes the pedicle, or base, of the flap. The side opposite the base is called the free margin. Because the adequacy of the subdermal plexus varies from location to location, the area of skin that can be supported by the vessels of the pedicle also varies. As a general rule, a random-pattern flap with a length not exceeding the width of the pedicle—in other words, a rhomboid—is considered to be reliable with respect to blood supply. This is the one-to-one (1:1) rule. It does not always apply, however. For example, it is too cautious for the face (and usually the hand) and too bold for the foot. Observation of this rule and the need to protect the pedicle from undue distortion that would impair blood flow through the subdermal plexus clearly limit the range of applications for the random-pattern flap.

The relatively inadequate blood supply of a random-pattern flap may be enhanced by a "delay" procedure[71] and will often allow a flap larger than the 1:1 rule to be rotated. In a delay procedure, the margins of the flap are incised, but it is not lifted off the underlying tissue and the incisions are sutured. This causes enhancement of the vascularity via the pedicle by interrupting that blood supply to the skin of the flap through the incised margins. The optimal time of delay has been shown to be around 10 days. During that time, both arteries and veins that were random become enlarged and oriented parallel to the axis of the pedicle. They are therefore better able to support the flap when it is transferred.

Axial-Pattern Flaps

When a flap receives its blood supply from a single, constant vessel, it is termed an *axial-pattern flap.* Such a single vessel is materially larger than the vessels of the subdermal plexus. For example, the superficial circumflex iliac artery that supplies the groin flap (see following description) has an average diameter of 2 mm, or five times that of the largest subdermal vessel. Although Poiseuille's law of flow in rigid tubes cannot be applied precisely to blood vessels, it indicates that flow would be approximately 625 times greater through the axial vessel of the groin flap than through a subdermal vessel. The area of skin supplied by such an axial vessel is termed a *vascular territory.*

The area where the vascular territories of two axial pedicles meet is termed a *watershed,* and the small arteries that cross it, *choke vessels*. In these areas, veins have no valves and can be said to allow blood to oscillate between territories. Occlusion of one of the two pedicles results in a shift of the watershed toward the site of occlusion, extending the vascular territory of the other, open pedicle. In raising an axial-pattern flap, it is safe to increase the length of the flap beyond the known vascular territory by the amount that would constitute a random-pattern flap. That is, a safe axial-pattern flap equals the normal vascular territory of the flap with a 1 : 1 extension on the distal portion of the flap.

The vessel of an axial-pattern flap may be purely cutaneous (Figure 44.12, *A*), supplying skin alone and proceeding directly to it. The superficial circumflex iliac artery to the groin flap is such a vessel. In reaching its cutaneous territory, the axial vessel may first supply fascia. In such circumstances, the vessel commonly reaches the fascia by running in an intermuscular septum. Because this is attached to bone, a segment of bone may be taken with skin and be vascularized by the same pedicle. Axial flaps whose vessels first pass through fascia are termed *fasciocutaneous vessels* (see Figure 44.12, *B*). As with the musculocutaneous flap, fascia may be transferred without skin, but not skin without fascia. Such a flap is the lateral arm flap supplied by the posterior radial collateral artery. The axial vessel may first supply muscle (see Figure 44.12, *C*). The secondary vessels to the overlying skin are multiple, so the muscle must be taken with the skin to ensure survival of the skin, but the muscle may be transferred without skin. Such flaps have been called *musculocutaneous, myocutaneous,* and *myodermal flaps.* An example of this type of flap is the latissimus dorsi flap, supplied by the thoracodorsal artery.

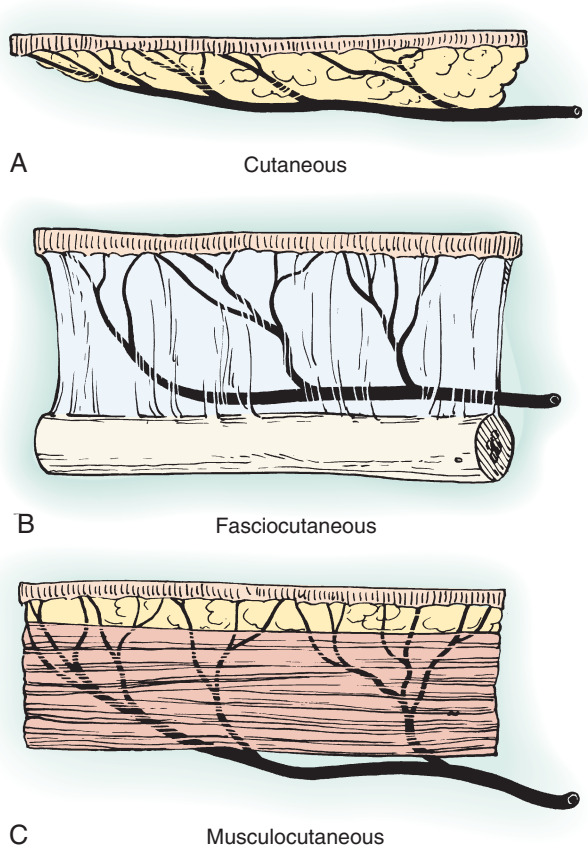

FIGURE 44.12 Axial-pattern flaps are either cutaneous **(A),** fasciocutaneous **(B),** or musculocutaneous **(C),** depending on the source of the major portion of their blood supply. Fasciocutaneous vessels commonly run in intermuscular septa and therefore supply the periosteum of underlying bone. The flap can be taken with a segment of that bone where necessary. (From the Christine Kleinert Institute for Hand and Microsurgery, Inc., with permission.)

Axial-pattern flaps clearly have several advantages over random-pattern flaps. The 1 : 1 ratio can be disregarded in flaps with an axial vessel. Axial-pattern flaps have a blood supply superior to that of random flaps. It has been shown experimentally that axial-pattern flaps resist infection better than do random ones. Because axial flaps can be made longer, they can cover a larger primary defect. In addition, the flap tissue adjacent to the pedicle need not be applied to the defect, permitting much more freedom of movement of the part to which the flap is attached. This bridge segment between the primary and secondary defects may be sutured free edge to free edge, creating a tube that closes off all exposed subcutaneous tissue, or a so-called *tubed pedicle flap*. A further advantage of the axial-pattern flap is that the pedicle can be made much narrower, even to the point of reducing it to the (neuro)arteriovenous bundle itself, in which event it is called an *island pedicle flap*. This permits much more movement of the flap than is possible with a wide skin pedicle. Finally, with the advent of reliable microvascular technology, the pedicle can be divided and anastomosed to vessels adjacent to the primary defect, the so-called *free flap*.

The disadvantage of an axial-pattern flap is that its vascular pedicle must always be preserved at the time of elevation of the flap; at that first stage, it cannot be thinned to the same degree as a random-pattern flap that depends on the subdermal vessels. The vascular advantages of the axial flap are lost if the pedicle is divided in the process of thinning the flap. Indeed, in those instances in which skin from the bridge segment is to be used on an area adjacent to the primary defect, it is prudent to divide the artery in the pedicle 1 week before complete detachment. This constitutes a delay of sorts, as it promotes increased blood flow across the inset wound into the primary defect.

Staging of Flaps

Flaps that come from skin adjacent to the primary defect are called *local flaps* and require only one operative procedure for their completion. Flaps that come from elsewhere on the limb and commonly require two stages are called *regional flaps*. Those from other parts of the body are called *distant flaps*. With the exception of free flaps, all distant flaps require at least two stages for completion. In the first, the flap is raised and applied, attached, or inset. In the second, the pedicle is divided and the free margins inset. In certain instances in which the blood supply is doubtful after division of the pedicle, the final inset may be left until a third stage. This may be necessary if the most distant portion of the divided pedicle has questionable vascularity (as in a pedicled groin flap transfer).

Preparation of the Wound for Flap Transfer

The wound to which a flap is to be applied is called the *primary defect*, or *recipient site*. This may be simply the wound created by trauma or a wound created by excision of a lesion. However, the skin margins are rarely perfect in a traumatic injury, and

generally the wound margins should be excised back to healthy skin prior to flap transfer. Similarly, it is important to recreate the original defect in secondary reconstruction and all scarred skin should be excised so that the flap will be sutured to healthy margins. A pattern of this final primary defect may be taken for future use. This is easily done by marking the margins with ink and taking an imprint of this with a pliable, nonporous material (e.g., a piece of Esmarch bandage), the surface of which has been moistened with alcohol. The wound from which the flap is taken is termed the *secondary defect.* The secondary defect may be closed directly, as in a groin flap, or may require application of a skin graft, as in a cross-finger flap. The region from which a skin graft is taken is called the *donor site.*

Raising a Flap

Between the vascular strata defined earlier—subdermis, subcutaneous tissue, fascia, and muscle—lie relatively avascular planes, the optimal planes of dissection. It is evident that, in order to attain these planes, it is necessary to cut through the vessels of the more superficial strata. Thus, in raising a fascial flap, one must first incise the subdermal and subcutaneous plexus and then the fascia. Only when the surgeon has cut through the peripheral ramifications of the vessels from which the flap obtains its blood supply is he or she in the correct plane. To be one plane too superficial results in division of the vessel, or branches of the vessel, supplying the flap. To be one plane too deep results in a time-consuming, often bloody, and entirely unnecessary struggle.

Applied tension plays a major role in flap dissection. Once the marginal incision has been carried down to the correct plane for dissection, skin hooks or stay sutures are applied to the corners of the flap. Firm upward traction away from the bed displays the plane for dissection. Often this contains only loose areolar tissue that can be stroked away with a knife. Care must be taken not to create a "cave" beneath the flap, that is, a central recess between two marginal pillars of unincised skin, muscle, or fascia. No tension can be applied to the tissues in such a cave, and dissection therein may result in damage to the pedicle. Rather, the marginal pillars are incised progressively in such a way as to avoid caves and permit tension to be applied evenly, thereby protecting the pedicle. Tension on a flap lifts the pedicle off the floor of the secondary defect, on which the knife is dissecting, into the roof formed by the inclined vascular stratum. If dissection proceeds far enough, a point will be reached where the pedicle emerges through the floor to gain the roof. At that point, the surgeon decides whether to proceed. To do so requires dissection of the pedicle. All progress thus far is best made with a scalpel. A scalpel is the instrument of choice both to incise the vascular strata and to dissect the planes, provided that appropriate tension can be applied to the tissues. Cutting with a knife is a result of two opposing forces: the pressure applied to the knife, and the resistance offered by the tissues. The traction applied to a flap produces, and varies, that resistance. It therefore plays a primary role in determining which tissue is cut and which is not. This is why the blade must always be equally sharp, and why the assistant who holds the flap must do so at the same tension first applied by the surgeon. If the assistant cannot do so, the surgeon must apply the necessary tension by grasping and lifting surrounding tissues with dissecting forceps as he or she proceeds.

Scissors provide both the pressure and the resistance required to cut tissue. They are required when the surgeon cannot efficiently control the relationship between tissue tension and knife pressure. When scissors are introduced closed into the tissues and then opened under gentle pressure to clear planes, they can be both precise and innocuous. They create and enter caves, defining structures to be preserved and those to be divided. When scissors are introduced open and then closed to cut, they are less precise than a knife and can do harm in the hands of even the most experienced surgeon. It is therefore important when using scissors that the surgeon sees both surfaces of the tissue to be divided so that he or she is confident what tissues are included between the jaws of the scissors. This often requires that closed-to-open scissor dissection proceed until the instrument can be seen through the tissue to be cut. Such scissor dissection is required as a vascular pedicle is mobilized. Although it has been shown that metal clips are not always secure and that bipolar coagulation may harm the pedicle, both are routinely used in dissecting the pedicle. The clips must be applied with sufficient force to ensure that they will not slip, and the vessel to be clipped should be placed in the middle of the clip, rather than the base (where the clip bends to come together). When dividing small vessels between surgical clips, it is likewise helpful to leave a small amount of tissue surrounding the vessels. This approach gives adequate tissue purchase for the clips so that they do not fall off. The setting on the control box of the coagulator must be of adequate temperature to allow coagulation and sealing of the vessel. The pedicle (i.e., the main vessel) is insulated by holding the branch with a smooth forceps between the pedicle and the point of coagulation.

Local Flaps

Because they have identical or similar qualities to the skin lost, local flaps are the most desirable means of providing cover for a defect. They are, however, severely limited in their availability. This is because there is relatively little skin on the hand and because much of it must remain inviolate to preserve function. The skin of the webs, for example, should never be used for flaps, nor should areas of daily contact. Some skin, such as that of the palm, will not move to the extent necessary for most local flap design. The surgeon must carefully weigh these considerations in selecting a flap. "Lines of maximum extensibility" around which the flap should be planned are selected by pinching the skin. These are the lines along which skin is most available and therefore pinches up more easily. This should be done with the hand in various positions to ensure that function will not be impaired. For example, the skin of the dorsum appears superfluous in extension, but not in flexion.

There are three types of local flaps: transposition, rotation, and advancement. In the advancement flap, the pedicle is that side of the flap opposite the primary defect. In transposition and rotation designs, the flap moves laterally relative to the pedicle to cover the defect. These two differ in that the transposition flap leaves a secondary defect that is closed either directly or by application of new skin cover, whereas the rotation flap leaves no secondary defect, the flap skin being stretched to close the primary defect. This is achieved by differential suturing, in which a slightly smaller amount of the flap edge than of the edge of the bed is included between each two adjacent sutures, thereby advancing the flap. Transposition and

advancement flaps may be random or axial pattern in design. The vascular basis of the axial pattern may be simply a subcutaneous pedicle rich in small vessels or, more reliably, a single known vessel. The advantage of the axial pattern, apart from its potentially larger area and greater reliability owing to superior circulation, is the fact that its pedicle can be reduced to the vessels alone, giving greater mobility. In the advancement flap, the gain is measured in millimeters. In the axial-pattern transposition flap, the gain is limited by the length of pedicle that can be developed. The longer the pedicle, the more the flap becomes a vascular island flap rather than a simple transposition. The distinction between a long axial transposition flap and a vascular island is arbitrary. For the purposes of this chapter, a flap is classified as a vascular island flap when the pedicle is the proper digital artery or larger.

Transposition Flaps

Random-Pattern Flaps

"Z"-Plasty. The "Z"-plasty is one of the simplest forms of random flaps commonly used in hand surgery and is considered a "transposition" flap. The sides of a standard "Z"-plasty should always be of equal length, but the angles vary according to the needs of the situation and the local skin topography. The angles of the design may also differ. As the angles increase, so does the lengthening that occurs along the line of the central limb of the design when the flaps are transposed. The commonly used 60-degree "Z"-plasty theoretically results in 75% lengthening along the line of the central limb (Figure 44.13). The skin that is introduced into the line of the central limb is derived from the transverse axis of that line. Said another way, skin must be available lateral to the central limb before a "Z"-plasty can be used. If sufficient skin is not present for one large "Z"-plasty, multiple "Z"-plasties can be used in series, for the longitudinal gain is aggregate, whereas the transverse loss is not. The following are important points in technique:

1. The angles and limbs should be measured with a ruler and a protractor. When this is not done, mistakes are made, the most common being to cut the angles at 45 degrees when believing them to be 60 degrees.
2. The incisions of the "Z"-plasty should be cut and tested in sequence (Figure 44.14).

First, the central limb and one side limb are incised. The flap created is raised and carried across the central limb with a skin hook. If the side limb cut on the flap can be brought by at least half its length across the central limb, there is sufficient tissue transversely, and the design has been well chosen. If it goes further, a larger "Z"-plasty will work if more lengthening is required. Such a larger design can be made simply by lengthening both initial cuts and testing again. If this first flap can be carried less than halfway across the central limb, the design is too ambitious and must be modified. Because only two limbs have been cut, this modification can be done relatively easily by shortening both the proposed central limb and the as yet uncut second side limb. The excessively long first side limb is simply shortened with one or two stitches.

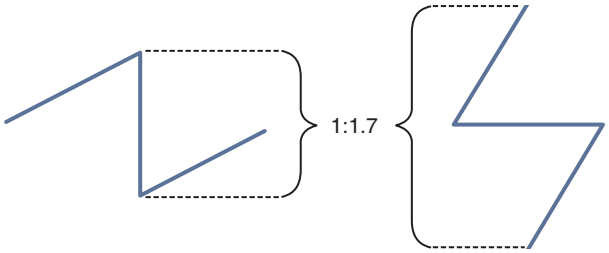

FIGURE 44.13 Standard 60-degree "Z"-plasty. Here all limbs of the "Z"-plasty are of equal length, and the angles between the limbs are 60 degrees. When the flaps are transposed, the lengthening that is achieved along the line of the central limb is 70 to 75% of its original length.

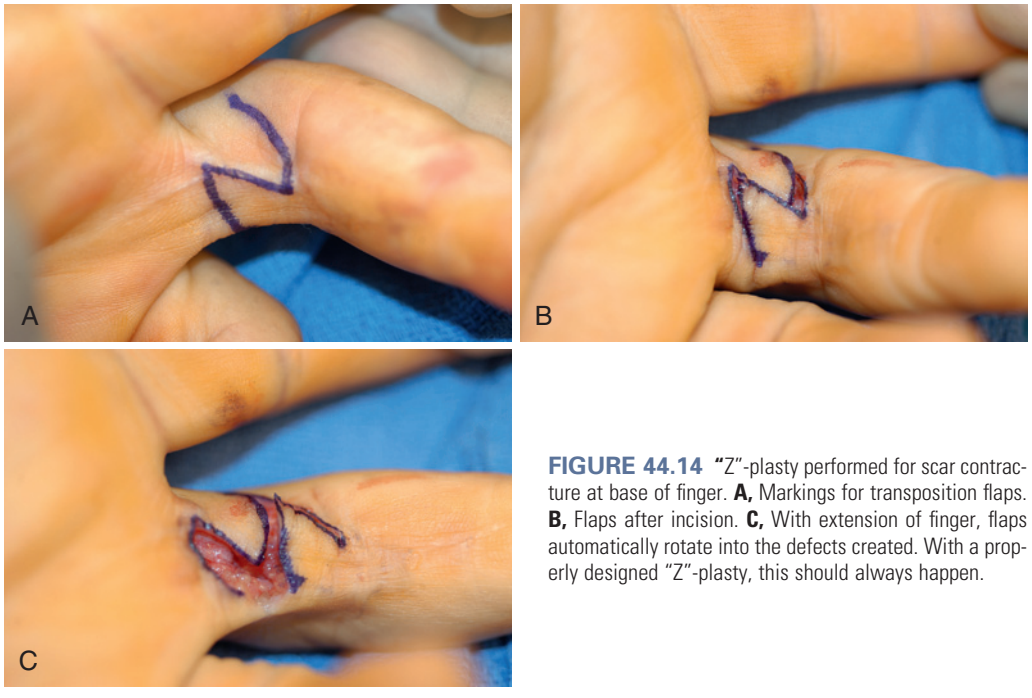

FIGURE 44.14 "Z"-plasty performed for scar contracture at base of finger. **A,** Markings for transposition flaps. **B,** Flaps after incision. **C,** With extension of finger, flaps automatically rotate into the defects created. With a properly designed "Z"-plasty, this should always happen.

CRITICAL POINTS *"Z"-Plasty*

Indications
- Scar contracture, especially on volar surface of fingers
- Minimal web space contracture

Preoperative Evaluation
- Must examine surrounding skin for elasticity and scars
- Generally should not "Z"-plasty grafted skin

Pearls
- Central limb of "Z" goes along line of scar
- Lateral limbs should be designed in areas with loose skin
- Limbs should be 60 degrees to central limb; the tendency is to make them 45 degrees
- Avoid sewing the flaps back where they came from

Technical Points
- Central tight scar should be excised
- Tips of small flaps should not be grasped with forceps
- Base of flap should be thicker than tip when elevating
- Cut only enough skin so that flap will transpose without tension
- Avoid placing sutures in midportion of flap
- Tip suture (half-buried horizontal mattress suture) for tip of flaps
- Only enough sutures to hold flaps in place

Pitfalls
- Poor design
- Flaps with scar at base
- Undermining base of flap so that it is thinner than tip
- Suturing flaps under too much tension

Postoperative Care
- If flaps fit easily, immobilization may not be necessary
- Massage and stretching when healed

Four-Flap "Z"-Plasty. To gain greater lengthening along the central limb, the angles of the "Z"-plasty may be increased. When 120-degree "Z"-plasty flaps are transposed, the resultant central limb lengthening is theoretically 164%. However, flaps with angles much over 60 degrees are difficult to transpose; the pivot points cannot be brought to meet the promontories. This difficulty can be overcome by dividing each flap into two (Figure 44.15). Such four-flap "Z"-plasties are applicable only in very acute contractures, often in the first web. The angle at which the dorsal skin meets the palmar at the web, the ridge angle, must not exceed 30 degrees, or the flaps will not move sufficiently.

Rhomboid Flap. This is a transposition flap designed in the form of a rhomboid, which allows primary closure of the donor site as seen in Figure 44.16. It was described by Limberg in 1963[59] and is a random-pattern flap that is based on assuming that the defect can be imagined in the shape of a rhomboid. It is a parallelogram with two 120-degree angles and two 60-degree angles. All sides of the flap are of equal length, and the flap is designed so that the donor site can be closed primarily. There are theoretically four flaps that can be designed for each defect, and the donor area should be chosen based on skin laxity and resting skin tension lines to allow for closure (Figure 44.17). As with all flaps, knowledge of vascular anatomy can improve viability by basing the flap over a known perforator.

Axial-Pattern Flaps. Vessels that serve to enhance the vascularity of transposition flaps have been isolated at the level of the distal and proximal phalanges. Dorsal digital branches of the digital artery and nerve at the level of the distal phalanx were first described by Holevich.[38] They form the pedicle for dorsolateral flaps transposed to cover digital pulp defects. Pho[85] demonstrated similar vessels arising from the radial digital artery of the thumb and used flaps based on those vessels and the radial

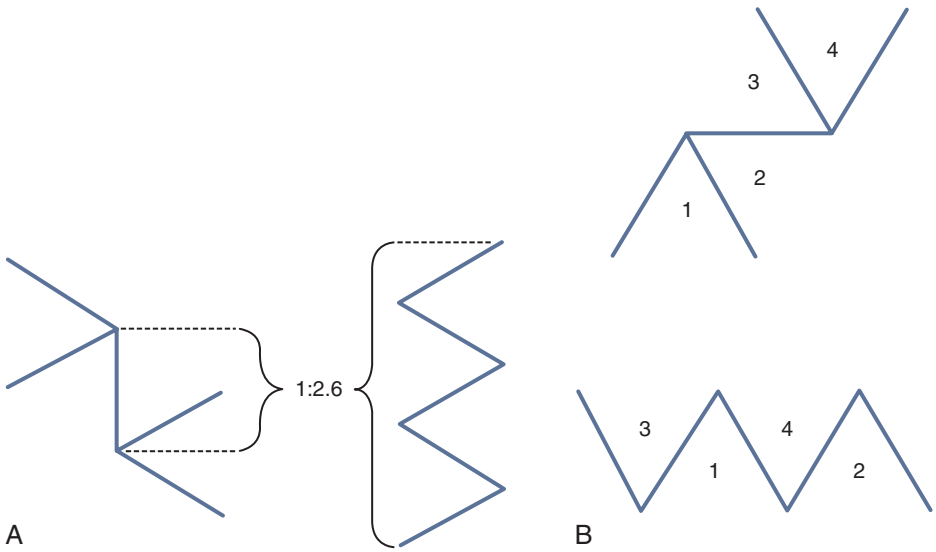

FIGURE 44.15 Four-flap "Z"-plasty. **A,** In the four-flap "Z"-plasty, all measurements are equal, that is, each limb of the design is of equal length but so also are the distances between any two adjacent points in the design. When the flaps are transposed, the two 120-degree angles are closed. As a result, the distance between the points at either end of the initial central limb is some 264% of its original length. **B,** The transposition that is achieved is shown by numbering the flaps. It will be seen that the two 120-degree angles are closed, putting two in the right-hand incision and three in the left-hand incision and interdigitating flaps 1 and 4.

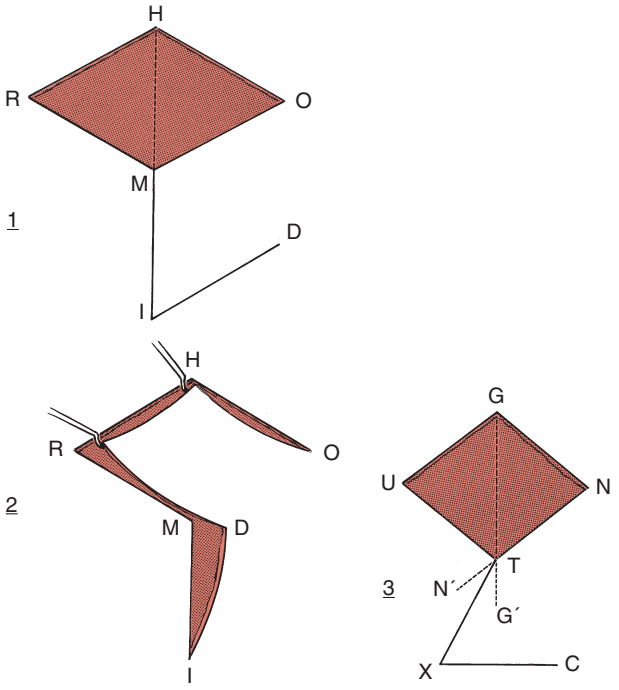

FIGURE 44.16 Rhomboid flap design. *1*, In the Limberg design, all dimensions of the rhomboid that form the primary defect *HOMR* are equal, including the transverse diagonal *HM*. This has been extended by the same length to *I* and the line *ID* drawn parallel to *MO*. *2*, The flap is transposed by moving the pivot point *D* to the promontory *M*. If this can be achieved, the flap will fit. *3*, In the Dufourmentel flap, the transverse diagonal can be of any length. The transverse diagonal *GT* and one of the adjacent sides *NT* are extended to *G′* and *N′*, respectively. The angle that they form is bisected by a line of equal length to one of the sides of the primary defect *TX*. *XC* is then drawn parallel to the longitudinal diameter diagonal *UN*. Transposition is performed by approximating the pivot point *C* to the promontory *T*. (Modified from Lister GD: The theory of the transposition flap and its practical application in the hand. *Clin Plast Surg* 8:115–128, 1981.)

digital nerve and artery to resurface the pulp of the thumb. He states that skin can be taken from the metacarpophalangeal (MP) joint out to within millimeters of the nail fold but advises that a skin bridge be retained until tourniquet release demonstrates satisfactory flow.

These dorsal digital branches allow for advancement of the dorsal finger skin for coverage of defects distal to the proximal interphalangeal (PIP) joints. A flap can be raised by making an incision along the side of the finger (roughly along the midline) back to the MP joint area, at which point the base of the flap is incised as a "V" to allow advancement and closure as a "Y." The skin on one side of the finger is left intact, and the skin is elevated off the dorsal finger at the level of the epitenon. This dorsal skin flap is fed by many dorsal perforators from the digital artery on the side opposite the skin incision. The flap will advance more if the dorsal fibers of the Cleland ligament are released on the side on which the flap is based. This flap has great utility in coverage of small defects over the dorsum of the middle phalanx and distal interphalangeal (DIP) joint and is very reliable. If the base cannot be closed as a "Y," a small skin graft can be placed over the tendon here.

In 1973, both Vilain and Dupuis[114] and Iselin[43] described a "flag" flap raised on the dorsum of the middle phalanx; it was named because the pedicle, narrowed by a generous back-cut, was further mobilized by parallel incisions resembling the pole of a flag. No arterial pedicle was described for this flap; however, it is undoubtedly based on the dorsal branches of the palmar digital arteries.

The skin of the dorsum of the proximal phalanx, especially of the index and middle fingers, has been shown to receive axial flow from the branches of the first and second dorsal metacarpal arteries, vessels that are present in 90% and 97% of hands, respectively. Both of these vessels arise from the radial artery or

its communications with the dorsal carpal arch, the posterior interosseous artery, the deep palmar arch, and the ulnar digital artery of the thumb. Stated more simply, both vessels arise from arteries around the base of the second metacarpal. They pursue courses either immediately above or immediately below the fascia of the interosseous muscles. At the web space, the second dorsal metacarpal artery has a constant anastomosis with the palmar metacarpal artery, which is doubly significant in flap design. This communicating vessel must be divided if a longer arc of rotation is to be achieved on a proximally based flap, and it also serves as the axial vessel of reversed dorsal metacarpal flaps.[86] According to the dissections of Johnson and Cohen,[46] the branches of these vessels supply the dorsal skin no further than the PIP joint. The venous drainage of these flaps is excellent, being through either end of the proximal venous arcade, which is of very large caliber. These dorsal vessels form the axial basis of four distinct flaps, the axial flag flap, the first dorsal metacarpal artery (FDMA) flap (or kite flap), the second dorsal metacarpal artery (SDMA) flap, and the reversed dorsal metacarpal flap. Those proximally based on the first dorsal metacarpal artery can readily transfer sensibility by incorporating the branches of the radial nerve to the dorsal skin.

Axial Flag Flap. This simple flap requires no pedicle dissection, for it is based on the web space of the donor finger. The dorsal metacarpal artery has been shown to be reliably present in the second interspace, and less so in the others, but flag flaps can be safely raised from any of the webs (Figure 44.18). Because the pedicle need only be as wide as the vessels, the mobility in this flap is its single major advantage. From the dorsum of the middle finger, for example, it can be rotated to cover the dorsum of either the proximal phalanx of the index finger or the MP joint of either the index or middle finger (Figure 44.19, *A*). It can also, by being passed through the web space, cover the palmar surface of either proximal phalanx of either MP joint (see Figure 44.19, *B*). Before commencing elevation of the flap, the presence of the vessel can be confirmed by Doppler examination. As with the cross-finger flap, the entire skin of the dorsum of the selected proximal phalanx is raised, from midlateral line to midlateral line, and from the proximal extension crease of the PIP joint distally to the level of the free margin of the web proximally. As with all random flaps, the plane of dissection is beneath the subcutaneous vascular stratum, leaving the loose paratenon on the extensor hood. The donor site will usually require a skin graft.

Kite Flap (First Dorsal Metacarpal Artery Flap). This is an island pedicle flap proximally based on the first dorsal metacarpal artery and veins.[28] The skin flap is generally designed on the radial side of the distal portion of the second metacarpal and/or MP joint. With its pedicle fully dissected, it can reach

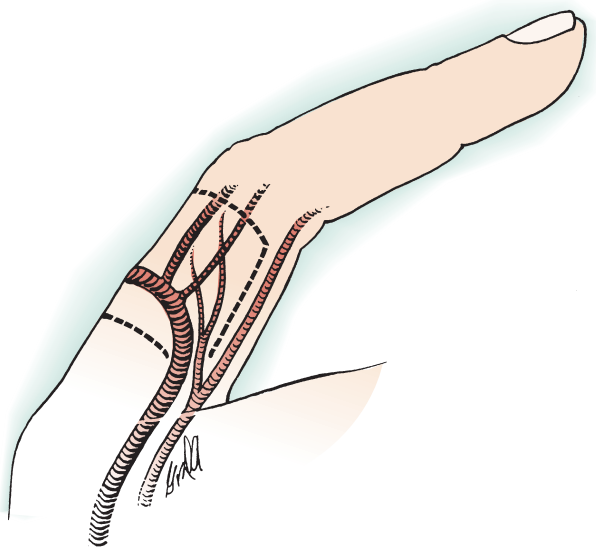

FIGURE 44.18 Axial flag flap. The axial flag flap receives its blood supply from a dorsal digital artery that originates either from the proper digital artery to that finger or from an extension of the dorsal metacarpal artery. Drainage is through the proximal venous arcade to the web space veins. (Modified from Lister GD: The theory of the transposition flap and its practical application in the hand. *Clin Plast Surg* 8:115–128, 1981.)

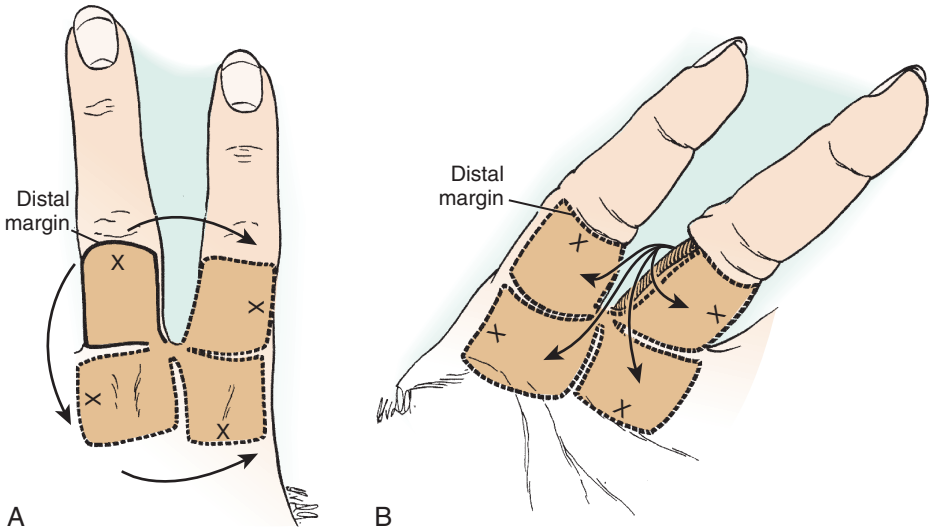

FIGURE 44.19 **A,** An axial flap flap raised on the dorsum of the middle finger can be rotated to cover defects on the proximal phalanx of the index finger or over the metacarpophalangeal (MP) joint of either of those two digits. **B,** By carrying the flap through the web space, it can reach defects on the palmar surface of the MP joint of either the index or middle finger. (Modified from Lister GD: The theory of the transposition flap and its practical application in the hand. *Clin Plast Surg* 8:115–128, 1981.)

the dorsum of the thumb to about the interphalangeal joint. The course of the vessel should be marked with a Doppler ultrasound prior to elevation, but it runs over the first dorsal interosseous muscle from the radial artery as it courses distal to the snuffbox. The flap is elevated from distal to proximal. The skin incision is just deep enough to elevate the skin flaps just above the soft tissues, and a wide swath of tissue is taken along the course of the artery to prevent damage to the draining veins. No effort is made to isolate the vessels in this flap, or they may well be damaged. If a sensory flap is desired, the branch(es) of the superficial radial nerve to this area of skin may be taken with the pedicle. The fascia is carefully lifted off the first dorsal interosseous muscle to near its base to allow rotation of the flap on its pedicle. Once an adequate pedicle has been lifted, the flap can be taken under a skin bridge of the proximal thumb to reach the defect. The donor site requires closure with a skin graft (Figure 44.20).

This flap may be also raised distally based on the perforator near the radial base of the second metacarpal. The arc of rotation of this flap will allow coverage of the index finger to near the DIP joint. The donor site may be closed primarily (in smaller flaps) or with a skin graft.

Second Dorsal Metacarpal Artery Flap. This flap is based on the second dorsal metacarpal artery and venous system in the second interspace. It may be proximally based for coverage of an adjacent dorsal finger or distally based. If it is raised on its proximal pedicle, the rotation point is based near the base of the second metacarpal. The skin off the dorsum of the middle finger proximal phalanx can be raised based on these vessels and transferred to the dorsum of the index MP joint for coverage. The presence of the vessel is confirmed prior to elevation with a Doppler. The dissection proceeds from distal and lateral. The tissue of the second intermetacarpal space is carefully dissected off the interosseous muscle to include the fascia. The dissection is continued proximally, and great care must be taken to prevent damage to the pedicle. The donor site can be closed with a full-thickness skin graft.

The reverse[86] dorsal metacarpal flap is raised in similar fashion but from the dorsal skin of the hand, using the communication between dorsal and palmar metacarpal arteries as the axial vessel. The proximal limit of this flap is the confluence between the extensor indicis proprius and extensor digitorum communis to the middle finger. This flap is raised from proximal to distal and is based over the second intermetacarpal space. Its arc of rotation is generally limited to about the level of the PIP joint based on the pedicle in the second web space. Some have suggested that this flap can be safely transposed more distally; however, the distal end of this flap in this situation tends to be unreliable in our experience. The donor site can sometimes be closed primarily, or it may require a skin graft (Figure 44.21, *A* to *C*).

Digital Artery Island Flaps. The digital artery island flap is based on the radial or ulnar digital artery of the finger. It is a distally based flap and has been used for repair of fingertip injuries.[29] Flow depends on the integrity of the palmar digital arch that lies beneath the palmar plate, and drainage depends on retrograde flow in the fine veins around the artery. It has the advantage of confining the reconstruction to the injured finger: This flap is most useful in the middle or ring fingers, as the digital vessels are codominant in these fingers, and loss of one is unlikely to cause problems with later flow. The index and little fingers, in contrast, may have very small vessels on their radial

and ulnar sides, respectively, which theoretically could lead to problems with cold intolerance after flap harvest.

When used for fingertip coverage, a pattern is made of the defect first and is used to draw an outline of the proposed flap near the base of the involved digit, centered over the digital vascular pedicle. The majority of the flap is taken from the lateral side of the finger, however, to avoid loss of the important palmar skin near the MP joint crease. The anterior border of the flap is incised down to the level of the tendon sheath. The distal portion of the incision is made along the midaxial line. The digital bundle is identified, and the digital vascular pedicle is dissected free from the digital nerve. The veins present the greatest challenge in dissection of this flap, as they are quite small and easily damaged. They may be entwined around the digital nerve and must be carefully removed, using bipolar cautery on a low setting to control branches. The vascular pedicle should not be skeletonized but is rather taken with a small amount of surrounding tissue, again to avoid damaging the veins. This dissection is carried to a level just proximal to the DIP flexion crease, at which level there is usually adequate pedicle to allow easy rotation of the flap to the fingertip defect. The skin incision is carried all the way out to the tip, and the pedicle is carefully placed in this incision. If fascial fibers cause kinking of the pedicle, they must be released, but again, damage to the venous structures in the pedicle must be avoided. The donor site is covered with a small split-thickness skin graft, usually taken from the medial upper arm (Figure 44.22, *A* to *C*).

This flap has several advantages over other pedicle flaps for fingertip coverage: damage is confined to a single finger, the finger may be mobilized sooner, and the cosmetic defect is minimal. We limit its use to the middle and ring fingers for the reasons outlined earlier, however. It provides an excellent option for coverage when one is presented with a significant loss of the palmar pulp of the distal finger.

Advancement Flaps

A simple advancement flap for use in thumb tip amputation was described by Moberg[73] (Figure 44.23), which in fact is a bipedicled flap (based on the two neurovascular bundles of the thumb). This is reserved for amputations through the distal phalanx, because flexion of the interphalangeal joint may be required to assist in closure of the defect. The two parallel incisions to create the flap are made just dorsal to the two neurovascular bundles of the thumb, which are carefully preserved throughout dissection. The flap is elevated from the flexor tendon sheath. Because the bundles are included in the flap, there is theoretically no limit to the length of the flap, but customarily the base is placed at the MP joint skin flexion crease. It is usually best to design the base of the flap with a "V"-shaped incision, which allows the flap to be advanced further and may be closed as a "V-Y" advancement flap (Figure 44.24). Alternatively, a full-thickness graft may be applied to the secondary defect overlying the neurovascular bundles and tendon sheath. This advancement is usually safe in the thumb, for the dorsum is well perfused by dorsal branches from the radial artery. If the base of the flap is too proximal, however, necrosis of a portion of the distal thumb skin can occur. The dorsal neurovascular branches of the digital vessels should be preserved on one or both sides of the flap, which will obviate any vascular problems of the distal dorsal skin. This will decrease the length that the flap can be advanced, however.

A similar procedure has been reported in the finger,[101] but greater care must be exercised here, or loss of the dorsal skin may result. Macht and Watson[63] reported 69 cases with no skin necrosis in either the palmar or dorsal region, two-point discrimination within 2 mm of normal, and a maximum flexion deficit of 5 degrees. However, they emphasized the importance of maintaining the dorsal branches of the proper digital arteries

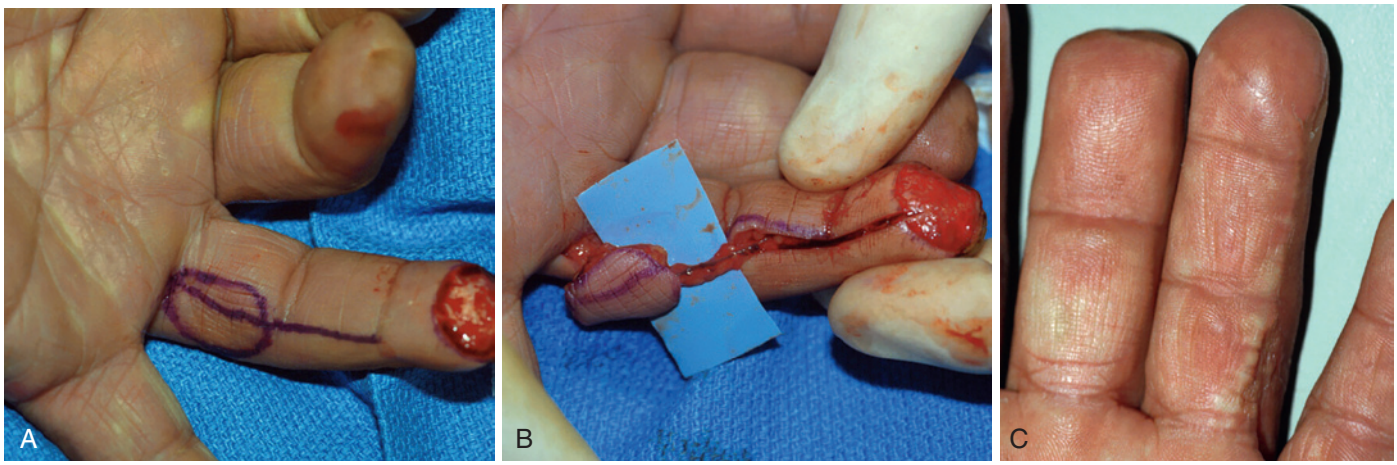

FIGURE 44.22 **A,** Patient with fingertip amputation and reverse digital artery island flap marked over proximal digital vessel. **B,** Flap dissected out on digital vascular bundle. **C,** Flap after healing; donor site was managed with split-thickness skin graft.

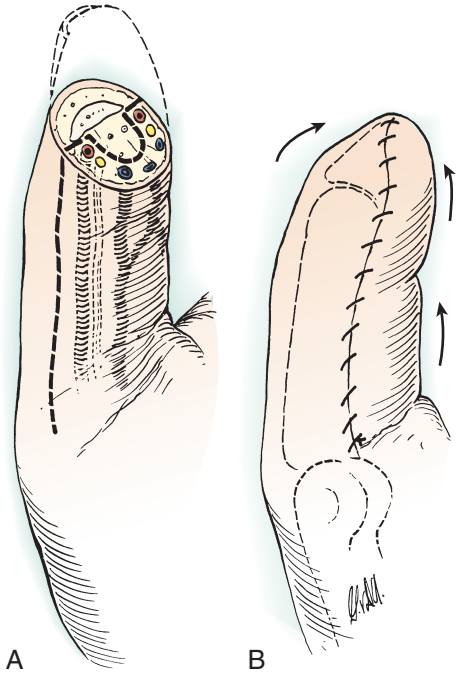

FIGURE 44.23 Moberg advancement flap. **A,** Most useful for amputations distal to the thumb interphalangeal joint, the Moberg advancement flap is composed of the entire palmar skin of the thumb, including the neurovascular bundles. **B,** Flexion of the interphalangeal joint assists in coverage of the defect by the advancement flap. (Modified from Lister GD: The theory of the transposition flap and its practical application in the hand. *Clin Plast Surg* 8:115–128, 1981.)

as noted above. Likewise, the risk of flexion contracture after a volar advancement in the finger is much higher than in the thumb and probably not worth the risk.

"V-Y" Advancement Flap. Commonly used to repair fingertip amputations, the "V-Y" advancement may be a single midline (Atasoy[1]) or double lateral (Kutler[54]) element. Which one is used, and whether the technique is appropriate at all, is determined by examining the primary defect. *It should be stated from the outset that the great majority of fingertip amputations are best managed by allowing secondary healing to occur.* Even if a small portion of the bone is exposed, it can be trimmed back, and wound contracture will close the wound. Allowing secondary healing and wound contraction pulls normal pulp skin into the defect, and is usually superior to a badly scarred tip resulting from ill-advised local flaps. If more tissue has been lost from the palmar than from the dorsal surface, a local palmar flap is unlikely to provide the necessary cover, and a cross-finger or thenar flap may be required. If the loss is equal, or greater on the dorsal aspect, a "V-Y" flap can be used, provided the skin from which it comes is not also damaged.

There are three facts to remember if a "V-Y" flap is to be raised successfully. First, more problems arise through inadequate mobilization than excessive mobilization; the flap should advance easily into position (Figure 44.26). Second, only nerves and vessels need be kept intact. Third, the nerves and vessels in the pulp are slender and elastic and will not resist appreciably the movement of the flap; a corollary of this rule is that any tissue that does offer firm resistance can be divided with impunity. The apex of the "V" in a single midline advancement[107] for most fingertip amputations worthy of reconstruction (i.e., at or distal to the midportion of the nail) should be at the distal digital crease. In the rare case in which length is deemed sufficiently important to justify a "V-Y" advancement in more proximal amputations, the apex can be placed more proximally. The base of the triangle, which lies on the free distal margin, should be as wide as the nail bed but no wider, or the tip will have a flattened appearance. The incisions are made through the skin with a knife, carrying it to bone at either end of the base, where there are periosteal attachments but no vessels. These periosteal attachments should be divided. The deep surface of the flap is freed completely from the underlying tendon sheath as far as its apex. The skin and subcutaneous tissue some 6 or 7 mm on either aspect of the apex are incised down to the sheath. With skin hooks on one lateral margin of the flap distracting the flap away from the digit, the lateral subcutaneous tissues that contain the pedicle of the flap are spread apart with microscissors. Using loupe magnification, any restraining bands are accurately defined and divided, remembering that nerves and vessels will not resist gentle traction.

(An anatomic point should be made here. The veins that accompany the artery of the digital neurovascular bundle are at different levels and of differing, smaller calibers. Therefore, in

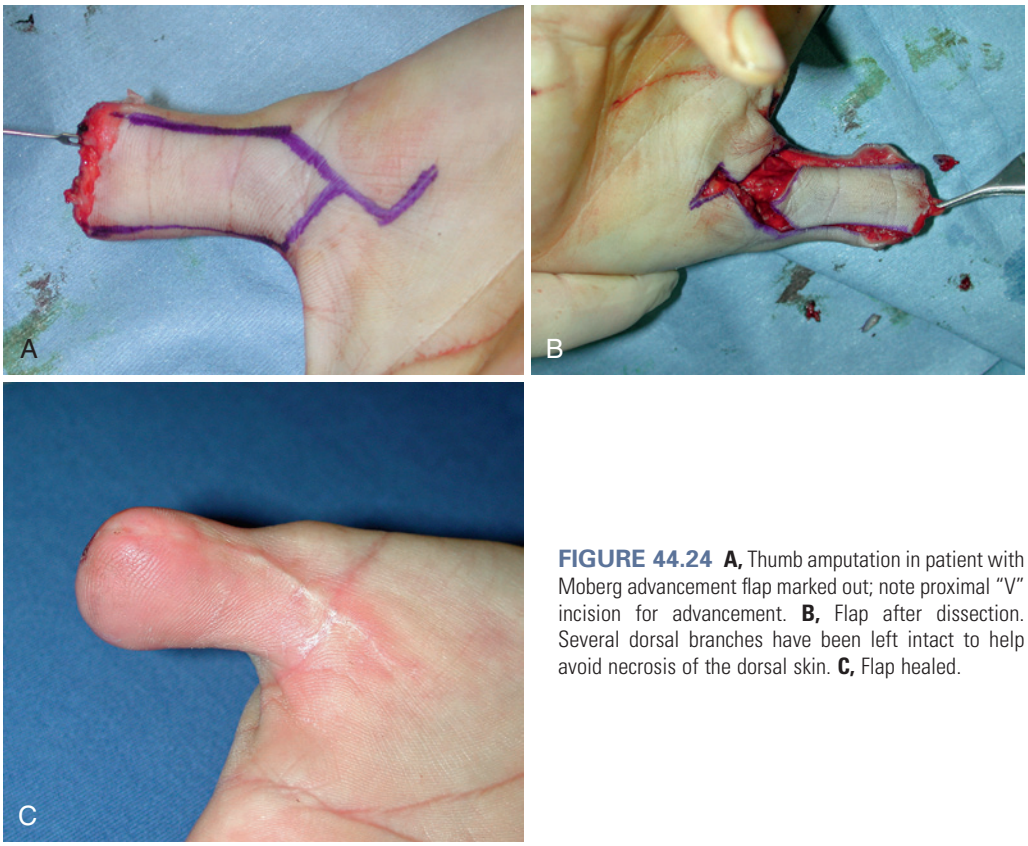

FIGURE 44.24 **A,** Thumb amputation in patient with Moberg advancement flap marked out; note proximal "V" incision for advancement. **B,** Flap after dissection. Several dorsal branches have been left intact to help avoid necrosis of the dorsal skin. **C,** Flap healed.

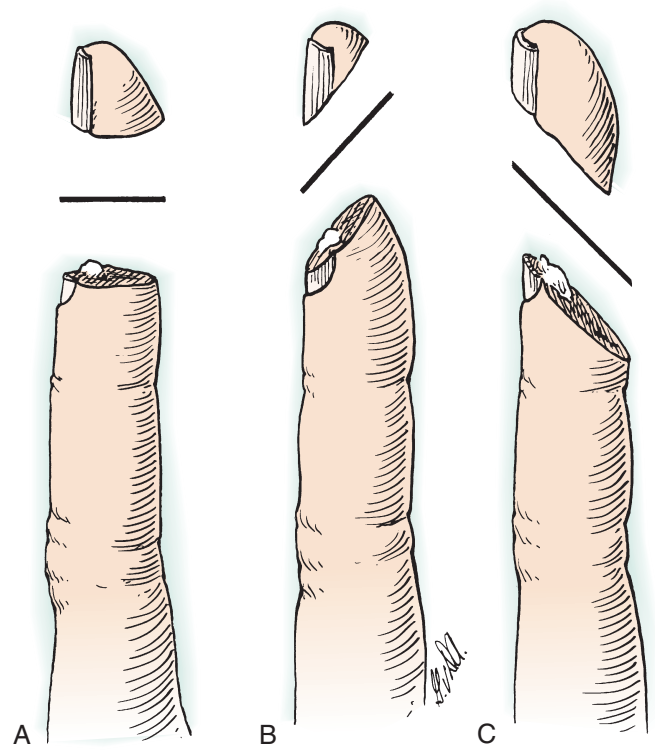

FIGURE 44.25 Suitability for coverage with local flaps is determined by looking at the angle of amputation. Amputations that are transverse **(A)** or have more dorsal loss **(B)** can be treated by local flaps. Where the loss is more palmar **(C)**, palmar flaps have been described (see text) but regional flaps are more reliable. (Modified from Lister GD: The theory of the transposition flap and its practical application in the hand. *Clin Plast Surg* 8:115–128, 1981.)

dissecting a neurovascular bundle for any form of island flap in the digit, no attempt should ever be made to define the artery and nerve independently, for such skeletonization will serve only to damage the veins and thereby seriously impair flap venous drainage.)

The flap should advance easily into place (see Figure 44.26). If it does not, and firm resistance is encountered, one of the fibrous septa must still be intact and must be divided. This process is repeated until the flap moves easily. If the distal end of the flap fails to easily reach the nailbed, it is better to place a small split-thickness skin graft over the raw distal edge of the flap rather than close it too tightly. Closure of the flap is begun at the apex, creating the vertical stem of the "Y" and so advancing the flap. The flap can be inset with the tourniquet inflated, and upon completion and after tourniquet release, color usually returns to the flap. If it does not, time and warmth in the form of hot packs should be permitted to play their valuable role for 20 timed minutes. If there is still inadequate flow, the most distal suture(s) in the vertical limb of the "Y" should be released, which usually produces the desired effect.

The lateral or Kutler[54] "V-Y" advancement flap[99] (Figure 44.27) is raised in identical fashion to the midline "V-Y," with the exception that there is only one neurovascular bundle to be protected in each flap. These flaps tend to lead to a scarred fingertip, however. "V-Y" flaps need not be based on a single known pedicle such as the proper digital artery and nerve. They can be raised on a pedicle of subcutaneous tissue, relying on random vessels contained therein. In such flaps, the pedicle is made as wide as possible. Such "V-Y" flaps have been described for closure of defects and release of contractures. The use of

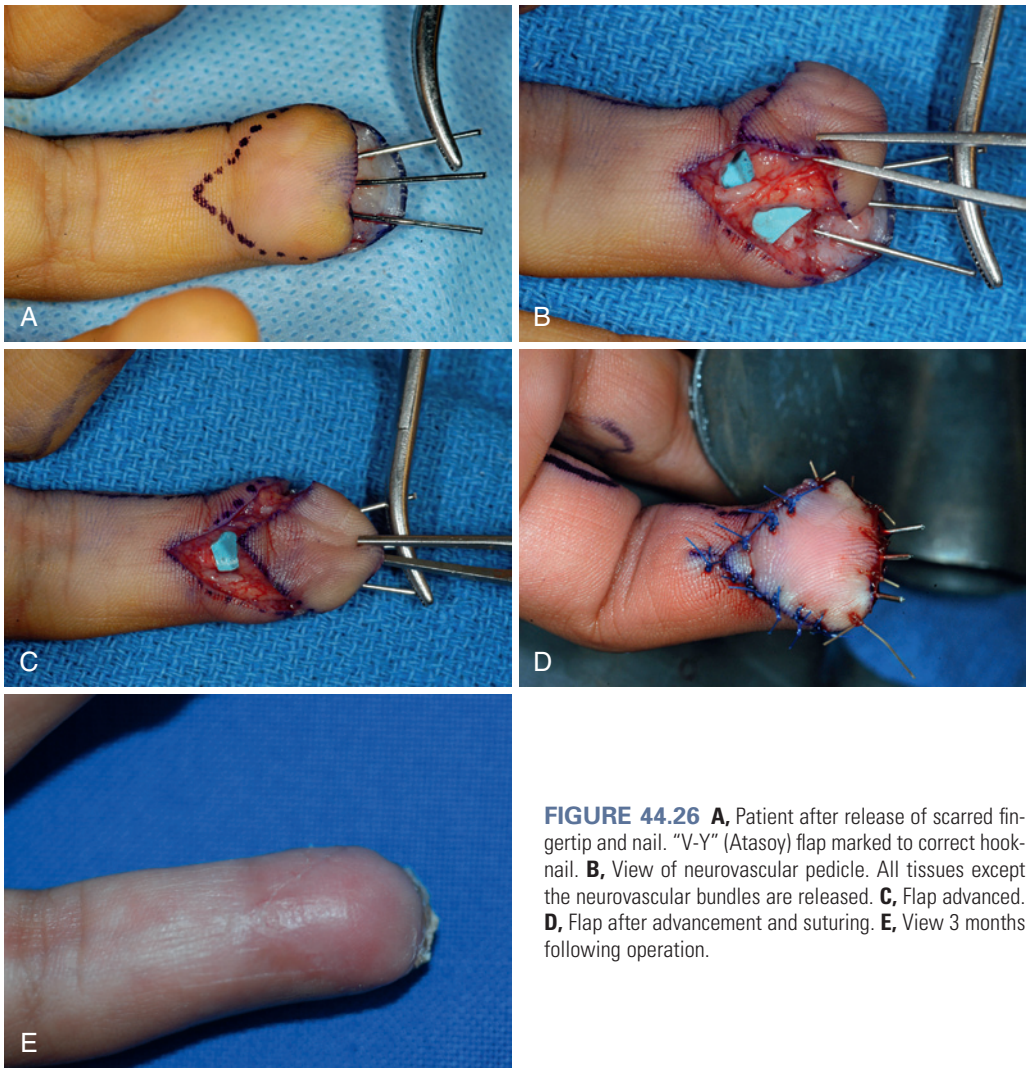

FIGURE 44.26 **A,** Patient after release of scarred fingertip and nail. "V-Y" (Atasoy) flap marked to correct hook-nail. **B,** View of neurovascular pedicle. lateral "V-Y" flaps should be limited, however, as they lead to significant scarring of the fingertip and are rarely indicated in clinical practice.

Regional Flaps

Regional flaps derive from tissues not immediately adjacent to the primary defect but in its vicinity. Thus most regional flaps in the hand are raised from another part of the hand. They are both random-pattern and axial pattern flaps with respect to their blood supply. In regional flaps, the merit of the axial design is apparent, for all require only one surgical procedure, whereas regional flaps of random design require at least two procedures. At the first operation, the flap is raised and applied to the primary defect. At the second, the pedicle is divided and inset.

Random-Pattern Regional Flaps

The cross-finger and thenar flaps are random-pattern regional flaps. Both are used in the repair of fingertip defects, in particular, those with bone exposed and with more loss of palmar tissue than dorsal tissue. Although the cross-finger flap continues to be used at time, the thenar flap has largely been abandoned in recent years due to problems with flexion contracture of the recipient finger. Fingertip tissue loss is much better managed with secondary healing or a digital artery island flap as described previously.

Cross-Finger Flap. Although the cross-finger flap has several variants that are outlined later, the basic design is for loss of palmar digital tissue and is fashioned on the dorsal aspect of the middle phalanx of the adjacent finger (Figure 44.28). For pulp loss, the middle finger is used for the index finger, but otherwise, the donor finger is the finger radial to the injured one. Flaps to and from the thumb are discussed later. The cross-finger flap can be tailored to fit a pattern of the primary defect. The margin of the defect that is adjacent to the donor finger is designated "the hinge." It corresponds closely to the base of the flap, which is also called a hinge. It is similar to the pivot point of transposition flaps, in that it is a fixed reference around which tissues move. It differs in that it is a line rather than a point. A pattern of the primary defect is made and turned through 180 degrees around the hinge and applied to the dorsum of the donor finger. By adjusting the position of the hinge, the necessary flap can be derived entirely from the skin of the dorsum of the middle phalanx. The flap to be raised is

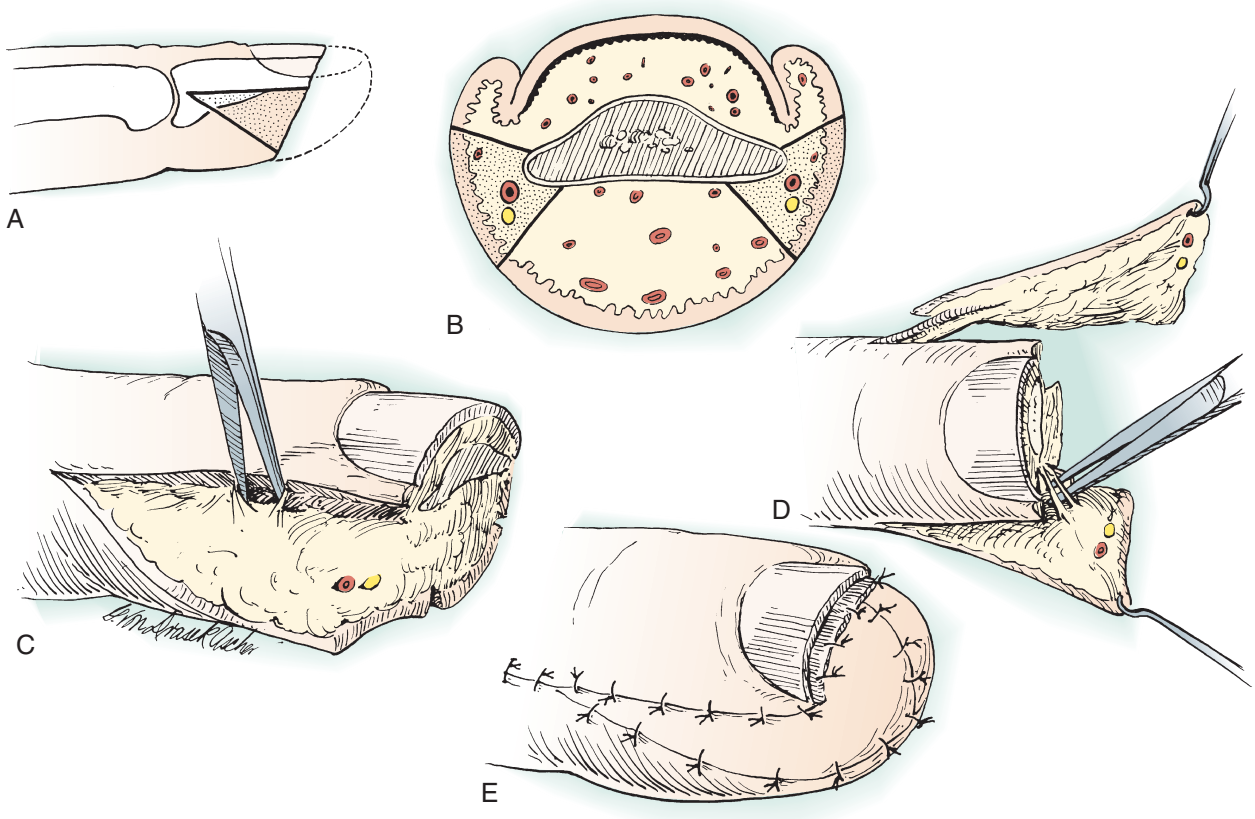

FIGURE 44.27 Kutler double lateral "V-Y" advancements. **A,** The advancement flaps are designed over the neurovascular pedicles and carried right down to bone **(B)**. The fibrous septa are defined and **(C)** divided, permitting free mobilization **(D)** on the neurovascular pedicles alone. The flaps then advance readily to the midline **(E)**. (From the Christine Kleinert Institute for Hand and Microsurgery, Inc., with permission.)

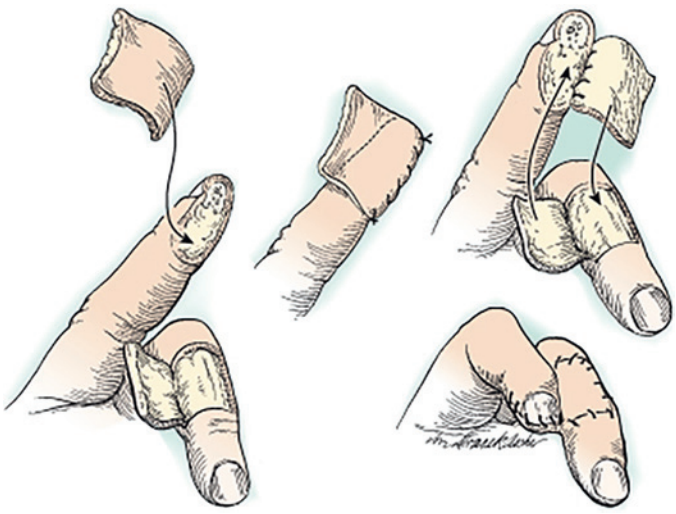

FIGURE 44.28 Cross-finger flap. The flap is raised from the dorsal middle phalanx of the adjacent finger. In this case, a skin graft is tacked to the side of the defect on the finger first, but this is used to close the donor defect. The flap is then sewn in place. (From the Christine Kleinert Institute for Hand and Microsurgery, Inc., with permission.)

outlined to include not only the necessary flap but also all the skin of the dorsum of the middle phalanx, from midlateral line to midlateral line and from the proximal extension crease of the DIP joint to the distal extension crease of the PIP joint. In marking the hinge, one should recall that in all random-pattern flaps, the direction that they face can be altered by extension cuts. Thus, in the cross-finger flap, a proximal transverse incision that extends more palmarly than the distal transverse incision will cause the deep surface of the flap to face proximally; one in which the distal cut extends more palmarly will face distally. The former is more often required, causing the flap to fit well to an amputation stump. The latter is needed only in longer, more palmar defects when considerable flexion of the injured finger is necessary.

The flap margins are incised. Immediately beneath the skin, multiple longitudinal veins are encountered. These are coagulated and cut in order to reach the correct plane, which lies immediately superficial to the extensor tendon. Once the veins are divided, the flap is raised with ease, because only loose areolar tissue lies in the plane of dissection. The flap is hinged away from the donor site and applied to the primary defect to check the fit. If the pedicle is kinked to reach the defect, this can often be eliminated by extending either the proximal or distal transverse cut of the flap. When the flap does not fold easily away from the donor finger, the Cleland ligament may be restraining it. The ligament can be incised to permit easier

folding of the flap. The vessels to the flap penetrate the more superficial part of the ligament and may be damaged unless care is taken to incise it at its depth, against the skeleton.

Once the flap has been raised satisfactorily, a pattern of the full-thickness graft required for the secondary defect is taken. The tourniquet is released at this juncture, and hemostasis is achieved. During this process, the full-thickness graft to cover the secondary defect is obtained. This is commonly taken from the same limb, usually the inner aspect of the upper forearm or arm. This practice is unacceptable in all except perhaps an older working man in whom scars may be of little consequence. In a young patient and, especially, female patient, the infliction of a wound in any of these sites is to be condemned. Rather, the grafts should be taken from over the iliac crest. Skin taken from the groin crease tends to be much darker than the skin on the hand and should be avoided, but skin over the anterior superior iliac spine is generally hairless and a more acceptable color match.

As in all flaps, it is desirable to close all raw surfaces. When one considers the hinge of the cross-finger design, the only free edge to which the skin graft can be sutured is the hinge margin of the primary defect, which is inaccessible after the flap has been sutured in place, lying as it does between the fingers. To overcome this difficulty, the skin graft is first laid on the primary defect, as if it were intended to use it to cover the primary wound rather than the flap already raised. The graft is sutured to the hinge margin of the primary defect. It will be appreciated that there are now two "flaps," the cross-finger and the graft, with contiguous hinges. If both are swung 180 degrees around their hinges, the flap will come to lie on the primary defect and the graft on the secondary defect. One last time, the positioning of the flap is checked. If the flap has been well chosen, any kinks can be eliminated by lengthening the extension cut. The flap can now be inset and sutured into position, trimming as necessary. The skin graft is sutured to the secondary defect. The circulation to the flap should be good, although a little blanching around the margins is common and acceptable. If the flap appears very pale and has been designed and raised correctly, it may be that the recipient finger is extending, thereby exerting undue pressure on the flap and its pedicle. This can be overcome by flexing the recipient finger until circulation returns and then maintaining the position by inserting a suture or Kirschner wire between the fingers, usually transfixing the middle phalanx of the injured finger and the proximal phalanx of the donor. This is rarely necessary.

Reversed Cross-Finger Flap. Primary defects on the dorsum of the finger cannot be covered by a standard dorsal cross-finger flap, as described earlier. They can be treated with a flap taken from the palmar surface, but the skin is rather unsuitable, and the secondary defect would be in a more significant area functionally than the primary defect; this is never a satisfactory solution. In such circumstances, a reversed cross-finger flap should be used. This is designed on the dorsal aspect of the middle phalanx of the adjacent finger, as with the standard flap, the hinge being adjacent to the primary defect. The first step, however, is to raise a full-thickness skin graft from the donor site, commencing the elevation at the hinge and leaving it attached on the opposite margin of the design. This is done at the level of the deep dermis above the layer of subcutaneous veins and below the hair follicles and requires a scalpel. The underlying subcutaneous tissue is raised in the same manner as for the standard cross-finger flap, with its hinge adjacent to the defect. When this flap is swung through 180 degrees around the hinge, its superficial surface lies on the primary defect, and the deep surface becomes superficial. A full-thickness skin graft is harvested and laid on the flap, and both are sutured to the margins of the primary defect. The full-thickness graft previously raised from the donor finger is sutured in place to cover the secondary defect.

Division of Random Regional Flaps. I prefer to divide most regional flaps at between 2 and 3 weeks. The decision whether or not to divide a flap is predicated on the apparent healing of the margins to the defect. If healing appears to be delayed, early division may lead to partial or total loss of the flap. Division is usually performed under local infiltration anesthesia. The pedicle may be inset or not, but the possibility of necrosis exists if too vigorous dissection of the flap is done at this stage. Immediate mobilization is mandatory, and the one benefit of regional over local anesthesia is that the joints can be taken gently through a full range of motion under its protection.

Axial-Pattern Regional Flaps

Regional flaps applicable to the upper extremity that have a known pedicle are the neurovascular island flap, the fillet flap, and those axial cutaneous, fasciocutaneous, and musculocutaneous flaps that may be used in the upper extremity.

Neurovascular Island Flap. The neurovascular island flap (*Littler flap*) has been used historically for reconstruction of the thumb pulp to provide stable and sensate coverage for loss of a significant portion of the touch surface of the thumb. It is described generally as using the ulnar side of the ring finger transferred as a neurovascular island flap to the thumb (Figure 44.29). One has to be sure that the contralateral digital artery is patent to avoid ischemia of the donor finger (Figure 44.30). Although the neurovascular island pedicle flap should be in every hand surgeon's armamentarium, it has little application today. Most significant thumb defects can be managed by other local or regional flaps or vascularized toe pulp transfers. These procedures avoid the donor site problems presented in the finger and provide adequate soft tissue reconstruction, with toe transfers offering the "best" reconstruction of the thumb with little in the way of donor site morbidity. Although one may argue that microvascular toe pulp transfer suffers from the need for microsurgical expertise, the successful dissection, rotation, and tunneling of a neurovascular island flap approaches the difficulty of a microsurgical tissue transfer. The reader is referred to previous editions of this chapter if a complete description of the dissection of this flap is desired.

Fillet Flap. Fillet flaps are developed from a well-vascularized digit that is otherwise worthless due to extensive injury to skeleton, nerves, or tendons and commonly to all three.[14,81] The technique of filleting a finger requires that the skeleton and tendons be removed, preserving all other soft tissues on one or both vascular pedicles. Because the circumference of a finger at the free edge of the web is equal to the distance from the web to a point just proximal to the nail fold, a fillet flap as described here is roughly a square. The difficulties in planning to use such a flap are, first, determining whether or not it can reach the presenting primary defect, and second, incising it to ensure that it does. Measuring the distance from the web of the digit to be

FIGURE 44.29 **A,** Patient with loss of thumb pulp. **B,** View of neurovascular island flap after dissection of pedicle from ulnar side of ring finger into palm. **C,** Flap after passage under palmar skin to reconstruct thumb.

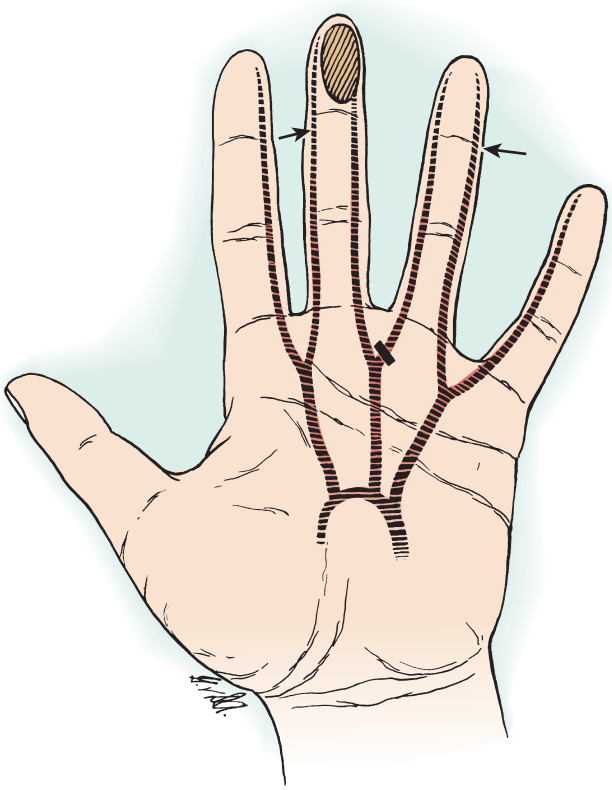

FIGURE 44.30 Neurovascular island flap: preliminary evaluation. It is necessary to ensure by Doppler studies that flow exists not only in the vessel that will supply the flap and in the vessel that will maintain the donor digit after the flap has been raised *(left arrow)* but also in the contralateral digital artery of the adjacent finger *(right arrow)* because the ipsilateral vessel will be divided *(bar)* in mobilizing the pedicle. (From the Christine Kleinert Institute for Hand and Microsurgery, Inc., with permission.)

sacrificed to the nearest point of defect provides only a rough guide, particularly in the secondary situation in which scar in the soft tissues of the digit reduces their elasticity significantly.

In preparing to fillet a finger, the patency or occlusion of the two proper digital vessels is determined. With this knowledge, the surgeon then plans the longitudinal incision in the digit by visualizing how the flap will first open in a lateral direction and then fold over proximally into the defect. For example, if the middle finger is to be filleted for a defect on the dorsum of the hand, the incision in the finger should be on its radial aspect if that defect is predominantly to the ulnar side of the third metacarpal, on the ulnar aspect if the defect is on the radial side. A further consideration when middle or ring fingers are to be sacrificed is whether the adjacent ray (index or small finger, respectively) is to be transposed into the defect left by the ray ablation. If it is, then the fillet flap is best reduced to an island flap by appropriate excision of palmar skin. Although technically more demanding, this gives a more mobile flap and a more pleasing final result. Once these decisions have been made, the appropriate longitudinal incision is made down to the skeleton (Figure 44.31). At its distal end, a circumferential incision is made around the finger at a point 5 mm proximal to the nail fold. This means discarding the pulp tissue, because its bulk makes it a rather unsatisfactory cover for its new location. At the proximal end of the longitudinal incision, its continuation depends on whether the metacarpal of the digit is to be resected and an adjacent digit transposed. If the metacarpal is not to be resected, a transverse incision is made over the dorsum of the finger so as to create a hinge along the side of the finger opposite the incision. All dorsal veins are ligated with the exception of the end of the proximal venous arcade that corresponds to the hinge. This single vein alone gives excellent venous drainage. If

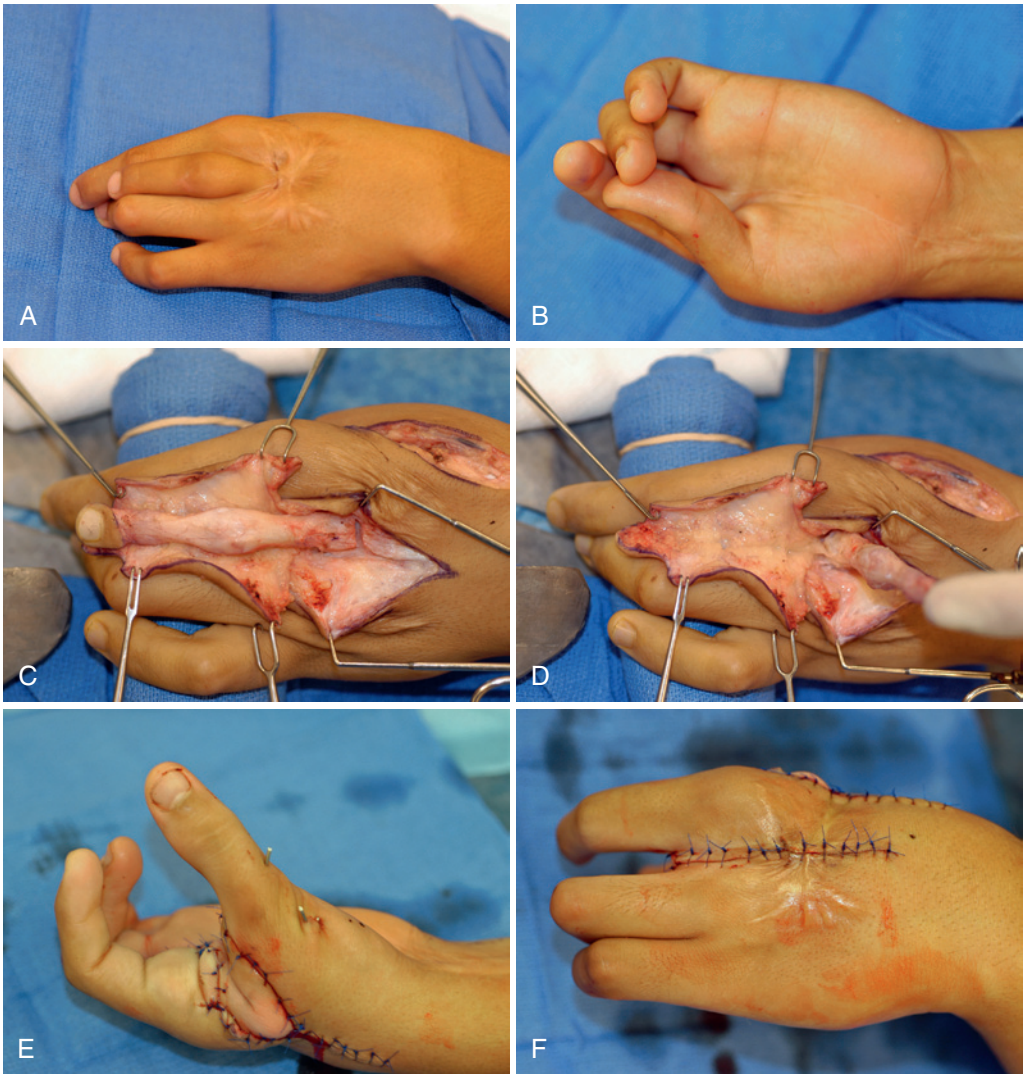

FIGURE 44.31 **A,** View of patient's hand 1 year after gunshot wound through hand with loss of metacarpal length and soft tissue deficit. **B,** Palmar view; note first web space contracture. **C,** Middle finger being dissected for use as fillet flap for first web space release; skin has been dissected off of tendons and bones. **D,** View of skin with bone retracted out of the way. **E,** Thumb after release and rotation of fillet flap through the palm as an island flap. **F,** Donor site after resection of metacarpal and closure.

there is intention to transpose a digit, thereby making the fillet an island flap, the incision is again circumferential at the level of the proximal digital crease, that is, at the free margin of the web. A further incision is made in a zigzag manner proximally into the palm, through which the necessary neurovascular bundle is dissected. This is always done before the skeleton is removed, as dissection of supported tissues is easier. To remove the digital skeleton, skin hooks are applied to the margins of the longitudinal incision distally, and the soft tissues are peeled off the underlying extensor tendon, bone, and flexor tendon sheath. The deep branches and tributaries of the vessels are ligated as this is done. The flap can now be opened and folded onto the primary defect. The necessary movement of the flap is more readily obtained if the injury to the donor digit is fresh and if the fillet has been raised as an island. Now, for the first time, the surgeon can really judge whether the flap will fit the primary defect. If it is too small, other solutions must be added. If it is too large, but the defect is deep, the excess should not be discarded; rather, it should be deepithelialized and turned in to fill the depths of the wound. If the hole in the depths of the wound is caused by a segmental bony defect, a portion of phalanx can be taken as a vascularized bone graft with the fillet flap.

Axial Cutaneous Flap

The scapular flap,[23] commonly used as a free flap, can reach the upper extremity as an island and can be used after the release of burn contractures of the axilla. This flap has some utility in reconstruction of the scarred axilla, but it suffers from the potential to be bulky when placed in this position. This can be obviated by making sure the fascia of the flap is tacked deep into the axilla and can also be improved by later thinning of the flap. The scapular flap will cover the superior shoulder as well if taken as a long "parascapular" flap. It has little value as a pedicle flap in coverage of the elbow and lower arm because the pedicle is not lengthy and the flap will not reach these areas. For a description of this flap, see Chapter 45 on free tissue transfer.

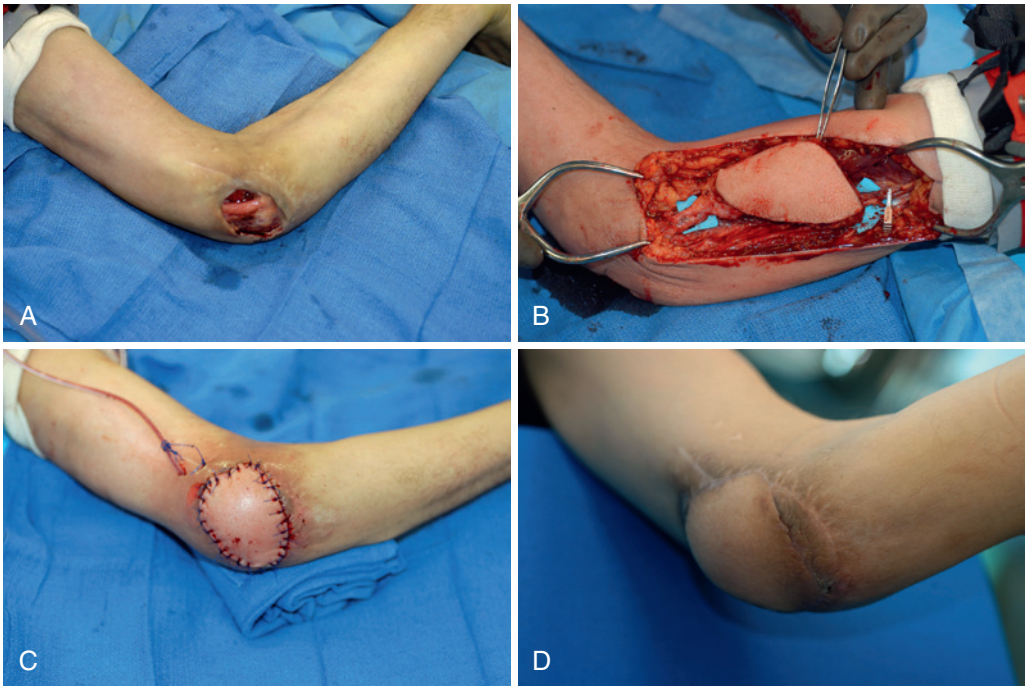

FIGURE 44.32 **A,** View of recurrent elbow wound in patient after radial forearm flap for coverage. **B,** Lateral arm flap dissected on distal vessels (radial recurrent). **C,** Flap after transposition from lateral arm to medial elbow. **D,** Flap healed at 6 months.

Fasciocutaneous Flap

Regional fasciocutaneous flaps have been described from the forearm to the periolecranon region and from the medial arm for release of axillary and elbow burn contractures. However, the major fasciocutaneous flaps of the upper extremity are the lateral arm flap; the radial artery forearm, or "Chinese," flap; the ulnar artery flap; and the posterior interosseous artery flap.[118] The lateral arm flap is primarily used as a free flap for hand coverage, but a small area of the elbow can be covered by a distally based flap (Figure 44.32). This procedure may leave an unsightly scar and also lead to numbness in the proximal forearm. By contrast, the reversed radial artery flap, with its potential area of much of the forearm skin and a pedicle located at the anatomic snuffbox, is capable of covering almost any defect in the hand.[102]

Radial Artery Forearm Flap

The radial forearm flap represents one of the best flaps for coverage of hand defects. Based on its distal pedicle, it can cover nearly any wound of the hand and can import a variety of tissues, including skin, fascia, tendon, and bone. It has been called a "reconstructive chameleon" because of its versatility.[51] It can also be based proximally and used for elbow coverage. The two primary disadvantages of this flap are the necessity for harvesting the radial artery and the poor cosmesis of the donor site, particularly in younger patients. One study noted that the radial artery was the dominant vessel to the hand in 12%,[73] and acute ischemia and cold intolerance have been reported. The absolute need for reconstruction of the radial artery after harvest is not known, although some have suggested that this may decrease the incidence of cold intolerance. In personal experience with several hundred radial forearm flaps (both pedicled and free), I have seen only two patients who required vein grafting of the radial artery who had a normal Allen test preoperatively. This experience is borne out by several studies, with one group noting that while flow to the hand was initially decreased, this improved over time to normal levels via the remaining circulation of the ulnar artery.[42] Although functional problems are minimal, the cosmesis of the donor site remains problematic. The donor site usually requires skin grafting, and it remains ugly, particularly in younger patients. Proposals to improve cosmesis include suturing the superficialis muscle over the flexor carpi radialis tendon to improve skin graft "take" and various local flaps to avoid the need of a skin graft.[52] In many instances, the cosmetic defect can be minimized by taking a fasciosubcutaneous flap only. This modification will be discussed below.

The radial artery (Figure 44.33) pursues a relatively superficial course in the forearm from its source at the division of the brachial artery to the point where it passes deep to the tendon of the abductor pollicis longus to reach the anatomic snuffbox. In the proximal forearm, it lies on the superficial surface of the pronator teres, just beneath the anterior margin of the muscle belly of the brachioradialis. Leaving the pronator teres, it comes to lie in turn on the radial head of the flexor digitorum superficialis and the flexor pollicis longus, here being palpable through the skin. Throughout its course, the artery gives branches to a plexus of vessels in the overlying deep fascia, and this plexus supplies the skin of the anterior and radiodorsal surfaces of the forearm. By means of similar fascial branches it also supplies the periosteum of the distal half of the radius between the insertions of pronator teres and brachioradialis. This allows construction of osteocutaneous flaps if so desired. The artery is accompanied by two or more venae comitantes. The multiple anastomoses between these veins permit reversal of flow in the venae comitantes without valvular obstruction.

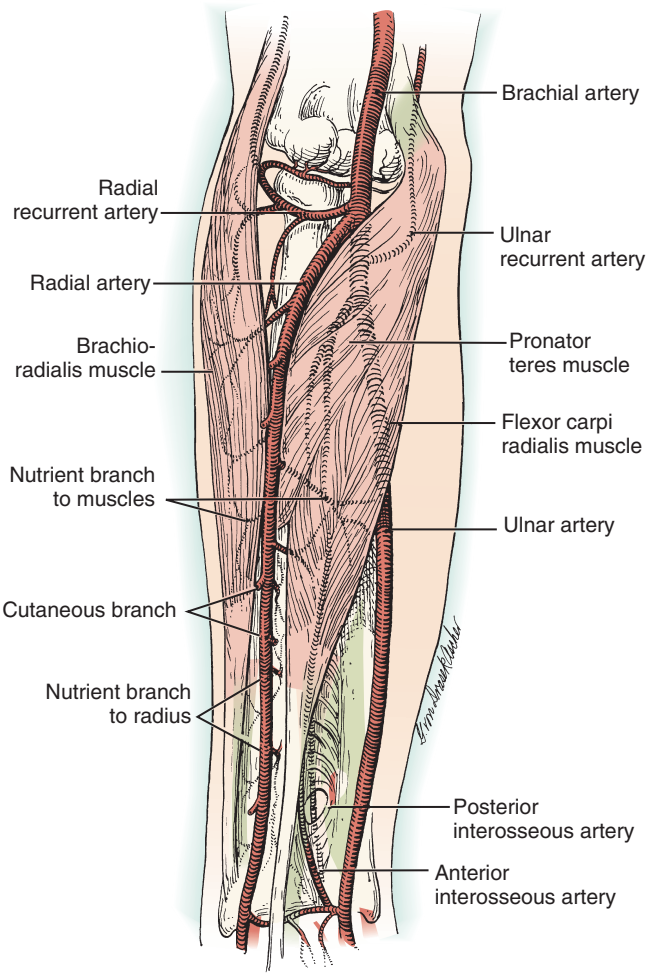

FIGURE 44.33 The course of the radial artery is superficial throughout much of the forearm, lying just beneath the margin of the brachioradialis on the pronator teres and the flexor digitorum superficialis. The cutaneous branches supply the overlying skin and nutrient branches of the radius. (From the Christine Kleinert Institute for Hand and Microsurgery, Inc., with permission.)

Thus the artery and veins can be divided proximally, and no venous engorgement will result (valvulotomy has been described to enhance flow[82]). The minimal precaution that should be taken before raising a forearm flap is a timed Allen test to ensure that flow is present and adequate through both vessels. Conversely, a "dynamic" Doppler examination can be done with the arch identified with the Doppler pencil and flow through the ulnar artery confirmed by digital pressure on the radial artery at the wrist.

The course of the radial artery is mapped out with a Doppler study and marked on the skin, as is the course of the major veins in the region of the flap. Using a soft inelastic material, the distance from the radial styloid to the closest margin of the primary defect is measured and transposed to the forearm to determine the location of the distal edge of the flap outline. I prefer to leave approximately 1 inch of pedicle in-site proximal to the volar wrist crease. I believe that this allows improved backflow to the flap via the multiple vascular interconnections around the wrist. The pattern of the primary defect is drawn out proximal to this point, remembering to place the proximal pattern to the distal flap, because the flap will be reversed on its pedicle. The margins of the flap are incised. A straight incision is extended distally from the flap margin over the course of the radial artery. The skin margins adjacent to the flap are elevated from the underlying deep fascia. I prefer to begin the dissection along the ulnar border of the flap and to continue all the way under the vessels prior to beginning the radial-side dissection. Once the skin has been elevated for 1 cm or so from the flap margin, the deep fascia is incised all around the flap, thereby gaining the plane of dissection. The flap is now raised by dissecting in the loose areolar tissue beneath the deep fascia. In larger flaps, some intermuscular deep extensions may be encountered, which should be incised. In the pedicle forearm flap described here, it is less likely that the secondary defect will lie distally over the wrist tendons than when it is used as a free flap. Nonetheless, whenever a tendon is encountered in elevating the flap, care must be taken to preserve the overlying epitenon. Once the flap has been raised across the flexor carpi radialis from the ulnar margin, traction reveals the radial artery and its venae comitantes (Figure 44.34). Multiple small branches to the muscles must be divided as the dissection proceeds from the ulnar side. Once the underside of the pedicle is freed up, the radial dissection is begun. From proximal to distal, the fascia and septum are carefully dissected off the brachioradialis muscle and tendon. Great care must be taken here to avoid dividing the perforators to the skin as they run along the brachioradialis. While both the aforementioned muscles are retracted away from each other, the lateral intermuscular septum in which the artery runs is incised parallel and deep to the radial artery. The pedicle is now dissected distally, and the entire pedicle with its surrounding fascia should be taken together. No attempt should be made to separate the veins from the radial artery. The radial artery can now be ligated proximally and the flap transposed to the primary defect (see Figure 44.34, *B* to *E*), passing it through a tunnel beneath intervening intact skin. Some surgeons prefer to make an incision and resuture this after passing the flap, but if the tunnel is made at least two to three fingerbreadths wide, most flaps will pass without difficulty.

Once the flap is in place, the previously proximal radial artery in the flap, now distal, can be anastomosed either immediately or at a later procedure to supply more distal tissues, such as a devascularized finger or a toe transfer.[65] The forearm flap can be used for forearm defects, provided that their location is appropriate. In such cases, one or more superficial veins can be rejoined proximally to make venous drainage more efficient. The quality of circulation in the hand can be evaluated once the flap is raised and the tourniquet let down. If it is necessary to reconstruct the radial artery, the gap between the end of the radial artery proximally and the radial artery at the pivot point adjacent to the snuffbox is measured. A vein graft of that length is harvested from the cephalic vein and interposed end to end proximally and end to side distally, using standard microsurgical techniques.

The secondary skin defect is closed with a split-thickness skin graft. Generally, take of the graft is improved if the tendon of the flexor carpi radialis tendon is covered with some of the flexor pollicis longus and/or superficialis muscle bellies, as noted above. This is cosmetically unsightly, but it rarely if ever causes the problems of distal edema that were feared when this flap was first used. The poor appearance of the secondary defect can be eliminated by raising the flap as fascia alone. In this

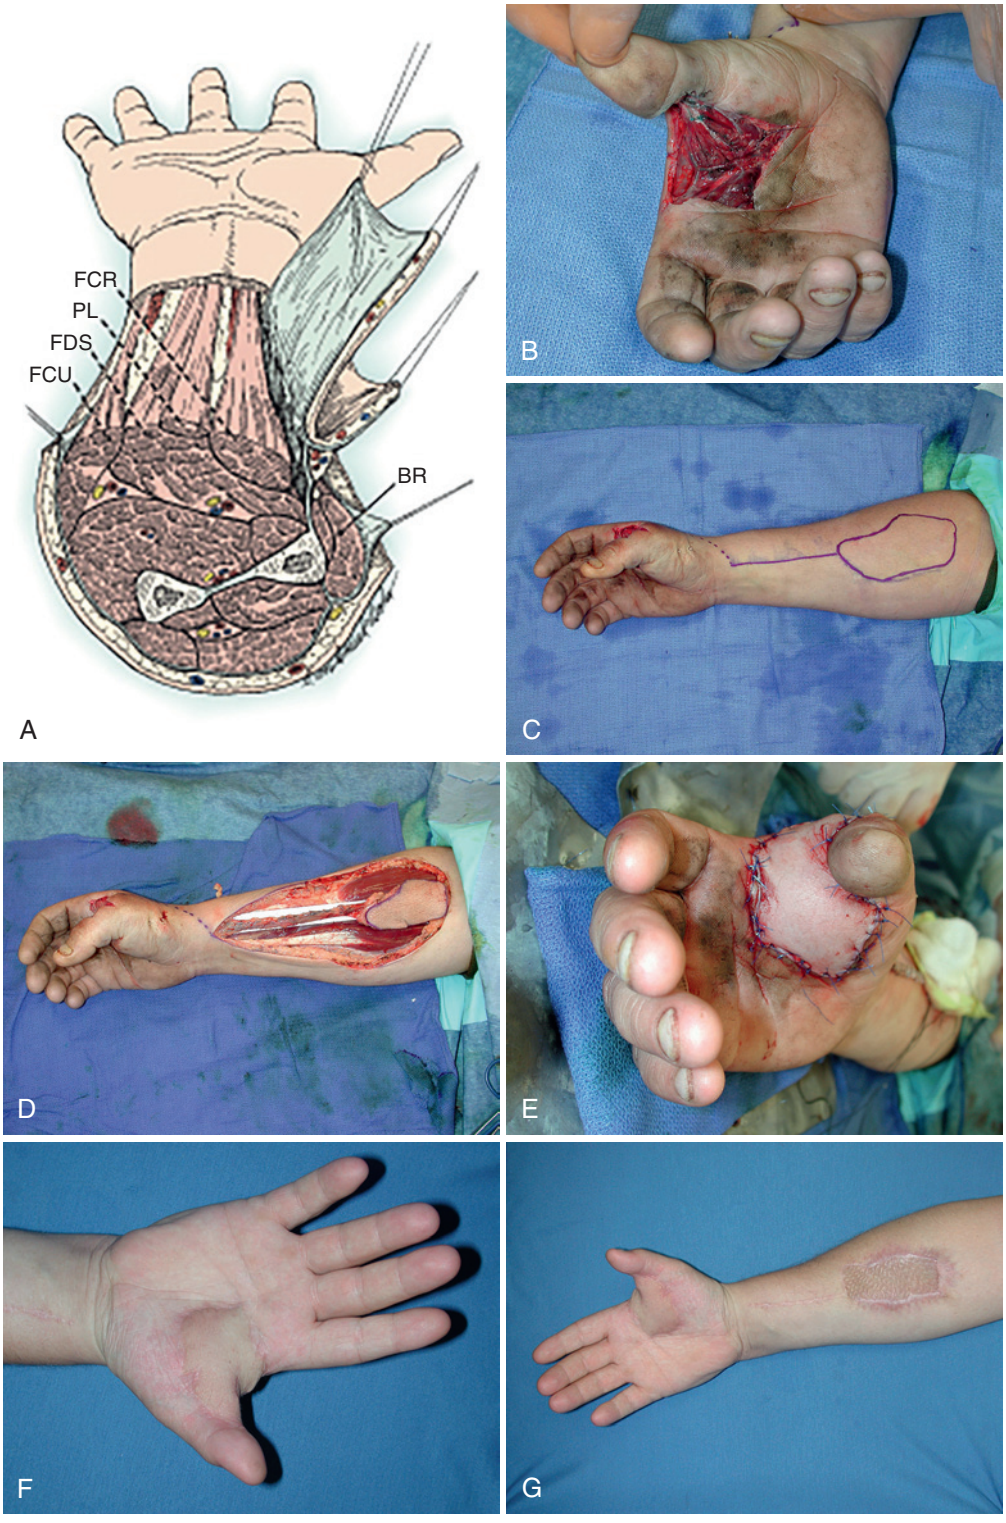

FIGURE 44.34 Radial forearm flap. **A,** Diagram of dissection of radial forearm flap with forearm skin based on radial artery. **B,** Hand of patient after débridement of gunshot wound to first web space. **C,** Markings for harvest of distally based pedicled radial forearm flap for coverage. instance, the fascia is raised alone without the overlying skin. The area of fascia necessary to cover the soft tissue defect is marked on the forearm, adequately proximal to allow rotation of the pedicle (Figure 44.35). The skin is elevated off the fascia in the manner of a full-thickness graft, but care must be taken to avoid damage to the underlying fascia. Once the skin is elevated, the dissection deep to the fascia proceeds as described earlier for the standard radial forearm fasciocutaneous flap (see Figure 44.35, *C*). The radial artery with its fascia is then rotated into the defect. The fascia is usually covered with a full-thickness skin graft. This type of flap affords appropriately durable and thin coverage of the hand and avoids the need for skin grafting of the donor site. Although there has been some question about the efficacy of graft take over fascial flaps, my experience and that from reported series have been reasonable.

The radial forearm flap can also be used for coverage of the elbow as a proximally based pedicled flap. It offers excellent thin, stable coverage of elbow defects at the expense of a potentially noncosmetic donor site. The dissection is similar to that for distally based flaps, but the flap is based on the distal forearm and the pedicle is dissected proximal to its branching from the brachial artery and divided distally (Figure 44.36).

Ulnar Artery Forearm Flap

Like the radial artery flap, the ulnar artery flap can be based proximally to cover defects around the elbow[45] or distally for hand cover. First described in 1984,[62] it has gained less popularity than the radial artery forearm flap, despite offering the advantages of less hairy skin and a less obvious secondary defect, which, having more muscle and less tendon, should take skin grafts more readily. The donor site of this flap can often be closed primarily, particularly in older patients who may have excess skin on the ulnar border of the forearm. This flap is particularly useful in the management of distressing chemotherapy burns to the dorsal hands in elderly women. In this group of patients, a large flap can be taken to cover the dorsal hand with primary closure of the donor site in most instances. This flap may also be used as a free flap to the hand in appropriate circumstances.

Dissection is similar to the radial artery forearm flap, except that the vascular septum from artery to skin lies between the flexor carpi ulnaris and flexor digitorum muscles and that care must be taken not to harm the ulnar nerve lying immediately deep to the vessel. If taken very proximally on the arm, the septum can be tenuous, with very small perforators, but the flap is very reliable in my experience. Owing to the proximity of the dissection to the ulnar nerve (and possibly devascularization of the nerve with flap harvest), most patients experience a period of ulnar nerve dysesthesia postoperatively. This generally resolves in a few months.

Reversed Posterior Interosseous Artery Flap

In 1986, the anatomic basis[84] and clinical application[120] of a flap based on the posterior interosseous artery (PIA) were first reported. Initially used as a proximally based flap to cover the elbow, its popularity has increased since the description of more detailed anatomy became available and also because of its use as a reversed flap.[12,104]

The PIA arises in the anterior compartment from the common interosseous artery, which also gives rise to the anterior vessel. The PIA immediately passes dorsally through the interosseous membrane some 6 cm distal to the lateral epicondyle, emerging just below the distal edge of the supinator. Throughout its course, it lies between the extensor carpi ulnaris and the extensor digiti minimi, initially lying on the abductor pollicis longus muscle belly in close approximation to the

CRITICAL POINTS *Radial Forearm Flap*

Indications
- Wounds of dorsal hand, forearm, or elbow
- For acute coverage of trauma or tumor resection

Preoperative Evaluation
- Allen test and Doppler examination to ascertain adequacy of ulnar artery flow to hand
- Forearm skin without injury or scar (where flap is to be designed)

Pearls
- For distally based flaps, design pedicle to allow room for rotation
- Dissect pedicle out as a unit, without separation of artery and veins
- Begin dissection on ulnar side of flap

Technical Points
- Take skin, subcutaneous tissue, and fascia off muscle
- Great care must be taken to elevate flap off of brachioradialis tendon to avoid injury to perforators
- Identify and protect radial nerve under brachioradialis and distally
- Avoid separation of artery and venae comitantes
- With exposure of flexor carpi radialis tendon, suture superficialis muscle over this to improve skin graft take at donor site
- Avoid kinking pedicle with distal rotation
- If tunneling flap under intact skin bridge, make sure this is very loose

Pitfalls
- Elevating fascia with perforators away from skin when dissecting over brachioradialis tendon
- Kinking pedicle with distal rotation
- Loss of skin graft at donor site due to flexor carpi radialis and brachioradialis tendon exposure

Postoperative Care
- Immobilize wrist, MP joint, and PIP joint for 2 to 3 weeks for skin graft to take
- Motion may begin after graft has taken

Expected Outcomes
- The radial forearm flap supplies excellent supple skin to the hand with a good color match
- There should be little functional problems from the donor site of this flap over the long term
- The cosmetic aspect of the donor site may present problems in younger patients and women
- Minor revision (defatting) of the flap may be necessary in the future, but this is not always necessary

posterior interosseous nerve. Some 2 cm proximal to the ulnar styloid, it has an anastomosis with the anterior interosseous artery, and it then passes on to the dorsum of the carpus, where it anastomoses with branches of the radial artery. Throughout its course, the PIA gives septocutaneous perforators that supply the skin over the dorsum of the forearm.

To raise the flap, a line is first drawn from the lateral epicondyle to the distal radioulnar joint. A point on this line 2 cm proximal to the ulnar styloid is marked, which represents the pivot point of the distally based flap. Measurements are taken from this point to the proximal and distal edges of the primary defect. These represent the distances from the pivot point along the line initially drawn at which the distal and proximal margins of the flap outline, respectively, are marked (Figure 44.37). The radial margin of the flap and a distal extension to the distal radioulnar joint are incised. The distal extension can be made 1 cm radial to the previously made surface marking of the PIA. The flap is raised, and the fascia over the extensor digiti minimi is incised 5 mm radial to the thick fascial septum. While retracting the muscle radially, the posterior interosseous artery, its branches, and the anastomosis to the anterior interosseous artery distally are dissected, taking care to preserve the perforating vessels to the skin. Provided no anomalies are encountered, a similar skin and fascial incision is now made on the ulnar aspect over the extensor carpi ulnaris, which is again mobilized by division of the muscular branches of the PIA. Most authors suggest keeping a segment of dorsal forearm fascia intact with the septal vessels distally, which may contain veins to improve venous outflow in the distally based flap (see Figure 44.37, *C*). The relationship of the motor branch of the extensor carpi ulnaris to the PIA and its most proximal relevant perforator (MPRP) must now be inspected, for if it passes superficial to the PIA and the MPRP is the major septocutaneous perforator, which it may be, the surgeon may decide to divide and repair

FIGURE 44.37 Posterior interosseous flap. **A,** Hand after explosive injury to first web space. **B,** Markings of posterior interosseous flap. Perforators and posterior interosseous artery have been located and confirmed with a Doppler probe. **C,** Flap after elevation. Note posterior interosseous pedicle to the left. *Arrow* points to posterior interosseous nerve, which can be entwined with perforators if the flap is taken too proximally. **D,** Flap rotated to recipient site. **E,** Flap after insetting. Donor site was closed with split-thickness skin graft. **F,** View of hand 6 months following operation. **G,** Donor site at 6 months.

the nerve in that circumstance. This anatomy is one of the primary factors that mitigate against the choice of this flap, in my mind. The potential morbidity of dividing and repairing the posterior interosseous nerve in a flap that often has questionable viability makes this flap often less than an ideal choice. Once the pedicle and flap have been fully mobilized so that they are attached only by the proximal and distal vascular connections, there is merit in placing a microvascular clamp on the PIA proximal to the MPRP and releasing the tourniquet. If flow is good, ligation can replace the clamp, and the flap can be turned into place on the hand.

The reach of the flap has not been clearly defined. It can certainly reach the first web space and the MP joints. Büchler and Frey[8] have taken the flap to the PIP joint, but they reported a 21% incidence of partial necrosis. Although statistical analysis of their results indicated that this necrosis was not related to pedicle length, this incidence of partial flap loss is higher than that encountered in other series, with only one case of remediable venous congestion out of 32 flaps performed. Nonetheless, this flap remains somewhat problematic in most hands, regardless of the length of the pedicle. Despite enthusiasm for this flap, Brunelli reported a 14% incidence of at least partial necrosis of 113 posterior interosseous flaps.[7] Another more recent report found anatomic variations in 24% of 88 flaps elevated, which led to inability to harvest the flap in 5 patients (6% of cases).[19] This same group noted variable degrees of flap necrosis in 13% of cases. For these reasons, this flap should not be attempted without knowledge of both the anatomy (and its variations) and an acceptance of a rather high rate of either partial or complete flap failure.

Musculocutaneous Flap

The blood supply of muscles has been classified into five types[69]:

Type I. One vascular pedicle, e.g., tensor fascia lata
Type II. One dominant plus other minor, e.g., gracilis
Type III. Two dominant, e.g., gluteus maximus
Type IV. Several, equal, segmental, e.g., sartorius
Type V. One dominant plus peripheral, e.g., latissimus dorsi

In types I, II, and V, one so-called dominant pedicle is capable of supporting the entire muscle if the others are ligated. Theoretically, therefore, any muscle in the upper extremity that belongs to one of these three types can be transposed on its pedicle. Several have been described: latissimus dorsi to the shoulder and upper arm; deltoid to the shoulder; brachioradialis, extensor carpi radialis longus, and flexor carpi ulnaris to the elbow; flexor digitorum superficialis to the antecubital fossa; extensor carpi ulnaris and flexor digitorum profundus to the proximal ulna; pronator quadratus and abductor digiti minimi[90] to the wrist; and the first dorsal interosseous to the first metacarpal and to the third metacarpal. Because the majority of these lie beneath a well-vascularized deep fascia, most have been used as muscle flaps to which split-thickness skin grafts have been applied. These flaps have limited value, for they all eliminate a functioning motor. Furthermore, their contour is good only when the defect has a volume similar to that of the muscle belly. The function of the transposed muscle can be preserved where necessary,[68] provided the correct tension is maintained. The fascia overlying a muscle, if it is thick, has a rich plexus supplied through vessels of the intermuscular septa. In the absence of a direct axial cutaneous vessel, that plexus supplies the overlying skin, which is therefore best raised as a fasciocutaneous flap, leaving the muscle in place. Where the fascia is thin or absent, the supply to the skin comes more from small branches that perforate the muscle; such vessels supply the skin over the latissimus dorsi. In this case, the muscle and the skin overlying it can be moved efficiently as a block to provide skin cover and, where needed, function. Whether the cover achieved is better when the muscle alone is moved and then skin grafted, or when a musculocutaneous flap is used, is still a matter of debate, but most feel today that musculocutaneous flaps are generally too bulky.

Two muscles in the type V classification have been used in this manner to the upper extremity, the pectoralis major and latissimus dorsi. As with other type V muscles, the main vascular pedicle of the pectoralis major, the pectoral branch of the acromiothoracic axis supplemented by the lateral thoracic artery,[88] enters close to its insertion. There are numerous small vessels entering the periphery or origin of the muscle, notably from the internal mammary artery. Unlike all the regional axial muscle flaps listed earlier, the pectoralis is left attached at its insertion and released from its origin. It can be split longitudinally to cover two adjacent defects. The pectoralis muscle without skin (and it may be used with the addition of the pectoralis minor) has long been used for restoration of elbow flexion lost as a result of nerve injury[15] or arthrogryposis. With an island of overlying skin, it has been used as an axial regional flap for reconstruction of the axilla and shoulder. However, the secondary defect, even when it can be closed directly, is entirely unacceptable to women and largely so to men. Because all primary defects in the upper extremity that can be reached by the pectoralis can be covered with ease and with a much more acceptable donor site by the latissimus dorsi flap, the latter is preferred in virtually all cases.

Latissimus Dorsi Flap. The wide arc of rotation around its pedicle makes the latissimus currently popular for reconstruction of the breast, the abdominal wall, the head and neck, and the shoulder.[24,72] The diameter of the artery (1 to 2.5 mm) and the length of the pedicle (11 cm) has made it the most robust and therefore popular tissue for free transfer, especially to the extremities. Functional transposition of the latissimus dorsi to restore lost biceps function has been known to the orthopedic surgeon for over 30 years.[121] Its use to restore both function and skin cover[56] and to restore cover alone is a more recent development.

The latissimus dorsi arises from the lower six thoracic vertebrae, from the thoracolumbar fascia, and from the posterior part of the iliac crest. From this extensive origin the muscle fibers converge to wrap around the lower border of the teres major and end in a quadrilateral tendon that inserts into the intertubercular sulcus of the humerus. Together with the teres major, it forms the posterior axillary fold. Furnas and Furnas[32] reported one patient in whom the lower part of the muscle was absent, but its anterior border felt quite normal preoperatively. Its main blood supply derives from the vessel popularly known as the thoracodorsal artery, which is the continuation of the subscapular artery after it gives off its circumflex scapular branch some 2 cm distal to its origin from the axillary artery. The thoracodorsal artery gives a variable number of branches to the chest wall, notably one to the serratus anterior, before reaching its hilum on the latissimus dorsi some 11 cm from the

axillary artery. Immediately distal to the hilum, the artery divides into two branches in most patients. The upper branch runs parallel to and 3.5 cm from the upper margin of the muscle; the lateral branch runs parallel to and 2.1 cm from the lateral margin of the muscle. This arrangement permits the surgeon to split the muscle longitudinally when a narrow flap is required. One might suppose that absence of the artery would preclude use of the latissimus dorsi flap; however, this need was disputed in the belief that previous injury to the vessel served as a delay. Certainly, if the serratus branch remains intact, it has been shown that collateral circulation is established and the flap can be safely transposed. This would, however, severely limit the reach of the flap when it is taken to the arm and carries the risk of kinking the pedicle. The muscle can also be used in "reverse," based on the vessels of the T9, T10, and T11 intercostal spaces, but rarely in this fashion for coverage of the upper extremity. Any significant defect of the upper arm and elbow can be covered with a pedicle latissimus dorsi flap (Figure 44.38), and it has been transferred successfully to the forearm.

When the latissimus dorsi is to be transposed to a defect in the upper extremity, the involved limb, together with the entire ipsilateral hemithorax and distally to the iliac crest, is prepared and draped. The axilla can be displayed by wrapping the forearm with soft padding and then applying upward traction with the help of an assistant. Some have advocated placing the arm on a Mayo stand or the equivalent in a fixed position, but I have seen cases of injury to the brachial plexus from prolonged placement in this position. I prefer to avoid placing the arm in a fixed abducted position and simply have an assistant hold the arm abducted with periodic relaxation of the patient's shoulder (and the assistant). A zigzag incision is made in the axilla, avoiding the hair-bearing area, extending down along the anterior border of the muscle. Through this incision, the anterior border of the latissimus is located and sharply freed up. Once the anterior border is freed up, the submuscular dissection is done easily in the areolar plane next to the chest wall. The thoracodorsal vessel can best be found where it approaches the muscular hilum. This is approximately at the nipple line in a man or a child. With good retraction and light, the vessel can be traced proximally, identifying first the serratus branch and then the circumflex scapular artery. These are ligated and divided. If they are not, they tether and kink the pedicle after transposition. The most proximal extent of the dissection constitutes the pivot point or axis of the flap.

FIGURE 44.38 **A,** Elbow of patient with wound dehiscence after total-elbow arthroplasty. **B,** Latissimus dorsi muscle pedicled to cover elbow. This will be covered with a split-thickness skin graft.

At this juncture, the distance from this pivot point to the proximal margin of the defect in the limb is measured and transposed to the anterior border of the latissimus dorsi previously marked. This second point represents the proximal edge of the proposed flap. Using a pattern of the primary defect, the flap can now be marked out over the posterolateral thorax. The anterior margin is incised, and the anterior border of the latissimus is elevated with the overlying skin. The inferior border of the flap can now be raised by incising through skin, subcutaneous tissue, and muscle, using cutting cautery for all but the skin. The distal and medial muscle may also be divided using one of the gastrointestinal anastomotic stapling devices (Endo GIA, Covidien-Medtronic, Minneapolis, MN), which places a line of small hemostatic staples and divides the muscle between these two rows. The use of this instrument can make the dissection very rapid. Once the inferior and medial muscle is divided, the latissimus dorsi can be swung away and posterior from the trunk, permitting a clear view of the vascular tree of the thoracodorsal artery. Where a narrow flap is all that is needed, the lateral branch is located, and the posterior border of the flap is incised as was the inferior border, while carefully avoiding that lateral branch. The upper branch (situated also medial and posterior) is ligated and divided. The thoracodorsal artery is now dissected off the latissimus dorsi, working from the axilla distally as far as possible without injury to it or its muscular branches. The proximal margin of the flap can be incised in a similar manner to the inferior (or distal) and posterior, while retracting the pedicle anteriorly and so protecting it from harm. Raising the flap in this manner rather than taking the whole muscle, as was done in the past, yields a flap tailored exactly to the primary defect. In particular, it avoids both a bulky proximal portion to the flap and the difficult task of separating the latissimus dorsi from the teres major. The bulk proximally was not only unsightly but also difficult to fit into the upper arm. This is particularly so in the common circumstance in which the flap is to be passed beneath an intact skin bridge. The flap can now be passed to the primary defect and sutured in place. The secondary defect is always closed directly, for a skin graft in this location presents many difficulties in terms of graft take and wound care. Seroma formation is common, and prolonged suction drainage is indicated.[87] More tissue is available for superior to inferior closure than in the line of the trunk; therefore, small defects are best closed transversely. No significant loss of function has been shown following use of the latissimus dorsi.[93]

CRITICAL POINTS *Latissimus Dorsi Pedicled Flap*

Indications
- Coverage of upper arm, elbow, proximal forearm
- Functional reconstruction of elbow flexion or extension

Preoperative Evaluation
- Presence and function of latissimus (especially for functional reconstruction)
- Absence of scars in axilla (axillary dissection, mastectomy, thoracotomy)

Pearls
- May take skin paddle for coverage or place skin graft over muscle
- If not needed for functional coverage, should cut thoracodorsal nerve to prevent muscle from pulling loose with movement
- Artery and vein in pedicle should be left together in areolar tissue to avoid kinking of vein
- Should divide tendon from humerus to obtain the most length
- Distal muscle may not be viable, especially if overstretched

Technical Points
- Elevate skin from muscle with knife or cautery
- Identify pedicle running under proximal portion of muscle
- Deep surface can usually be elevated with finger dissection
- Divide distal muscle with cautery once pedicle is identified
- Dissect pedicle carefully with muscle flipped over
- Should ligate or clip the large paraspinous perforators (not cautery)
- Once pedicle is identified and isolated, can divide muscle proximally
- If taken under an intact skin bridge to defect, tunnel must be adequate to prevent pressure on muscle
- Avoid suturing the muscle too tightly distally

Pitfalls
- Damage to pedicle during dissection
- Passing the muscle under a skin bridge that is too tight
- Suturing the muscle under too much tension

Postoperative Care
- Large drains in donor site for 5 to 7 days (seromas common)
- Immobilize shoulder and elbow for 2 to 3 weeks
- Begin gradual mobilization

Expected Outcome
- The patient should have excellent tissue reconstruction with the muscle
- There should be little in the way of donor site morbidity
- The rate of seroma formation is high and requires aspiration in the office on occasion
- There will occasionally be some tightness from the scar and numbness of the anterior chest wall

Distant Flaps

Distant flaps come from body parts outside of the upper extremity. Both random-pattern and axial-pattern varieties exist. All distant flaps require a period of attachment between the operated limb and the donor part. They therefore all require at least two stages: attachment and division. When the blood supply to a random-pattern flap is doubtful, preliminary delay and later inset operations may be necessary, making four operations in total. Distant random-pattern flaps were formerly the routine method of providing skin cover to the hand where free grafts would not suffice,[11] but the necessary hospitalization time was long and the outcome unpredictable. When these factors (i.e., attachment, multiple stages, prolonged hospital stay, and doubtful result) are considered together, it is readily understood why the random-pattern distant flap has been largely superseded by the axial-pattern distant flap and it, in turn, by free microvascular flap transfer. There are, however, still indications for the use of both types of conventional distant flaps. The axial flaps all have defined territories based on pedicles that run in the vascular strata previously defined. The need to ensure that the vessel is included in the flap restricts the surgeon's ability to invade its vascular territory too boldly in trying to harvest a flap for a small defect, and the license to thin an axial flap is strictly controlled by the need to preserve the nutrient vascular plane. It follows that for small defects or for ones requiring thin skin, distant axial flaps, either conventional or by free transfer, are unsuitable. Normally, local or regional flaps satisfy the need, but where they are not suitable or available, distant random-pattern flaps are still required. Such a circumstance may arise in loss of palmar skin, circumferential avulsion of soft tissue from the thumb, and small but significant defects (e.g., when bone is exposed on the dorsum of the thumb) in a hand already extensively injured.

Conventional distant axial flaps are indicated in quite different circumstances. They are the most reliable form of coverage when microsurgical expertise is not available. When it is, free flap transfer is the method of choice, not only because it eliminates the problems of attachment and multiple procedures detailed above but also because it ensures a permanent, vigorous blood supply to the injured area. It may be difficult, however, to transfer much spare soft tissue with a free flap. Thus, if it is intended at a later stage to transfer the index finger by pollicization or toes from the foot to restore an amputated thumb or fingers, a conventional axial-pattern flap should be used for skin cover. Its tube pedicle can provide the additional skin necessary to cover the proximal portion of the later digital transfer. The presence of such additional skin allows a minimum of skin to be taken from the foot, so that closure there can be achieved entirely with local skin, a desirable objective. In the case of toe transfer, the use of a conventional flap has the additional benefit over free flap transfer of preserving the vessels of the hand untouched for the later anastomosis to those of the toe. As experience in microvascular surgery increases, this consideration becomes less valid.

Random-Pattern Distant Flaps

As the blood supply of the random-pattern flap derives from the subdermal or subcutaneous plexus, it can be raised at any site on the body. This apparent freedom is severely restricted by considerations of suitability, availability, positioning, and appearance. To give extreme examples, scalp skin is not suitable, penile skin is not available, leg skin would not be comfortable, and neck skin is not cosmetically acceptable. Indeed, when all factors are weighed, few donor sites remain. In the male patient, any site on the torso or the other uninjured arm may be used if no better alternative is available. In the female, only the inguinal region, where the defect can be closed directly and concealed beneath a two-piece swimsuit, is universally acceptable. In practice, this means that random-pattern flaps are rarely used in females, except to transfer thin skin from the region of the iliac crest. In some instances, this type of flap may be indicated

despite the donor site and circulatory difficulties. These would include suture of cutaneous nerves in the flap to branches of the radial nerve in the defect to reinnervate a thumb reconstruction, the use of double flaps to cover both dorsal and palmar wounds and to create a new first web,[114] and the use of several interdigitating flaps to resurface multiple finger injuries.

With the advent of regional axial-pattern flaps (i.e., the radial forearm flap) and the availability of the axial groin flap, there is in fact little application for these flaps today. The donor defects are generally quite ugly, particularly from the chest, even in male patients who usually find these sites marginally acceptable. For these reasons, we feel that these are generally not only a secondary choice for coverage but should be considered as a last resort.

Axial-Pattern Distant Flaps

Groin Flap. The groin flap is an axial-pattern flap of the cutaneous variety (Figure 44.39). Its axial vessel is the superficial circumflex iliac artery, which is a relatively constant vessel, being present in 96% of a series of angiograms.[48] The vessel arises from the femoral artery in the femoral triangle, which forms a vascular "hub," for the pedicles of several flaps converge here. The superficial circumflex iliac artery emerges from the triangle by passing over the medial border of the sartorius immediately after giving off a deep muscular branch. Initially below the deep fascia, the vessel emerges through that fascia as it crosses the sartorius. It passes laterally, parallel to and some 2 cm below the inguinal ligament. At a point below the anterior superior iliac spine, the vessel divides and supplies the skin immediately below the iliac crest. The vascular territory of the superficial circumflex iliac artery therefore ends at some point lateral to the anterior superior iliac spine. Common wisdom and practical experience dictate that the flap can safely be extended beyond the spine by a distance at least equal to the width of the flap. The venous drainage, which is as important as the arterial supply, and lymphatic outflow of the flap have both been studied in detail.[16,83] The report by Penteado[83] gives details of venous variations in the femoral triangle that are important to the microsurgeon; a surgeon intent on using the flap as an axial pedicle need only know that all drainage of this region is to the femoral triangle and therefore will lie within the pedicle. Commonly, no reinnervation of the flap is attempted, but Joshi[47] pointed out that the lateral cutaneous branch of the subcostal or 12th thoracic nerve consistently crosses the iliac crest 5 cm posterior to the anterior superior iliac spine. This can be dissected, divided, and sutured to any available cutaneous nerve ending in the hand. The groin flap can provide skin cover for any defect on any aspect of the hand or of the forearm in its distal two thirds. It can safely be made wide enough to replace massive loss, with the only drawback being that the widest secondary defect that can be readily closed directly is about 12 cm. For defects on both aspects of the hand, the flap can be split longitudinally or used in conjunction with a hypogastric flap, a tensor fascia lata musculocutaneous flap, or a contralateral groin flap. Where a relatively large block of bone is required in the hand in the depths of a soft tissue defect, the iliac crest immediately beneath the flap can be taken as a vascularized composite extension,[10,89] although the bone taken with the superficial circumflex iliac artery does not have as good a blood supply as when taken on the deep circumflex iliac artery.

In planning the groin flap, a pattern of the primary defect should be made first. It is next decided from which direction the flap should approach the defect. For example, for defects primarily on the dorsal aspect of the wrist, the flap pedicle could lie to either the radial or the ulnar side. Time should be taken with this decision, for the obvious choice is not always the correct one. Factors to be considered are the precise location of the defect, the resulting configuration of the tube pedicle, the freedom of pronation and supination of the forearm, and the patient's comfort and exercise postoperatively. The major fact to be appreciated with respect to the configuration of the pedicle *is that it will do well if it is stretched gently and will do poorly if it is kinked*; flaps always perfuse more satisfactorily on a convex surface than on a concave one. To take another example, a defect on the dorsal aspect of the hand extending on

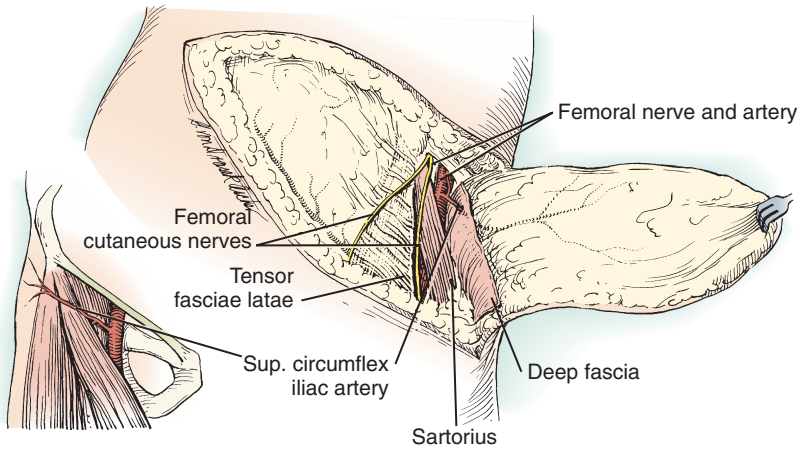

FIGURE 44.39 Groin flap. The groin flap is based on the superficial circumflex iliac artery, which runs parallel to and approximately 1 inch inferior to the inguinal ligament. It emerges through the deep fascia as it crosses the sartorius and breaks up into branches at the level of the anterior superior iliac spine. When the flap is raised, the lateral femoral cutaneous nerve should be preserved or, in certain instances (see text), divided and repaired. The fascia that is divided at the lateral margin of the sartorius can be seen. (From the Christine Kleinert Institute for Hand and Microsurgery, Inc., with permission.)

to the radial border might be best approached by a pedicle around the ulnar border, for full pronation and supination would place little stress on the suture line and would not kink the pedicle. The previously prepared pattern can be extended with a portion to represent the pedicle so that various approaches and positions can be tested. Once the approach and eventual position have been chosen, that edge of the primary defect that will be closest to the pedicle will be known. The original pattern should be laid on the skin immediately below and behind the anterior superior iliac spine, for the more medial, inguinal portion of the flap will largely be used to construct the tube.

A few words about constructing the tube are appropriate at this juncture. Two extreme possibilities should be considered. If a flap is not tubed at all, its distal and lateral margins can be made to fit precisely to the primary defect. The other margin of the defect, adjacent to the pedicle, has to be left unsutured, but the eventual contour of the flap to the hand is excellent, without revision. At the other extreme, if the flap is raised as a rectangle and tubed throughout its length, it could cover a circular defect, but it would approach the defect perpendicularly and would be most difficult to inset after division. Because the first (untubed) flap is unacceptable because of the open wound, poor flap fixation to the defect margins, and difficulties with postoperative exercise, and the latter is unacceptable because of contour, a compromise must be sought. The distal margin of the flap is cut to conform to the edge of the distal half of the defect. When this design is tubed, the distal few centimeters of the lateral edges of the flap come to meet the edge of the proximal half of the defect. After division of the flap, there will be too much skin at the proximal margin, which will require excision as dog-ears at the time of division or at a later stage. The surgeon's ability to tube the groin flap depends on the width of the flap, but also on its thickness. Because its axial vessel emerges through the deep fascia, the flap cannot be thinned appreciably in the part to be tubed, except at the margins. Thus, in choosing the width of the flap, the surgeon must pay heed not only to the width of the primary defect but also to the weight-height ratio of the patient. If this is high, the flap will be thick and must therefore be wide. Skin grafts may be necessary to close the secondary defect, but it is best to do everything to avoid having to skin graft the donor site. It is difficult to get a graft to take in this location, and it leaves a significant soft tissue defect in the side.

Once all these factors have been considered and the patient is prepared and draped, the midline of the flap is drawn out 2 cm (or two fingerbreadths) inferior and parallel to the inguinal ligament. In children, this vessel can be located by measuring below the inguinal ligament by a distance equal to the breadth of the child's index and middle fingers. In most patients, the circumflex iliac artery can be identified in approximately the midanterior thigh with a pencil Doppler, which aids in centering the flap. The elected width of pedicle to be tubed is measured out as far as the anterior superior iliac spine, and the distal, lateral margin of the flap is made to conform to the distal half of the pattern of the primary defect. The part of the flap to cover the primary defect can be wider than the pedicle. There must be a limit to the extent by which it can be wider, but this is not a problem in normal practice. The entire margin of the flap is incised down to the superficial surface of the deep fascia. The distal edge of the flap is placed under tension, and the subcutaneous plane is developed with a knife as far as the anterior superior iliac spine, making sure not to create a cave beneath the midportion of the flap. At this point, the flap is laid in a cephalad direction, and retraction is applied to the inferior incision. The deep fascia is incised at the level of this inferior incision and retracted toward the abdomen to reveal the sartorius, the tensor fascia lata lateral to it, and the intervening intermuscular septum. While the surgeon maintains traction on the flap cephalad and away from the thigh, the deep fascia is divided in the line of the fibers of the sartorius from inferior to superior and, at its lateral border, just medial to the septum between the tensor and sartorius. As this incision in the deep fascia proceeds, the subcutaneous plane previously developed laterally is advanced to meet it. The superficial circumflex iliac artery will be seen in the deep fascia as it is lifted from the sartorius. Incision of the fascia proceeds cephalad beyond the artery as far as the origin of the sartorius from the anterior superior iliac spine. Here the flap is drawn in the opposite direction, caudally, to facilitate dissection of the upper margin. The upper incision, if carried down to the external oblique aponeurosis, will, in the majority of cases, divide the superficial inferior epigastric artery. The flap is retracted caudally off the aponeurosis until the level of the anterior superior iliac spine is reached. The incision previously made in the sartorius fascia is located and turned medially to free the deep fascia of the thigh from the inguinal ligament. In the course of this incision, the lateral cutaneous nerve of the thigh will be encountered. Care must be taken not to injure this, for meralgia paresthetica may result.[75] Although this nerve usually passes deep to the vessel of the flap, in which case it can be freed by dissection, on occasion, it or one of its usual two branches may be superficial and is therefore more likely to be injured and also more likely to kink the vessel of the flap. Any such branches superficial to the artery are divided, placed deep to the vessel, and repaired. All fascial incisions are now completed.

It should be noted that it is possible to raise a groin flap without ever dividing either the fascia or the vessel. However, the consequences may be dire, for the superficial circumflex iliac artery is tethered by the intact fascia. The relaxed and redirected flap pulls on the vessel and may kink it severely (Figure 44.40). Herein lies the explanation for necrotic edges on otherwise well-designed and well-executed groin flaps. The fascia must *always* be incised.

Applying upward traction to the flap, the fascia is dissected from the underlying fibers of the sartorius, paying heed to the vessels, which can sometimes be seen through the elevated fascia. In preparing a pedicled groin flap, dissection can cease at the medial border of the sartorius (Figure 44.41, *B*). In dissecting for free tissue transfer, or where the flap is to be taken to the opposite hand, the pedicle is dissected further, using scissors and forceps. The main hazard is the muscular branch of the superficial circumflex iliac artery. This is isolated by retracting the sartorius laterally with instruments on either side of the pedicle, caudad and cephalad. Once dissected free under loupe magnification, the muscular branch is divided. The pedicle can then be freed as far as its origin.

The flap can now be thinned. This is done by having an assistant hold the flap vertically with hooks or stay sutures and proceeding with curved tenotomy scissors and forceps. Using the scissors with the concave surface uppermost, the surgeon

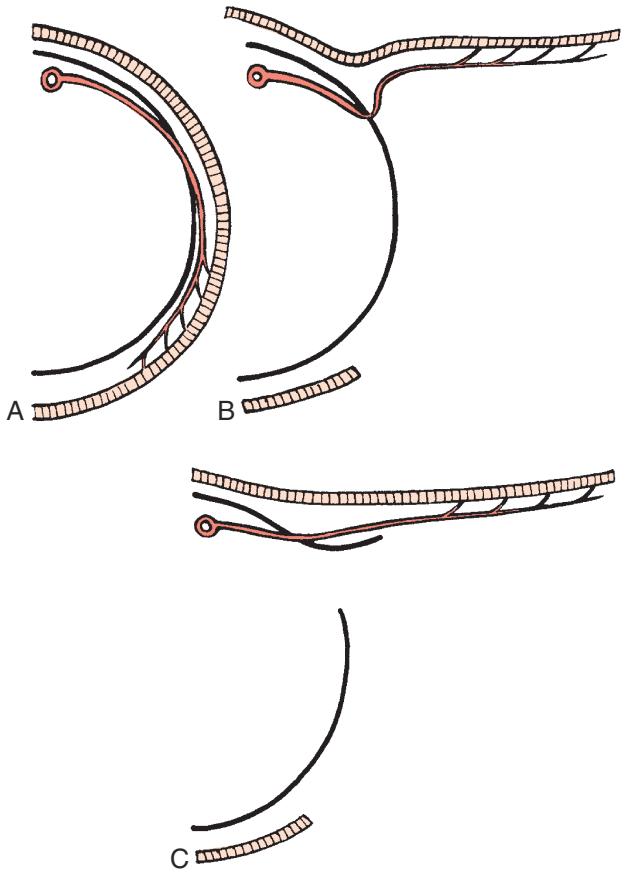

FIGURE 44.40 **A,** In cross-sectional diagram, the course of the superficial circumflex iliac artery is shown. The *black line* represents the deep fascia, and it can be seen that the superficial circumflex iliac artery pierces that fascia. **B,** If the flap is raised without dividing the fascia, the vessel is restrained and kinked by that deep fascia, reducing significantly the blood flow to the flap. **C,** If the fascia is divided, as recommended, at the lateral margin of the sartorius, this kink in the vessel is eliminated.

can thin the flap quite radically at the margins by trimming away fat. In the midline of the flap, the surgeon must be more cautious, or the pedicle may be damaged. Lobules of fat can be lifted with forceps and trimmed away, between periphery and midline, but the deep fascia that has been lifted *must not be transgressed*. Therefore, any fat that lies between it and the skin must be left alone. If there is a significant amount, it makes the tube necessarily bulky.

Closure begins at the lateral end of the secondary defect. It may be difficult, *but the surgeon should not undermine the margins in an attempt to facilitate closure*. Such action only increases the area of the potential dead space and does little to relax the skin. Instead, the surgeon should flex the thigh, take up a heavy suture, and proceed with the knowledge that closure is always possible if the defect was 12 cm or less when first outlined (see Figure 44.41, *C*). (The tension created will inevitably result in postoperative inflammation along the closure. Do not remove sutures for an inflamed wound. To do so would open the entire cavity created by the closure. If this then becomes infected, as is almost inevitable, one has created a disaster akin to a bedsore.) Closure of the secondary defect could continue medially all the way to the pedicle. However, a more comfortable closure is achieved if, in the last few centimeters, the flap is resutured from whence it came. Where these three suture lines meet, the tubing of the flap commences. This should be easily achieved, provided the width has been well tailored to the thickness. If it has not, further marginal thinning should be done. The tube is closed with interrupted sutures. The closure continues until the portion of flap remaining open for the defect is clearly too small. That is, the tube is closed too far. The reason for this is that once the flap is sutured to the hand, it is simple to release sutures from the tube but very awkward to insert them. The limb is now brought to the flap, the planned posture adopted, any minor adjustments made, and the flap sutured in place. It is good to commence this at the center point of the distal margin of the flap and then proceed progressively around both margins alternately toward the pedicle. In this way, little or no distortion is applied to the flap. With each stitch, the skin of the flap is stretched slightly to reproduce tension similar to that present in the margin of the defect. Whether or not this has been done correctly can be determined by looking at the wound edges between each stitch: neither should sit above the other.

On completion of application of the flap, the involved limb is immobilized. It has been suggested that this be done with external fixation between the iliac crest and the radius,[77] but this is not necessary and is disadvantageous if it limits motion of the hand throughout the period of flap attachment. Temporary control can be achieved by placing rolled bandages between the limb and the torso and then strapping the arm in place with tape from the abdomen, around the arm, to the back. The intent of this strapping is to control the arm in such a way that the flap is not kinked; indeed, it is held under gentle traction.

Care must be taken that the flap is not disrupted during recovery from anesthesia. Aside from the surgeon being present during this critical phase, another useful maneuver is to have the anesthesiologist do a brachial block just before awakening the patient. This minimizes stress on (and possible disruption of) the flap suture line during the occasionally turbulent immediate postanesthetic phase. It may be best to perform the block prior to placing the flap so that the arm may be properly abducted to allow the anesthesiologist access to the axilla.

Once the patient has fully recovered from anesthesia, on the first or second postoperative day, all restraints are removed, and the patient is placed in charge of his or her own flap. Clear instructions are given to maintain a little traction and avoid kinking the flap. The patient is shown how to exercise all joints. By depressing the shoulder and carrying the hand toward the umbilicus, the elbow can be flexed to 90 degrees. By elevating the shoulder and carrying the hand toward the knee, it can be fully extended. Taking excess flap to allow tubing of the flap will allow the patient more motion and hopefully prevent stiffness (Figure 44.42). Full pronation and supination, flexion and extension of the wrist, and motion of all the digital joints can be attained, and should be, every waking hour. It is in this respect that the axial flap with its tube pedicle is incontestably superior to even the best-designed random-pattern flap. Patients can be dressed soon after surgery by wearing either jeans or trousers with a pocket removed and a fastening incorporated in the waistband above the pocket.

The groin flap can be used in young children with no increased incidence of flap avulsion during the postoperative period. Unless unforeseen circumstances are encountered, the

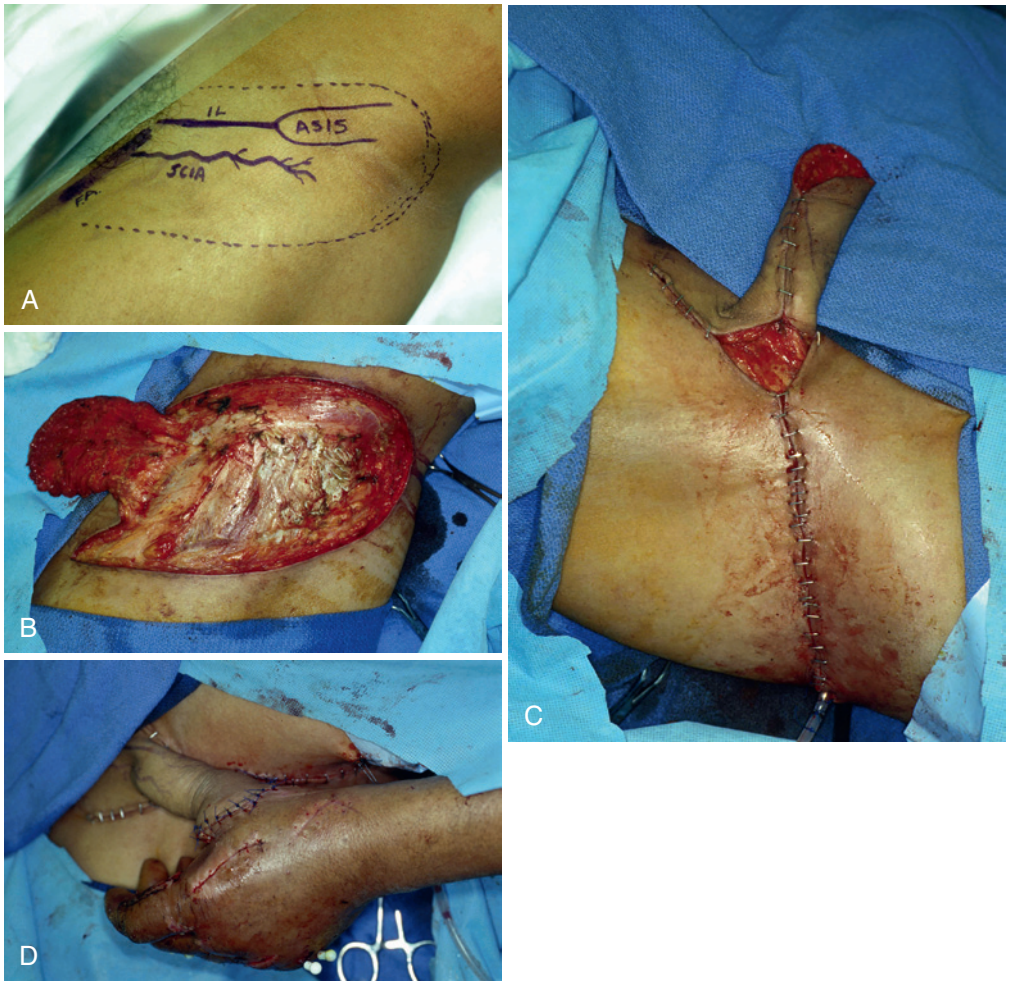

FIGURE 44.41 **A,** Markings for elevation of a pedicled groin flap. The center of the flap is located approximately two fingerbreadths below the inguinal ligament and the pedicle can be located here with a pencil Doppler. **B,** Flap after elevation. The dissection becomes suprafascial at the lateral border of the sartorius to avoid damage to the pedicle. **C,** The donor site has been closed primarily, and the flap has been tubed. This is done prior to inset. **D,** The flap after insetting on the hand.

FIGURE 44.42 Pedicled groin flap with long tubed section. This is ideal in order to allow for motion of the arm and forearm.

complete survival of the groin flap can be predicted with sufficient confidence that the practiced exponent should not hesitate to undertake extensive reconstruction in the bed of the primary defect, including joint replacement and tendon grafts.

Problems with circulation are understandably more likely to arise after division of the pedicle, for the flap, previously nourished by an axial vessel, is now dependent on flow across the lines of attachment. The optimal time at which to perform the division varies considerably, as shown by fluorescein studies.[70] The first requirement for safe division is perfect healing of the line of attachment. The second requirement is that the line of attachment be long when compared with the area of flap skin required on the hand. This is not so, for example, when much or all of the tubed pedicle is required for later use. Division of such a flap should be preceded by a delay procedure. The third requirement is that the surrounding skin of the limb be supple and unscarred. If all these requirements are met, the flap can be safely divided at 3 weeks and inset. If these criteria are not met, then one or more of the following steps should be taken. First, wait. No harm comes from a longer attachment. Second, test the flow. This is done by placing a rubber tourniquet around the tube pedicle and testing whether flow to the flap remains good. Flow can be assessed by the use of systemic fluorescein or by injecting atropine into the flap and measuring the time until the onset of visual disturbance. It may also be assessed by the simple clinical test of sticking a needle into the flap or observing whether reactive hyperemia develops in the flap after 20 minutes

of occlusion. Third, if the flap is divided, and bleeding from the flap on the hand is poor, do not inset it, but simply wrap the hand and return 1 week later, at which time any nonviable portion of the flap can be débrided and the flap inset. Fourth, and this is our routine practice when the tube pedicle is needed to cover a later digital transfer, perform a delay procedure. This is done under local anesthetic and consists of making an incision halfway around the tube pedicle, through which all deep soft tissue in the tube is divided. The wound is closed and the flap divided completely and with confidence 1 week later.

CRITICAL POINTS *Pedicled Groin Flap*

Indications
- Wounds of hand and/or forearm
- Especially when later toe transfers are to be considered

Preoperative Evaluation
- Absence of scars in groin in area of flap to be raised
- Doppler superficial circumflex iliac artery 2 cm below inguinal ligament

Pearls
- Center flap over Dopplered vessel (2 cm below inguinal ligament)
- Make flap longer than needed to allow some elbow/shoulder motion
- Tube excess flap at base
- Suture flap into as broad an area as possible of the wound to increase revascularization

Technical Points
- Begin dissection laterally; stay out of deep iliac fat
- Once over muscles, stay right on muscle
- Vessel may often be identified in depths of flap visually
- Take fascia of sartorius to avoid damage to vessel
- Stop dissection just at medial edge of sartorius
- May safely thin fat from margins of flap
- Close donor site securely *prior* to insetting flap into defect (flex hip)

Pitfalls
- Damaging vessel with elevation (dissection is too superficial)
- Making flap too small (no pedicle for tubing)
- Dehiscence of flap from wound in recovery room
- Dehiscence/infection of donor site

Postoperative Care
- Carefully protect flap until patient is fully awake, to avoid dehiscence
- Suture hand to abdominal wall with large suture
- Strap arm around torso
- May remove protection once patient is fully awake
- Encourage as much motion of elbow and shoulder as possible
- May divide flap in 3 to 4 weeks
- Must have healing of margins of flap to defect of hand
- May perform delay procedure of flap prior to division
- At time of division, if proximal flap (at site of division) is dusky, do not attempt closure (débride nonviable tissue after demarcation and close)

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Defects of the Hand and Forearm

Most experienced reconstructive surgeons feel that definitive skin cover at the time of injury is preferable to delayed closure, provided only that débridement is adequate. As is evident from the earlier account of local, regional, and distant flaps, all with both random and axial designs, we have a rich storehouse from which to select that skin cover. If one has microsurgical training, to that store must be added all the free tissue transfers described elsewhere in this book. However, for younger surgeons, these riches may be a source of confusion, causing them to make less than the best choice or, worse, to disregard or remain ignorant of the older techniques in favor of the more complex and more expensive, but more exciting, free skin transfers. In an attempt to offer guidance, we approach the matter of skin cover not from the viewpoint used throughout this chapter (namely, which flaps are available) but rather by the nature of the presenting skin defect (Table 44.3). We have assumed in all that

TABLE 44.3 Author's Preferred Methods for Specific Situations

Region	Palmar Injury	Dorsal Injury, Larger Defects
Distal to PIP joint	Loss more dorsal: "V-Y" advancement	Reversed cross-finger
	Loss more palmar: middle or ring finger–digital artery island flap	Dorsal skin "V-Y" advancement
	<40 years of age	
	Cross-finger	
	Digital artery island	
	>40 years of age	
	Not important: revise amputation	
PIP joint	Cross-finger	Reversed cross-finger
Proximal phalanx	Small defect: transposition from lateral aspect	Reversed cross-finger
	Large defect	
	Palmar alone: cross-finger	
	Plus lateral	
	Index or middle finger: axial flag	
	Ring or small finger: vascular island	
MP joint	Index or middle finger: axial flag	Index or middle finger: axial flag
	Ring or small finger: vascular island	Ring or small finger: vascular island
Metacarpus or several fingers syndactylized	Worthless digit: fillet	Worthless digit: fillet
	Small defect:	
	Vascular island	
	SDMA	
	Large defect (free lateral arm)	Free lateral arm
	Forearm fascia plus skin graft	Anterolateral thigh free flap
Thumb	Loss more dorsal: "V-Y" advancement	FDMA from index
	More palmar:	Forearm (preferably PIA)
	<2/3 pulp: Moberg	
	>2/3 pulp	
	Neurovascular island from toe	
	No donor digit, no microsurgical skills	
	FDMA or SDMA	

FDMA, First dorsal metacarpal artery; *MP*, metacarpophalangeal; *PIA*, posterior interosseous artery; *PIP*, proximal interphalangeal; *SDMA*, second dorsal metacarpal artery.

follows that the possibility of a free skin graft has been weighed and rejected. We look at defects on the fingers separately from those on the thumb, and palmar defects apart from dorsal defects. Dorsal defects can be subdivided further into small and large defects. All small dorsal defects we manage by transposition or rotation flaps taken from either the adjacent dorsal skin or the lateral aspect of the fingers. Wounds over the distal dorsal finger can be usually managed by advancement of the dorsal finger skin as noted above.

Palmar defects distal to the PIP joint are most commonly fingertip injuries.[41] The great majority of these injuries can be managed by allowing secondary healing; however, in such injuries in which more skin is lost dorsally or the amputation is transverse, a "V-Y" advancement flap (Atasoy) may be indicated. When more is lost from the palmar surface, a regional flap is required. In patients who have sustained an injury to the middle or ring finger, the digital artery island flap is the best option. With injury to the index or little fingers, one of the other regional flaps should be selected. A cross-finger flap may be the best option in this circumstance. In those older than 40 years, if the digit is of considerable functional importance, for example, the thumb or a finger where others have been lost, a neurovascular island flap may be justified, with a microvascular toe pulp transfer the preferred choice. When the digit is of less importance, we explain the thoughts outlined earlier to the patient and recommend revision of the amputation. If he or she balks, we proceed as if the patient were younger than 40 years, knowing that he or she understands the potential problems. On the dorsal aspect of the finger distally, if the defect is sufficiently large that we cannot use a local flap, a reversed cross-finger flap is indicated. Defects around the PIP joint we cover with cross-finger flaps, a conventional flap for the palmar surface and a reversed flap for the dorsal surface.

Small defects on the palmar aspect of the proximal phalanx, as are produced in releasing burn contractures, require transposition flaps from the lateral or dorsal aspect of the finger, as described by Green and Dominguez[34] and by Harrison and Morris,[36] respectively. Larger defects that are confined strictly to the palmar surface can be covered with an extended cross-finger flap. For defects that extend onto the lateral aspect to any great extent, we find it difficult to use a conventional cross-finger flap for cover and fear problems with kinking of the pedicle. In such circumstances, the axial flag flap is ideal for defects on the index and middle fingers. However, the vessel of the flag flap is not always reliable in the third and fourth web spaces. We listen for it there with a Doppler. If a vessel cannot be heard, we take a vascular island from the adjacent digit, as described by Rose.[91] For dorsal defects over the proximal phalanx, we prefer an axial flag flap in those digits with a demonstrable vessel, for the quality of the skin is identical to that lost. In others, the reversed cross-finger flap is adequate.

Palmar defects around the MP joint, as with palmar-lateral defects of the proximal phalanx, do well with an axial flag flap, taking care to ensure that the injury did not damage the pedicle. When the vessel cannot be heard, we employ a vascular island. Dorsal defects should be treated similarly. Thus, for example, for full-thickness loss over the middle MP joint, we might use an axial flag from the proximal phalanx of the index finger; for loss over that of the ring finger, an SDMA flap or a vascular island from the small finger might be used.

Injuries over the metacarpus are to the palm or dorsum of the hand. Although skin loss from several adjacent digits over the proximal phalanx can usually be covered by multiple local and regional flaps, on occasion this is not possible, and they should be considered as one large defect and managed as if at the metacarpus. The defects on the digits are temporarily covered by suturing their adjacent margins, thereby creating a syndactyly, which is later divided. Small defects in the palm can be covered with an SDMA flap or a vascular island. This may be in the form of a fillet flap when a vascularized digit is deemed of no functional value. This solution is also applicable to dorsal defects, a situation most commonly encountered in gunshot wounds. For larger defects on either aspect of the metacarpus, we use a free lateral arm flap: fasciocutaneous when its subcutaneous layer is not too thick; fascial when it is. If microsurgical expertise is not available, a pedicled fascial radial forearm flap (covered with a nonmeshed split skin graft or full-thickness skin graft) can be used for palmar defects.[26] For most defects of this location and size, we adopt a reversed radial forearm flap, using the fascia alone or an ulnar artery flap when the cosmetic defect of a fasciocutaneous flap would be distressing. For dorsal defects of the metacarpus, a forearm flap is similarly appropriate, the reversed posterior interosseous artery flap being preferred to the radial artery flap, provided that the vessel is present. For coverage of larger wounds in the hand, and in the absence of microsurgical skills, we believe that the groin flap remains an excellent choice for skin cover. This flap has none of the potential cosmetic and vascular problems that exist with the forearm flap. In practice, however, the groin flap is especially useful for those circumstances in which later microsurgical reconstruction is planned and we know that the skin of the tube will be needed to give additional cover, for example, a later toe transfer.

For dorsal defects on the thumb, we raise an FDMA (Kite) flap from the dorsal aspect of the proximal phalanx of the index finger. When that is not available owing to the extent of injury, we use a reversed PIA flap; if no vessel can be found, we use a radial forearm skin or fascial flap. Tip amputations in the thumb with more loss dorsally require a "V-Y" advancement. Those with loss that is more palmar but is less than two thirds of the pulp are ideal for a Moberg advancement or some variant thereof. When the entire pulp is lost, we replace it with a neurovascular island flap, preferably as a microvascular transfer from the toe. Today, we would rarely perform a pedicled neurovascular island flap from another finger. If no donor digit is available, usually when an island transfer is judged unsuitable for a particular patient, an FDMA or SDMA flap must be used.

Circumferential degloving injuries of the thumb require immediate cover with either a pedicled axial groin flap or an immediate great toe wraparound flap. We usually will perform a groin flap prior to any type of toe transfer, to avoid having to take too much skin from the foot. Toe-to-hand transfer and pollicization both require more skin than that needed simply to cover the primary defect on the thumb. Degloving of a single finger, in the presence of other normal digits, requires amputation; a ray amputation is needed when the degloving involves the proximal phalanx. When several digits have been degloved, we cover them all with a tube pedicle groin flap or pedicled radial forearm flap. Thereafter, for short stumps, we remove the

skin of the flap and skin graft the soft tissue over the stumps. In longer fingers, we leave the flap in place and the digits are used as a mitten. These can be separated only if the blood supply is improved. We have done this by transferring a neurovascular island, either from the foot or from the thumb, if an arteriogram shows the presence of two sufficiently long digital vessels in that digit.

For defects of the wrist, forearm, and elbow, we prefer free tissue transfers, because the patient is not immobilized and a permanent pedicle is provided to the skin cover.[31] We use the lateral arm flap for small defects, the anterolateral thigh[119] or scapular flap for medium ones, and the tailored latissimus flap or anterolateral thigh flap for large ones.[33] When these are not indicated or available, the groin flap can reach defects of both dorsal and palmar aspects as far proximally as the midpoint of the forearm. The pedicled latissimus dorsi flap can reach the elbow with ease and the forearm with difficulty. Defects of the proximal half of the forearm, where no local flaps suffice, can be covered with a pedicled rectus abdominis muscle flap, or, better, an anterolateral thigh fasciocutaneous flap or latissimus dorsi free muscle flap.

The first web space is the remaining specialized region worthy of mention. Contracture here is common, both of congenital and traumatic origin, and the solutions are numerous.[61] We release relatively long yet tight first web contractures, which are composed of normal skin, with a simple 60-degree "Z"-plasty or some variant thereof. When the web is shorter and the tight web margin produces an acute ridge angle, a four-flap "Z"-plasty works well. In other circumstances, when the skin is scarred or the adduction contracture is severe, skin must be brought into the web space by transposition from the dorsum of the thumb or index finger or by rotation from the dorsum of the hand. When these do not suffice or the donor sites are themselves scarred, other skin must be used. It is important that this skin be as thin as possible, for it is pointless to dig a hole, the web space, and promptly fill it with a fat flap. The lateral arm free flap is the best choice to fill a severely scarred first web. The lateral arm flap placed in the first web space can be small enough to primarily close the donor site and fits the defect after release of the web space well, and vascular access for anastomosis is easily obtained with the radial artery and cephalic vein in the snuffbox. If microsurgical skills are not available, then the posterior interosseous or radial forearm fasciocutaneous flaps can be used, donor site issues notwithstanding.

Chemotherapeutic Extravasation Skin Loss

The injury that created the primary defect is of significance mainly when its nature makes it difficult or impossible to define the extent of eventual skin loss. One instance of clinical significance is the chemical injury resulting from extravasation of chemotherapeutic agents, of which the most common is doxorubicin hydrochloride (Adriamycin). Identification of the agent in the tissues has been the subject of some debate.[17,20] However, all are agreed that wide excision of all potentially damaged tissues should be undertaken. A period of observation before applying definitive skin cover has been recommended.[60] The cover eventually chosen should be robust. In this situation, we prefer the ulnar forearm flap for the reasons outlined earlier. If this is unavailable, free tissue transfer is probably the procedure of choice.

Postoperative Care

Postoperative care is directed toward the comfort of both patient and flap and is the responsibility of a team of trained, trusted nurses. The comfort of the patient is pursued through the usual channels and should not be neglected because of concern for the flap. It is important that the patient be up and about as soon as possible, preferably starting on the first postoperative day. All joints are mobilized. Comfort of the flap is achieved mainly by avoiding kinks in its pedicle if the patient has been treated with a pedicled groin flap. This is ensured by correct positioning of the involved upper limb and of the patient. Once the correct position is attained, other patient positions that similarly avoid kinking should also be sought. If conscious, the patient is shown which part of the flap to inspect for kinking and which positions are acceptable. The earlier the patient takes charge of the flap, the better. If the patient is not conscious, the position must be maintained by strapping. Skin-to-skin contact produces maceration and the chance of consequent infection. Therefore, padding is used to ensure that all skin surfaces are exposed to air. A routine of wound cleansing is established, using hydrogen peroxide followed by a thin smear of antibiotic ointment. This routine has many benefits. It eliminates a nutritious medium for bacteria. It ensures that color assessment is neither obscured by blood staining nor impaired by vivid contrast within the observer's visual field. It permits assessment of the rate of bleeding from the wound, in itself a valuable index of venous insufficiency. Finally, it has an inestimable effect on the morale of the patient who can see the wound.

Flap Failure

Flaps fail for a number of reasons, some of which are still debated.[50,100] Therefore, having made the patient and the flap comfortable, the nurse observes the flap regularly to ensure its continued good health. There are several steps in this process.

1. *Observe the color of the flap.* Difficult to learn and impossible to convey adequately, color assessment remains a mainstay of care. The lighting must always be good. The observer can start by neutralizing his or her color perception by looking for 10 seconds at an area of normal skin, similar to the flap. He or she then assesses the flap. The random-pattern and axial-pattern flaps differ in their color. A healthy random-pattern flap is pink. If arterial supply is inadequate, it becomes pale with a faint blue-gray tinge. If venous drainage is occluded, it is first an angry red and then progressively purple-red and purple-blue. The axial-pattern flap, especially the groin flap, is pale to a degree that makes the novice nervous. It is not a pure white, as can be detected by comparing it with a sheet of white paper, but rather a very pale pink. Changes in a failing flap are much more rapid and dramatic in the random than in the axial pattern. Within 48 hours, the failed portion of a random-pattern flap becomes cyanosed and then blistered, and the margin between the part that will fail and that which will survive is represented by a clear line. The sick axial flap at first assumes a waxy pallor, white tinged with yellow or brown, that differs from its healthy pink pallor by a margin so subtle that only the experienced are pessimistic. The failed

margin then becomes indurated and may blister, but doubts concerning the extent of loss persist for as long as a week.

2. *Observe the refill after blanching by fingertip pressure or by running a blunt point across the flap*. If refill after blanching is slow and the flap is pale, arterial insufficiency is the likely cause. Very slow refill may be seen in a flap with no flow whatsoever, owing to the movement of stagnant blood by surrounding tissue pressures. If it is too swift and the flap has a bluish hue, venous outflow is impaired. This may be caused by kinking and should be corrected. Kinking of a flap pedicle is similar to strangulation of bowel. In both cases, the pressure is not high enough initially to occlude the arterial flow, but it impedes the venous drainage. The occluded area therefore becomes engorged, and tissue tension rises to a point at which arterial inflow is finally arrested and the tissue dies in engorgement.[108]
3. *Measure the temperature of the flap.* This may be done with the dorsum of the middle phalanx of the observer, comparing the flap with tissue adjacent both to the pedicle and to the primary defect. A marked difference is a significant index of impaired flow. When there is little or no difference, it cannot be concluded that the flap is undoubtedly well, however, for the warmth may be largely or entirely transmitted from the underlying bed.
4. *Stick the flap and adjacent tissue with an 18-gauge needle or a No. 11 scalpel blade*. Take care to go to the same depth, and observe the bleeding. Although this cannot be done repeatedly, it is permissible when the first three clinical tests leave serious doubt. A healthy flap should yield blood of the same color as the control and should bleed just a little longer. If no bleeding occurs or does so only briefly, arterial inflow is inadequate. If the blood is darker and bleeding persists much longer, there is venous congestion. For the same reason, persistent bleeding from the marginal wounds of a flap indicates venous inadequacy.

Many more complex tests of flap viability have been introduced. They fall into three broad categories: detection of an alteration in local tissue constituent, observation of the presence in the flap of systemically administered agents, and monitoring of pulsatile flow within the flap. These generally have little application in pedicled flaps, as problems with pedicled flaps are more usually due to poor design that is not amenable to surgical intervention. Although a pedicle flap can certainly undergo kinking or can be sutured in so that flow is compromised, these problems are usually apparent very early on and can be addressed. In most cases, however, there is little need to monitor pedicled flaps; they will either survive or they will not, primarily depending on the appropriateness of their design. A few problems can be seen later on, however, and their management is discussed in the following.

Salvage of a Failing Flap

What actions can be taken to salvage a failing flap?

1. *Seek and eliminate any kinks in the pedicle.* Multiple small kinks produce an accordion-like appearance and are equally as harmful as one large obstruction. Flaps do best if they lie on a convex surface and are gently stretched, thereby eliminating all possible occlusion and reducing edema to a minimum. This should be explained to the patient at an early stage so that he or she can take care of the flap in the case of pedicled flaps.
2. *Check the patient's general condition.* Hypotension, cardiopulmonary impairment, or a low circulating volume as revealed by urinary output may all affect oxygenation of the flap. Cold extremities may be caused by circumstances as grave as advanced shock or as simple as a low room temperature. Both should be evaluated and corrected.
3. *Look for signs of hematoma and evacuate if found.* Whenever the possibility of hematoma exists, the surgeon should have inserted a drain underneath the flap. Ensure that it is functioning. If no drain is present, the flap is swollen and discolored, there is persistent serosanguineous oozing from the flap wounds, and edema is revealed by pitting on pressure, a hematoma is likely. This has been shown to cause loss of a flap, but it can be saved by evacuation of the hematoma.[76] The use of a Penrose or a small, flat Silastic drain often allows expression of the hematoma via the drain site at the bedside (if it has not been sutured too tightly), which can improve a potentially bad situation. If the hematoma is larger, it should be evacuated in the operating room as a formal procedure.
4. *Look for unduly tight stitches and release them.* This should be done only by the operating surgeon, for only he or she knows their significance.
5. *Reposition the patient.* Determine in particular whether elevation or dependency of the limb improves the flow. If it does, make the patient comfortable in this new position.

There are as many publications in the literature concerning methods of enhancing flap survival as there are of monitoring it, possibly more. They appear to be equally fruitless. Once again, they fall into three main categories: alteration of the environment, physical applications, and administration of drugs. In the end, the surgeon is left with the knowledge that the only way to ensure that a flap will survive is to follow simple rules: assess the primary defect carefully, select the correct flap for that defect and execute it properly, and train nurses who can be trusted to protect and care for the work.

Free Flaps to the Hand and Upper Extremity

Neil F. Jones and Graham D. Lister

In contradistinction to a split-thickness or full-thickness skin graft, a flap receives its blood supply independent from the underlying bed on which it is laid. An *axial-pattern flap* derives its circulation through an inflow artery and an outflow vein, which is termed the *vascular pedicle*. When this pedicle of an axial-pattern flap is divided, the flap becomes a *free flap*. Alternative terms include *microsurgical free flap*, *microvascular flap*, and *free tissue transfer*. A free flap is any segment of skin, fascia, muscle, or bone, or composite combination of some of these tissues, that is completely detached from its donor site and transferred to a distant site and for which the blood supply is immediately restored by microvascular anastomoses of its inflow artery and outflow vein to recipient blood vessels in the vicinity of the defect. More than 40 years ago, the first successful free tissue transfers[26] were allied to a new understanding of the axial pattern of certain vascular territories. Published review articles have since attested to the rapid and continuing growth in the number and variety of such free tissue transfers, throughout the body and specifically to the upper extremity.[31,33,94,102]

INDICATIONS

The general indications for flap coverage (see Chapter 44) are (1) a defect with exposed joint cartilage, bone devoid of periosteum, or tendon devoid of paratenon that cannot support the neovascularization of a skin graft and (2) a defect at any specific location in which a skin graft might be subject to exposure and repeated ulceration or might impair later reconstruction.

But why use a free flap, which is the most complex technique in the reconstructive hierarchy? Local or regional flaps to the hand have a distinct advantage in that they provide skin of similar color, texture, and thickness and do not require a donor defect elsewhere in the body. However, they are limited in their size and availability. The larger the primary defect created by injury or excision, the less local skin remains to provide flap coverage. Even when the area is large enough, the thickness required to fill a defect is often lacking. Furthermore, raising a local flap inflicts additional injury on the traumatized limb. The resultant compound wound may impair hand function more than the initial defect.

If not local flaps, are there disadvantages to distant pedicle flaps? Distant pedicle flaps (e.g., the groin flap) can provide sufficient tissue for all but the most massive defects. However, circumferential defects are difficult to cover; the hand must be dependent during attachment; positioning may be uncomfortable; lack of exercise may result in more joint stiffness; the flap may be avulsed by a young or an uncooperative patient; and the thickness of the tube presents a later problem of inset and contour. Most importantly, a pedicled flap is no longer supported by its vascular pedicle after division, and the flap becomes something of a parasite, obtaining nutrition from the underlying scarred bed. In contrast, a free flap has a permanent vascular pedicle. Although the contention that a flap brings a new blood supply to relatively avascular tissue is fallacious, certainly at the time the flap is applied and probably in the long term, there is merit in the fact that it will not place additional vascular demands on the area of the defect, further compromising the limb. There is a strong similarity between tissues adjacent to a major wound and those that have been irradiated. The advantage of a "permanent pedicle, blood-carrying flap" in coverage of radiation ulcers was shown many years ago.

Free flaps offer an attractive alternative to the limitations of conventional techniques of skin coverage. They are now available in virtually any size and thickness and may be cut to fit the defect with incomparable precision. They permit elevation of the limb and early mobilization and are relatively unaffected by random movement in the infant or disoriented patient.

CONTRAINDICATIONS

Free tissue transfer in its early years was a lengthy, unpredictable undertaking. In one series of over 500 cases performed in Ljubljana between 1976 and 1983, only 12 of the first 100 free flap procedures took less than 6 hours to complete.[41] By contrast, 92 of the last 100 were finished in less than 6 hours, 24 of them in less than 4 hours. The failure rate in the first 100 was 26% and in the last 100, 4%. Similar survival rates have been reported from other centers. Free tissue transfer is now a relatively rapid and highly reliable procedure when performed by an experienced team.

Free flaps are equally successful in both pediatric and elderly patients.[54,108,125] The youngest patient on whom the authors have performed a free tissue transfer was 9 months of age; the oldest, 87 years. Both have done well, with no complications attributable to their ages. There were only 2 failures in a recent series of 433 free tissue transfers in children, a success rate of 99.8%.[125]

Inadequate Débridement

Free flaps will not help heal unsuitable wounds. Adequate débridement and preparation are mandatory (see later). In an emergency situation, especially in crush injuries, the wound may be so ill defined that radical débridement might needlessly destroy vital structures that otherwise may potentially survive

and continue to function. In these circumstances, débridement of unquestionably dead and contaminated tissue should be followed by the application of wet dressings or, perhaps better, copious application of a petrolatum-based ointment such as Neosporin or, more recently, application of a vacuum-assisted closure (VAC) dressing. At a second look within 72 hours, it may be possible to create a clean wound by further débridement, to which an "early" flap can be applied. If doubt remains much beyond 72 hours and further serial débridements are necessary, the chance of infection beneath the flap rises 12-fold.[41] Split-thickness skin grafts should therefore be employed wherever possible after the final débridement, and secondary flap reconstruction is left until the wounds have healed.

The alternative to this approach provides the rationale for an "emergency free flap."[18,41,55,78,104] The initial injury or subsequent débridement may expose vital tissues that will not (or should not) support a skin graft: bare bone, cartilage, ligament or tendon, and exposed vessels or nerves. A flap will therefore be required at some stage. Even with the wettest of wet dressings, exposed bone and tendon continue to desiccate and die and eventually have to be excised. It follows, therefore, that with exposure of such important but poorly vascularized structures, emergency or early flap coverage is mandatory to preserve function. Radical débridement with emergency free flap coverage has become accepted for both upper and lower extremity traumatic wounds; similarly, early free flap coverage of high-voltage electrical burn injuries is becoming the accepted standard of care.[102]

Although early flap coverage of traumatic wounds of the extremities has been advocated within 72 hours of injury, a recent systematic review of timing of upper extremity free flap reconstruction found no significant association between timing of reconstruction and rates of flap loss, infection, or bony nonunion.[50] However, early reconstruction seemed to decrease the length of hospital stay and limit associated medical costs.

Poor Limb Function

Free tissue transfer should not be used to salvage a limb with insufficient potential for eventual function. Such function can only be attained by an acceptably sensate hand with mobile joints controlled by sufficient musculotendinous units. In complex injuries, the potential salvage of a limb can often be assessed only by an experienced hand surgeon; one must weigh the benefits of the three options of primary amputation, radical débridement and emergency free flap coverage, or serial débridements and secondary free flap coverage.

CLASSIFICATION OF FREE FLAPS

The recognition that theoretically any vascular territory or angiosome could be transferred on its axial pedicle, led to a renaissance in studies on the vascular anatomy of the skin and underlying muscles[118] and the development of a wide armamentarium of potential free flap donor sites. Only those flaps that have stood the test of time or are currently evolving as potential free flaps for use in the upper extremity are included in Table 45.1. The customary division of axial-pattern flaps into cutaneous, fasciocutaneous, and musculocutaneous flaps has been outlined in Chapter 44 and is reiterated here for convenience.

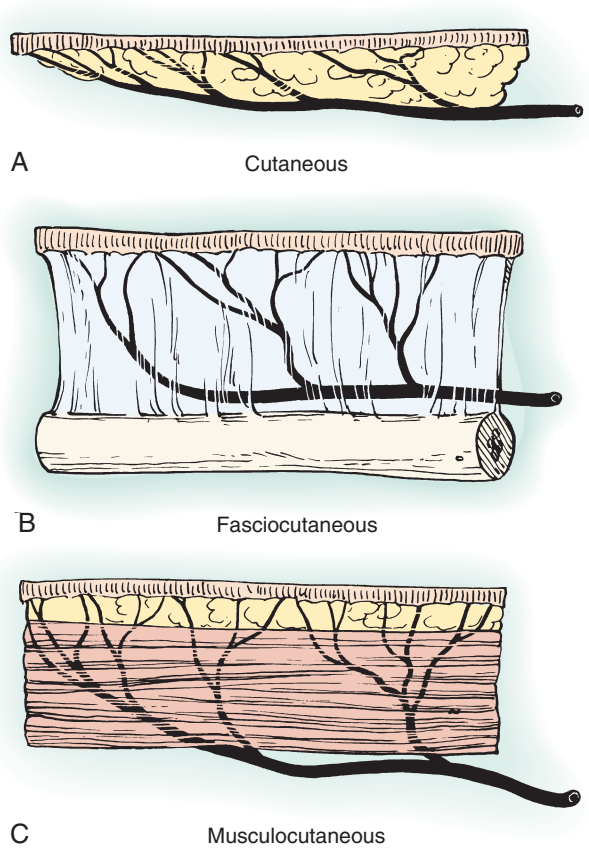

FIGURE 45.1 Axial-pattern flaps are either cutaneous **(A),** fasciocutaneous **(B),** or musculocutaneous **(C),** depending on the source of the major portion of the blood supply. Fasciocutaneous vessels commonly run in intermuscular septa and therefore supply the periosteum of underlying bone. The flap can be taken with a segment of that bone when necessary. (From the Christine M. Kleinert Institute for Hand and Microsurgery, with permission.)

Cutaneous Flaps

The vessel of an axial flap may be purely cutaneous (Figure 45.1, *A*), proceeding directly to and supplying skin alone. Free flaps based on these cutaneous vessels are termed *free cutaneous flaps* or *free skin flaps*. Typical free cutaneous flaps used for reconstruction of the upper extremity include the dorsalis pedis flap,[84,100,138] the groin flap,[22,48,54] and the first web space neurosensory flap.[82,86]

Fasciocutaneous Flaps

The axial vessel may first supply fascia before reaching its cutaneous territory (see Figure 45.1, *B*). The vessels commonly reach the fascia by running in an intermuscular septum. Because the septum is attached to bone, a segment of bone may be taken as a composite flap with the overlying skin and be vascularized by the same pedicle, for example, the fibular osteocutaneous flap. Axial flaps whose vessels first pass along the fascia are termed *fasciocutaneous flaps*. Just as with a musculocutaneous flap, fascia may be transferred alone without the overlying skin,[14,32] but skin cannot be transferred without the underlying fascia.

Typical fasciocutaneous flaps used for coverage of the upper extremity include the radial forearm flap,[51,64,87,112,134] ulnar forearm flap,[21] and lateral arm flap.[66,67,124] Pure fascial flaps

TABLE 45.1 Common Free Flap Donor Sites

Classification	Flap	Artery	Composite Tissues	References
Cutaneous				
	Dorsalis pedis	Anterior tibial–dorsalis pedis artery	Bone: second metatarsal Tendon: extensor tendons Sensory: superficial peroneal nerve	84, 92, 100, 138
	Groin	Superficial circumflex iliac artery Deep circumflex iliac artery	Bone: iliac crest	22, 48, 54, 110
	Scapular	Transverse branch of circumflex scapular artery		25, 39, 46
	Parascapular	Descending branch of circumflex scapular artery	Bone: lateral border of scapula	13, 89, 114
	Anterolateral thigh	Descending branch of lateral circumflex femoral artery	Sensory: lateral cutaneous nerve of thigh	4, 59, 73, 113, 127, 129
	First web space/toe pulp	Dorsalis pedis artery/first dorsal metatarsal artery	Sensory: fibular digital nerve to great toe; tibial digital nerve to second toe; deep peroneal nerve	12, 45, 72, 76, 82, 86
Fascial/fasciocutaneous	Radial forearm	Radial artery	Bone: radius Tendon: palmaris longus Sensory: medial and lateral antebrachial cutaneous nerves	6, 51, 64, 87, 93, 112, 121
	Ulnar forearm	Ulnar artery	Sensory: medial and lateral antebrachial cutaneous nerves	21
	Posterior interosseous	Posterior interosseous artery		15, 109
	Lateral arm	Posterior radial collateral artery	Bone: humerus Tendon: triceps Sensory: posterior cutaneous nerve of arm	66, 67, 124, 136
	Fibular osteocutaneous	Peroneal artery	Bone: fibula	128
	Medial plantar	Medial plantar artery		85, 90
	Temporoparietal	Superficial temporal artery		52, 53, 126
Musculocutaneous	Gracilis	Medial circumflex femoral artery		61
	Latissimus dorsi	Thoracodorsal artery		19, 42, 43, 75
	Rectus abdominis	Deep inferior epigastric artery		95, 96, 98, 117
	Serratus anterior	Thoracodorsal artery	Bone: rib	10, 49
Omentum	Right gastroepiploic artery			58, 105

include the radial forearm fascial flap, lateral arm fascial flap,[136] scapular fascial flap,[27] dorsal thoracic fascial flap,[70] serratus fascial flap,[11,32] and temporoparietal fascial flap.[8,126]

Muscle and Musculocutaneous Flaps

The axial vessel may first supply muscle (see Figure 45.1, *C*) with multiple secondary perforators supplying the overlying skin. The muscle must be harvested with the skin to ensure survival of the overlying skin, but the muscle may be transferred itself without the overlying skin and covered with a split-thickness skin graft. Flaps containing muscle and skin are termed *musculocutaneous flaps* or *myocutaneous flaps*, whereas transfer of the muscle alone is referred to as a *free muscle flap*. Useful muscle and musculocutaneous flaps for reconstruction of the upper extremity include the latissimus dorsi,[43] serratus anterior,[10] rectus abdominis,[95,96,98] and gracilis muscles.[61] In certain cases, free muscle flaps can be reinnervated by coaptation of the motor nerve to a recipient motor nerve in the forearm to restore otherwise irretrievable motor function.

Perforator Flaps

More recently, *perforator flaps*[103] have been developed in which a specific muscle perforator is dissected in continuity between the overlying skin and the main axial vessels, so that the skin component of a musculocutaneous flap can be transferred without the bulk of the underlying muscle; the base is only the single muscle perforator.[2,19,25,56,65,73-75,135] There are two options for dissection of perforator flaps and their anastomoses to recipient vessels. The skin flap can be harvested based on an individual perforator or multiple perforators that remain in continuity with the axial vessels to provide a long pedicle that can be anastomosed to recipient vessels of a similar caliber. Alternatively, the same skin flap can be harvested based only on a single perforator without dissecting the vessels of the main pedicle more proximally; this obviously simplifies the dissection and shortens the time necessary for it. However, anastomosis of these smaller-diameter vessels in the shorter pedicle may require *supermicrosurgical techniques*. Perforator flaps include the thoracodorsal artery perforator (TDAP) flap,[2,19,65,75,135] circumflex

scapular artery perforator flap,[25] superficial circumflex iliac artery perforator (SCIP) flap,[56,74] and anterolateral thigh perforator flap.[73]

Composite Flaps

Vascularized bone grafts and vascularized nerve grafts can also be transferred on their vascular pedicle (see Chapter 46). Apart from these "pure" tissue flaps, composite transfers usually containing two tissue components have been described: skin-bone (osteocutaneous),[91,128] skin-nerve (neurosensory),[82,84,86,92] and skin-tendon (tendocutaneous).[99,104,107,119] These composite flaps have very specific indications: osteocutaneous flaps such as the fibular osteocutaneous flap[128] and the deep circumflex iliac artery osteocutaneous flap[91,118] may be indicated for reconstruction of combined bone and soft tissue defects of the upper extremity; the radial forearm flap with the palmaris longus tendon[51,99] and the dorsalis pedis flap with vascularized long extensor tendons[104] may occasionally be indicated for reconstruction of a combined skin and extensor tendon defect due to a dorsal degloving injury of the hand; and neurosensory flaps[82,84,86] may be specifically indicated for restoring sensation to an important tactile area of the hand (the nerve within the flap itself can be used as a vascularized nerve graft and possibly provide more rapid return of sensation in the distal extremity).

Venous Flaps

Venous flaps[16,34,38,123] and *arterialized venous flaps*[30] have provoked sporadic interest during the past decade. In a pure venous perfusion flap, a small flap of skin and subcutaneous tissue containing a superficial vein that projects a few millimeters both proximally and distally beyond the flap is harvested from the flexor surface of the distal forearm. The flap is then reversed and can be used for simultaneous coverage of a defect over the dorsal aspect of the fingers or hand as well as for restoration of venous outflow by anastomosis of both the proximal and distal ends of the vein to a vein proximal and distal to the defect.[16,34,38,123]

There are two types of arterialized venous flaps.[30] In the first type, the flap inflow vein is anastomosed to a digital artery and the outflow vein is anastomosed to a vein proximal to the defect, in essence creating an arteriovenous fistula. The second type of arterialized venous flap can be used for simultaneous coverage of a defect over the palmar surface of a digit as well as for restoration of a segmental defect in the digital artery, by anastomosis of both the proximal and distal ends of the vein to the digital artery to create a *flow-through flap*. Clinically, arterialized venous flaps have better survival rates than pure venous perfusion flaps. The largest successfully surviving venous perfusion flap measured 10 × 8 cm, so it is unlikely that these flaps survive purely as a composite graft. Until the hemodynamics are more fully understood, pure venous flaps should only be considered for coverage of small dorsal or palmar defects of the fingers requiring simultaneous restoration of venous outflow or arterial inflow.

PREOPERATIVE ASSESSMENT AND PREPARATION

Complete examination of any limb on which surgery is being considered is mandatory. Where free tissue transfer is proposed, particular attention should be paid to the wound itself, the bony skeleton, the vascular anatomy, and any structures that may require simultaneous repair or reconstruction.

Tissue Defect

Preliminary examination of the wound should be directed toward those factors that will influence flap selection: size, depth, and special needs. In the fresh wound, the area may have been reduced somewhat by approximation, but the surgeon should remember two facts. First, one of the major benefits of importing additional tissue is that tension, with all its adverse effects of delayed wound healing, edema, and limitation of early motion, can be eliminated completely. Second, depending on the flap selected, additional area is required to accommodate the bulk of the flap itself. This bulk has its merits, because it serves to fill dead spaces in the wound. In the old wound that is to be excised, the full extent of excision should ideally include all scar tissue, with the incision being made in adjacent normal tissue throughout. If this is impractical (e.g., in extensive healed burns), the excision should include not only ulcerated skin but all the skin that is immobile due to fixation to deep tissues. It should be recognized that the size of flap required will be considerably larger than the area of skin excised, because of scar contracture affecting the surrounding tissues. For this reason, as emphasized below, the final pattern for the flap should not be made until after wound excision. In those cases in which some scar tissue has to remain on the limb, the surgeon must realize that its lack of elasticity may prevent closure of contiguous incisions, such as that over the pedicle and make allowances for that fact by planning for "pseudopods" on the flap to close such extensile incisions (Figure 45.2).

Radiographs and Computed Tomography, Magnetic Resonance Imaging, and Bone Scans

The bony skeleton should be fully evaluated by radiography and, if necessary, computed tomography (CT). Rigid fixation is an essential prerequisite, not only because a rigid skeleton supports the soft tissue reconstruction but also because motion at unstable fractures creates a dead space in which infection can develop. In chronic wounds, the presence and extent of any osteomyelitis can be assessed by four-phase technetium-99m bone scanning and indium-111–labeled leukocytes or magnetic resonance imaging (MRI) with gadolinium enhancement.

Angiography

The vascular anatomy of the limb should be evaluated by the surgeon by palpation of the brachial, radial, and ulnar pulses and also by using a handheld Doppler pencil probe, making sure to determine the direction of flow and any possible occlusion in the radioulnar arch system by selective occlusion. Blood flow distal to the wound in the recently injured limb should be assessed both before surgery and after fixation of any fractures. If blood flow is deemed to be inadequate, revascularization should be considered, either by means of an interposition vein graft or a flow-through flap,[18,132] such as the radial artery of the radial forearm flap.[9,93] For old injuries, information regarding the vascular anatomy should be obtained by noninvasive vascular studies and transfemoral angiography. Whereas some concerns have been expressed in the past regarding the possible adverse effect of angiographic dye injection in the days immediately preceding free tissue transfer, the authors have routinely

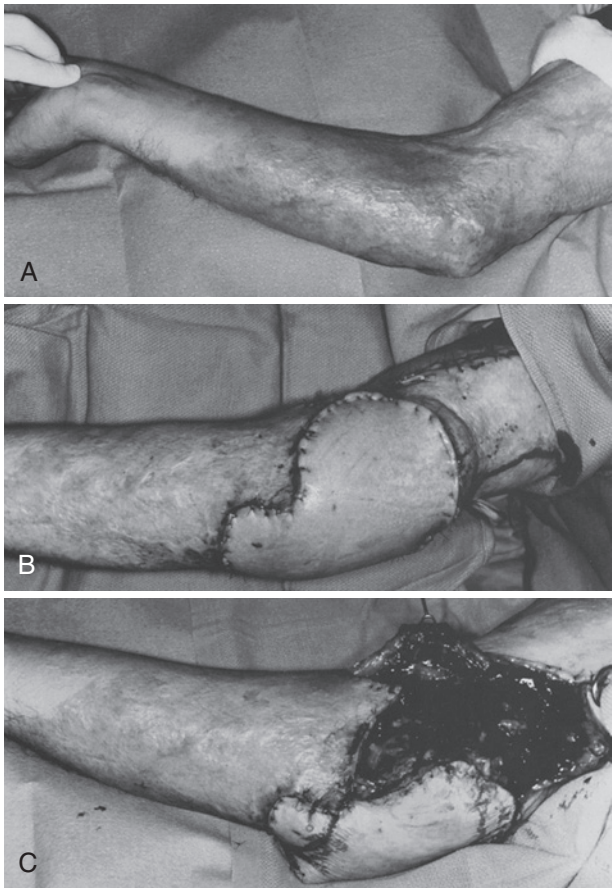

FIGURE 45.2 **A,** This patient had suffered 40% burns and required replacement of the skin over the extensor surface of the elbow together with excision of heterotopic bone. **B,** A free groin flap was harvested and inset into the defect. Although the extensile incision to dissect the recipient vessels had to be made in scar tissue, no "pseudopod" of the flap had been planned to relieve tension over the pedicle. The crease just proximal to the flap above the Penrose drain bodes ill for later circulation. **C,** The flap subsequently developed venous engorgement, and extensive hematoma beneath the congested flap was found on exploration.

obtained such studies during the 48 hours before surgery without adverse effect. The newer noninvasive techniques of magnetic resonance angiography and computed tomographic angiography may eventually supersede the need for invasive angiography of the recipient limb. Angiography of the flap donor site is not necessary, except possibly for some partial and total toe transfers. Instead the surgeon should examine all potential flap donor sites to ensure that there are no previous scars that might compromise harvesting the flap.

Preparation of the Patient for the Operating Room

As with all free tissue transfers, the patient should be brought to the operating room well perfused. To this end, the patient should be kept warm during the night preoperatively, and intravenous fluids should be commenced at midnight at a rate that ensures a urinary output of more than 100 mL/hour in the adult patient at the beginning of surgery. The operating room must be kept at a temperature above 70° F. Some surgeons use aspirin or heparin on a routine prophylactic basis, but this is not our custom.

The use of two surgical teams, one to harvest the flap and the other to prepare the recipient site, is common practice and provides the opportunity for the shared experience of two microsurgeons. However, the anecdotal experience of several microsurgeons suggests that little or no time is saved by using two teams and the incidence of complications may be somewhat higher than when one microsurgeon carries the responsibility for the entire procedure.

OPERATIVE TECHNIQUE

Wound Débridement

A wound that is to be covered by a free flap should lie over a stable skeleton. It should not contain any tissue that remains contaminated or has a compromised blood supply. The defect should present as flat a bed as possible for application of the flap. These prerequisites are achieved by rigid fixation and radical débridement (Figure 45.3). Such débridement may be performed with confidence only in the knowledge that good soft tissue cover is available. Similarities to tumor surgery exist in that resection of a malignant tumor with adequate clear margins is best achieved by the surgeon who knows he or she can close the resulting defect. As with cancer ablation, radical débridement demands incision through normal tissue. This should be done under tourniquet control; otherwise, the bleeding from muscle and viable soft tissue will conceal the lack of bleeding from tissues that are not viable. If a major vessel has to be repaired, tissues distal to the arterial injury will be better perfused after the vascular repair, and therefore débridement should be performed after reperfusion.

In severe limb trauma, adequate bone shortening can sometimes facilitate approximation of muscle and soft tissue, as in macroreplantation. In these cases, débridement must precede the arterial anastomosis. Those tissues that remain viable can be demonstrated by cannulating the distal end of the vessel to be repaired and perfusing the ischemic part with heparinized saline. Weeping of this fluid will indicate potential viability; absence of this weeping fluid indicates inevitable ischemia.

When immediate flap coverage is planned,[18,41,55,78,102,104] contaminated bone can be retained; it is scrubbed vigorously, and burrs and a rongeur are used to remove contamination. Even free fragments can be similarly treated and used as bone grafts, but only if they are rigidly fixed and are covered with well-vascularized soft tissue. In late cases, in which osteomyelitis has developed, two criteria are used for assessing bone viability. The *paprika sign* denotes the punctate bleeding that occurs when cortical bone has been burred back to the level at which there is adequate perfusion. The presence of adherent periosteum is usually indicative of viable bone, and therefore bone should be resected through adjacent adherent periosteum.

CRITICAL POINTS *Wound Débridement*

- The wound should be débrided in a manner similar to that of a "tumor resection."
- All foreign material must be removed.
- All nonviable tissue must be removed.
  - Neurovascular structures should be spared.
  - Débride back to bleeding tissue.
  - Remaining muscle should contract with stimulation.
- The extent of débridement should not be predicated on size.
  - A free flap can cover almost any defect in the hand or arm.

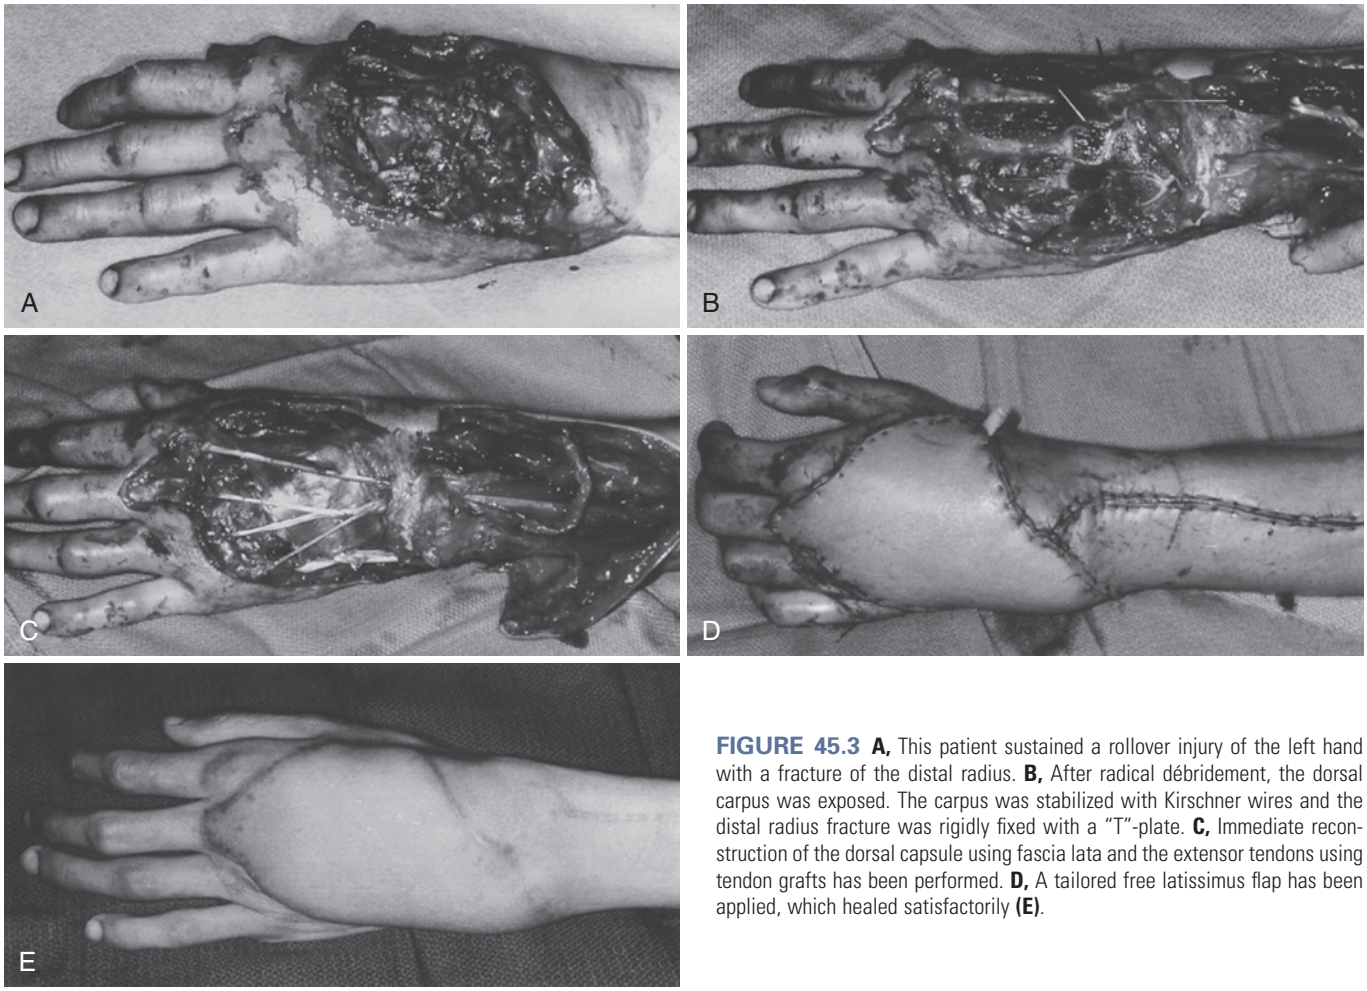

FIGURE 45.3 **A,** This patient sustained a rollover injury of the left hand with a fracture of the distal radius. **B,** After radical débridement, the dorsal carpus was exposed. The carpus was stabilized with Kirschner wires and the distal radius fracture was rigidly fixed with a "T"-plate. **C,** Immediate reconstruction of the dorsal capsule using fascia lata and the extensor tendons using tendon grafts has been performed. **D,** A tailored free latissimus flap has been applied, which healed satisfactorily **(E)**.

All marginally viable skin should be removed with the exception of highly specialized areas such as the fingertip or palm. If marginal tissue is retained, such skin may harbor infection and will certainly heal with profuse scarring. When débridement appears adequate, tissue samples are taken from several points in the wound for rapid gram-stained smear and quantitative cultures. Such tissue samples are only necessary in open wounds and where there has been previous infection. Samples are taken from tissues that are considered clinically to be noninfected at the completion of adequate débridement and therefore are indicative of inadequate débridement; they also identify the probable organism in the event of later infection.

After débridement, the wound may be uneven. Additional excision of vital but nonessential tissue is justified to create a flat wound surface. Close contact between flap and bed is thus assured, and dead spaces are eliminated that could later become the sites of infection or fibrosis. The only exceptions to the rule of radical débridement are longitudinal vital structures that carry the promise of function: intact tendons or nerves and major patent arteries. These should be retained and cleaned with the help of magnification.

Skeletal Stabilization

Once débridement is complete, rigid skeletal fixation should be applied. Compression plates are preferred for the radius and ulna, low-profile miniplates for the metacarpals, and type A intraosseous wiring or 90-90 intraosseous wiring for the phalanges. External fixation is employed for bony segmental defects. Small defects can be reconstructed primarily with cancellous bone grafts, whereas large defects can be obliterated either with the muscle component of the free flap or a temporary antibiotic-impregnated methylmethacrylate spacer, pending later definitive bony reconstruction.

After radical débridement of chronic osteomyelitis, secondary cancellous bone grafting should be delayed until 6 weeks after application of the flap, provided that soft tissue healing is uneventful.

Skin Pattern

The skin margins should be freshened and made even by excising any redundant promontories and peninsulas of no functional importance. A pattern of the defect is taken using any suitable material, such as a piece of an Esmarch bandage that has been moistened with alcohol (see Figure 45.9, *C*) or the paper of a glove wrapper.

Recipient Vessels

An additional incision will invariably be required to expose the recipient vessels. In the extremities, closure of the wound over the free flap pedicle may cause impairment of flow to the flap.

If this possibility has not been anticipated and a tongue or "pseudopod" of flap has not been incorporated, it may become necessary to apply a split-thickness skin graft over the pedicle. In situations in which no extension of the flap is planned, a zigzag incision is used to expose the recipient vessels, with a 60-degree angle between each limb. This not only improves exposure but also permits closure of the wound as a series of "V-Y" advancements, thus increasing the circumference of the limb and avoiding any possibility of vascular compromise of the flap.

With the use of loupe magnification, the recipient vessels are dissected in a preliminary manner, meaning that the vessels are exposed but are not prepared definitively for the microvascular anastomoses. This is for two reasons: the precise location of the anastomoses can only be determined with the flap sutured in place, and dissection is best achieved under relatively higher magnification under the operating microscope.

Avoiding the Zone of Injury

The key to dissection of the recipient vessels is that exploration should proceed from normal tissue toward the wound, not in the more obvious centrifugal fashion, working outward from the wound. This is especially true in reconstruction of chronic wounds, because the inflammation and subsequent fibrosis that follows the original injury spreads farthest from the wound along the vascular planes. If the surgeon dissects outward from the wound, stopping when the vessels clearly improve, the point at which one stops will be closer to the wound than if one dissects toward the wound, stopping when the vessels clearly deteriorate. The distance between these two stopping points may be small, but it is highly significant. Because the vessels still contain scar that is scarcely evident to the examiner, it makes them friable and inelastic, which causes problems in performing the anastomoses, and also the vessels may fail to dilate in response to increased flow, which is especially significant in the venous outflow of a free flap.

If prior examination has shown that only one artery to the limb is patent, that artery should be inspected with particular care for the presence of (1) large and expendable side branches to which an end-to-end anastomosis could be performed and (2) atherosclerosis. The latter may be seen as irregular, transverse striations on the vessel or felt as unusual hardness in the vessel wall detected with the touch of either the gloved finger or a jeweler's forceps. If atherosclerosis is detected in a single artery extremity in which an end-to-side anastomosis would normally be the technique of choice, the surgeon may elect to perform two end-to-end anastomoses by resecting a segment of the vessel and incorporating a "T"-junction in the flap pedicle (see Figure 45.19, *C*).[79]

Pedicle Length and Accessibility

As a final step, the length of vascular pedicle required should be measured between the point selected for the anastomoses and the closest margin of the defect. This should be done before the precise location of the flap on the donor site has been drawn and dissection of its pedicle completed. Pedicle length can be increased by extending the dissection of the pedicle farther than is customary, often with increasing difficulty. In some flaps, the pedicle can be lengthened relatively, by moving the skin pattern of the flap further away from the vascular pedicle but keeping the majority of the skin paddle within the vascular territory.

If the pedicle of the selected flap is not long enough, three solutions exist. First, choose a different flap. Second, harvest a vein graft. Third, create a temporary arteriovenous fistula using an interposition vein graft between the recipient artery and vein or create a recipient shunt by anastomosing a long length of a recipient vein end-to-side into the recipient artery. However, a recipient shunt should only be considered when the recipient vein is situated away from the recipient artery, continues distally into the limb away from the wound, and remains unscarred and of good caliber. This last solution is attractive not only when the selected flap pedicle is going to be too short, but also when the selected recipient artery is relatively deep and inaccessible and when there are two experienced microsurgical teams. When the intended end-to-side arterial anastomosis is deep and somewhat inaccessible, the additional presence of the flap in the way will make it even more difficult to see and do. Use of a temporary arteriovenous or recipient shunt can improve visibility and move the two end-to-end anastomoses of the flap to a more accessible location. When there are two teams, the team dissecting the recipient site will always complete its task before the team raising the flap. The whole operation will be accelerated if the recipient team performs the more time-consuming end-to-side anastomosis of the interposition vein graft or recipient vein to the recipient artery.

Harvesting the Flap

With knowledge of the anatomy of the selected flap, a template of the defect can be positioned on the skin in such a way as to optimize the desired thickness of the flap and the necessary pedicle length. It is usually prudent to maximize the length of pedicle because the microsurgical anastomoses can be moved more proximally away from the wound. A loose pedicle will also facilitate end-to-side anastomoses. Only one flap margin should be incised initially, with an extension over the presumed course of the pedicle. The vascular pedicle can be visualized and dissected through this incision. In those rare cases in which the pedicle is found to be anomalous or absent, this initial incision can be closed without compromising the circulation to the skin.

Between the vascular strata (the subcutaneous tissue, fascia, and muscle) lie planes that are relatively avascular. It is in these planes that the flap should be elevated. To reach these planes, it is necessary to cut through the vessels of the more superficial strata. For example, in harvesting a fascial flap, the surgeon must first incise the subdermal and subcutaneous plexus and then the fascia and elevate the fascial flap in the plane beneath the fascia but superficial to the muscle. To be one plane too superficial would result in division of the vessel supplying the flap. To be one plane too deep would result in a time-consuming, often bloody dissection.

Application of tension plays a major role in flap dissection. Once the marginal incision has been carried down to the correct plane for dissection, skin hooks should be applied to the corners of the flap. Firm upward traction away from the bed will display the plane for dissection. Often this plane only contains loose areolar tissue that can be stroked away with a knife. Tension on the flap lifts the pedicle off the floor of the secondary defect, on which the knife is dissecting, into the roof containing the vascular plexus. Care must be taken not to create a "cave" beneath

the flap, that is, a central recess between areas of unincised skin, muscle, or fascia. When closed scissors are introduced into the tissues and then opened under gentle pressure to clear planes, they can be both precise and innocuous. They create and enter "caves," defining structures to be preserved and those to be divided. When scissors are introduced open and closed to cut, they are less precise. It is therefore important when using scissors that the surgeon see both aspects of the structure to be divided so as to be confident about which tissues have been included between the jaws of the scissors.

Dissection of the Pedicle

Unrecognized damage to the vascular pedicle during dissection is one of the major causes of postoperative complications after free tissue transfer, often resulting in poor perfusion to the flap or culminating in thrombosis at the anastomosis. Any problem in the entire vascular tree either affecting arterial inflow or venous outflow may eventually result in anastomotic thrombosis. Meticulous dissection of the pedicle therefore plays a paramount role in achieving a successful outcome. Hemostasis must be perfect during dissection of any flap, because it is hazardous to achieve once the anastomoses have been completed. Although it has been shown that metal clips are not secure and that bipolar coagulation may harm the pedicle, both the clips and coagulation are routinely employed in dissecting the pedicle. The clips must be applied with sufficient force to ensure that they will not slip. If bipolar coagulation is being used, the pedicle should be insulated by using smooth forceps to hold the side branch between the pedicle and the point of coagulation.

On completion of the dissection of the pedicle, the flap should be allowed to perfuse after bathing the pedicle with either 2% lidocaine (Xylocaine) or papaverine, before dividing the pedicle and transferring the flap to the recipient site.

Flap Insetting

The flap is placed into the defect; check to see that the end of the pedicle comes to lie approximately at the predicted site of the anastomoses. The flap can either be sutured into place definitively or temporarily stapled into position. With definitive insetting, the completed anastomoses will be less likely to be at risk during final wound closure. Furthermore, the edema that will inevitably occur in the flap after reperfusion will be controlled and should not produce such swelling as to make complete closure of the flap impossible.

Once the flap is in place, the microscope is introduced, the pedicle is approximated to the recipient vessels, and the site of the anastomoses is selected. If the venous repair lies at some distance from the arterial repair, this is the stage when the surgeon can most safely separate the vein and artery within the pedicle. The recipient vessels should be dissected circumferentially over a sufficient distance to allow easy rotation to bring their back walls forward. When an end-to-end anastomosis is to be performed, the recipient vessel should only be dissected over a length necessary to accommodate a microsurgical approximator clamp. The techniques of microvascular anastomosis are described in the Classic chapter, Principles of Microvascular Surgery, available on ExpertConsult.com.

Both the arterial and venous anastomoses should be performed before removing the clamps from either vessel. The more difficult anastomosis is performed first.

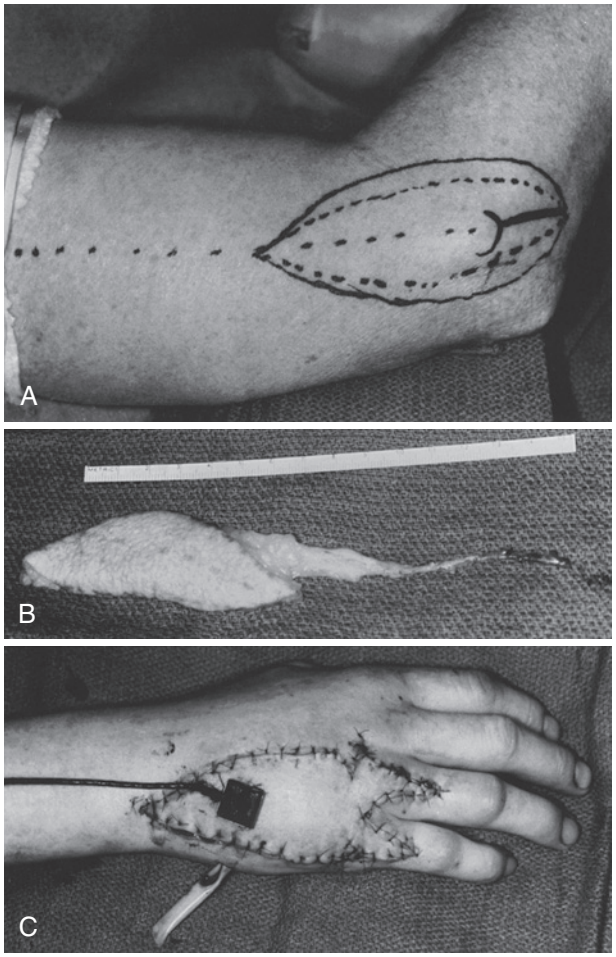

FIGURE 45.4 Lateral arm flap. **A,** The deltoid tubercle and the lateral epicondyle have been marked and joined with a *dotted line* that traverses the figure from left to right. The skin incision is marked with a *dotted line,* and the intended inclusion of the fascia is marked with a *solid line.* **B,** The distal location of the flap provides a long pedicle. **C,** The lateral arm flap has been inset to cover the ulnar aspect of the dorsal hand and also the proximal portions of the ring and small fingers. The anastomosis to the ulnar artery was performed proximal to the wrist.

If a monitor such as a photoplethysmograph, laser Doppler, or tissue oximeter is to be used, the sterile probe should be sutured to the flap and connected before the microsurgical clamps are removed (Figure 45.4). In this way, reperfusion of the flap can be charted, as can any changes that occur during wound closure.[62,115,116] If there is any persistent accumulation of blood in the wound that cannot be controlled, usually from scar or bone, a drain or drains should be inserted (see Figures 45.3, *D,* and 45.4, *C*). Suction can be applied but only very carefully, because however far from the pedicle the drain lies, the two may come together with disastrous consequences.

Dressings

No dressings should be applied to the flap surface; it is best for the flap to be easily observable at all times. The incisions can be covered with Neosporin ointment and a thin strip of nonadherent gauze. To protect the limb during sleep, a splint should be applied, leaving a generous window for inspection. A surgical glove is turned inside out to close the fingers and is packed with gauze sponges. The glove is laid over the flap, cast padding is

applied to the whole limb including the glove, and a plaster of Paris splint is made. Once the cast is dry, the prominence created by the packed glove is removed with a saw, rather as if one were opening a boiled egg, and the glove is removed, so that the flap is protected yet always visible.

POSTOPERATIVE CARE AND MONITORING

Patient Care

Postoperative care should be directed toward the comfort of both patient and flap and should be the responsibility of a team of trained, trusted nurses. The comfort of the patient is pursued through the usual channels and should not be neglected because of concern for the flap. It is important that the patient be up and about as soon as possible, preferably starting on the first postoperative day. All joints not included in the cast should be mobilized.

Several different anticoagulants such as intravenous dextran 40, intravenous heparin, subcutaneous low-dose heparin, and oral low-dose aspirin are used prophylactically by many surgeons to prevent thrombosis of the microsurgical anastomoses. There are no prospective controlled trials to confirm the efficacy of any of these anticoagulant regimens, and occasionally their disadvantages outweigh the theoretical benefits. One of the authors (NFJ) uses a 40-mL bolus of dextran 40 just before release of the microsurgical clamps followed by a continuous intravenous infusion of 25 mL of dextran 40 per hour for 5 days (based on an adult patient who weighs 70 kg) together with aspirin, 81 mg orally daily. The other author (GDL) does not use any anticoagulant therapy after routine free tissue transfer.

Routine wound cleansing should be accomplished using hydrogen peroxide followed by a thin smear of antibiotic ointment. This routine has many benefits: it eliminates a nutritious inoculum for bacteria; it ensures that color assessment is neither obscured by blood staining nor impaired by vivid contrast within the observer's visual field; it permits assessment of the rate of bleeding from the wound, in itself a valuable index of venous insufficiency; and it has an inestimable effect on the morale of the patient who can see the healing wound.

Flap Monitoring

The nurse should observe the flap regularly, usually every hour for the first 48 hours, to ensure its continued viability. Clinical evaluation of the flap is based on several criteria.

Color

Although difficult to learn and impossible to convey adequately, color assessment still remains the mainstay of clinical evaluation. The lighting must obviously be good. The observer's color perception can be neutralized by first looking at an area of normal skin for 10 seconds and then looking at the flap and comparing the colors.

A healthy free flap, especially a groin flap, is pale to a degree that makes the novice nervous. It is not pure white, when one compares it with a sheet of white paper, but rather it is a very pale pink. If arterial inflow is inadequate, a flap will become paler, with a faint blue-gray tinge. If venous drainage is compromised, the flap will at first become an angry red color and then progressively purple-red and purple-blue (Figure 45.5, *A*). The unperfused free flap at first assumes a waxy pallor, that is, white tinged with yellow or brown, which differs from its healthy pink pallor by a margin so subtle that only the experienced are pessimistic. The margins of the failing flap then become indurated and may blister, but doubts concerning the extent of loss may persist for several days.

FIGURE 45.5 **A,** This lateral arm flap on the ulnar aspect of the hand is clearly experiencing serious venous embarrassment, with significant discoloration of the proximal end of the flap, which is to the left. **B,** Exploration revealed thrombosis of the outflow vein of the flap. **C,** Thrombectomy resulted in salvage of the entire flap.

Capillary Refill

Capillary refill may be assessed after blanching by fingertip pressure or by running a blunt point across the flap. If the refill after blanching is very slow and the flap is pale, arterial insufficiency is the likely cause. If capillary refill is too swift and the flap has a bluish hue, venous outflow is impaired. Little stock can be placed on this test in isolation because entirely stagnant blood will move around in the tissues in response to pressure, although more slowly than one would see in a healthy flap.

Bleeding

Although the color and capillary refill of a flap can be assessed on a regular protocol, bleeding from the flap should only be evaluated if there is any suspicion of impending compromise to the perfusion of the flap. The flap and adjacent tissue can be punctured with an 18-gauge needle or a No. 11 scalpel blade and the resultant bleeding compared. A healthy flap should produce bright red blood of the same color as the control and should bleed just a little longer. If no bleeding occurs or if the flap only bleeds very briefly, arterial inflow is inadequate. If the blood is dark red or purple and bleeding persists much longer, venous congestion should be suspected. Persistent dark red bleeding from around the margins of a swollen flap is almost pathognomonic of venous occlusion.

Other Monitoring Techniques

Many techniques for postoperative monitoring of free tissue transfers have been developed and evaluated in experimental free flap models. Several of these techniques have been used in large clinical series.[29,60,62,68,69,111,115,116] There have been no prospective clinical trials of any monitoring technique, and there is still no consensus as to which will eventually become the standard accepted method.[5,23,62]

An ideal monitoring technique should provide a continuous recording of flap perfusion or flap metabolism, with immediate detection of arterial or venous occlusion. It is important that the criteria indicative of arterial or venous occlusion be easily interpreted by nursing personnel or junior medical staff. Finally, an ideal system should allow monitoring of both visible and "buried" types of free tissue transfers.[5,23,62]

Several techniques are currently used:

- Photoplethysmography
- Differential surface temperature monitoring[69]
- Doppler surface monitoring[80,111]
- Laser Doppler monitoring[60]
- Implantable Doppler probes[29,80,115,116]
- Implantable pH electrodes
- Implantable oxygen electrodes
- Pulse oximetry[63]
- Tissue oximetry[68,80]

Photoplethysmography has been shown to indicate early signs of compromised flap perfusion owing to excessive tension during skin closure. Photoplethysmographic waveforms can even be transmitted by telephone to a remote monitoring station to allow the surgeon at home to interpret any abnormal waveforms, so that the nursing personnel can be advised whether the waveform is normal or whether the flap should undergo reexploration. Tissue oximetry based on near-infrared spectroscopy is showing promise in providing continuous postoperative monitoring of tissue oxygen saturation in free flaps.[68]

A surface temperature probe can be used to compare the relative difference in temperature between the flap and a second control temperature probe on adjacent normal skin. Differential surface temperature monitoring has been evaluated retrospectively in a large series of 600 free tissue transfers.[69] A difference between the differential surface temperature measurements at two points in time of greater than 1.8°C has been shown to be diagnostic of arterial or venous occlusion.

The characteristic arterial pulsation of either a free skin flap or a free muscle flap resurfaced with a split-thickness skin graft can be heard with a handheld pencil 8-MHz Doppler probe.[111] The best arterial Doppler signal on the surface of the flap is marked by a suture and the arterial signal monitored both during closure and every hour postoperatively for the first 48 hours. Augmentation of the venous "hum" can also be produced by compression of the flap tissue, thereby confirming the patency of venous outflow. The laser Doppler flowmeter[60] has been used for postoperative monitoring of free skin flaps and musculocutaneous flaps and free muscle flaps resurfaced with split-thickness skin grafts.

An implantable 20-MHz ultrasonic Doppler probe can be used for continuous monitoring of the patency of the arterial anastomosis and will provide instantaneous detection of an arterial occlusion.[29,116] However, this technology also requires further refinement, both with regard to positioning the probe either on the artery or the vein and recognition of a venous occlusion.[115]

Paradoxically, because of the ever-increasing success rates of free tissue transfers, it will become more and more difficult to document scientifically the value of any postoperative monitoring technique. One of the authors (NFJ) uses Doppler surface monitoring of the arterial pulsation with a handheld Doppler probe every hour for postoperative monitoring of free skin, muscle, and osteocutaneous flaps and a pulse oximeter for postoperative monitoring of toe-to-hand transfers.[63] An audible alarm can be set to detect the lowest acceptable level of oxygen saturation or the loss of the arterial pulse rate, and this obviously reduces the frequency of nursing vigilance. Loss of the arterial pulse is indicative of arterial occlusion in a toe transfer, whereas an oxygen saturation level falling below 90% is suggestive of venous occlusion.

SAVING THE FAILING FREE FLAP

What actions can be taken to salvage a failing free flap?

1. The patient's general condition (e.g., hypotension, cardiopulmonary impairment, or a low circulating volume, manifested by a low urinary output) may all adversely affect oxygenation of the flap. A cold vasoconstricted extremity may be due to circumstances as grave as advanced shock or as simple as a low room temperature. Both should be evaluated and corrected.
2. Look for any unduly tight dressings or sutures. Remove the splint and all the dressings down to the flap. Cut any tight sutures.
3. Reposition the patient's arm; in particular, determine if elevation or dependency of the arm improves flap perfusion. If it does, make the patient comfortable in this new position.
4. Look for signs of hematoma and evacuate the hematoma. If the flap is swollen or edematous and discolored and there is persistent serosanguineous fluid oozing from the flap margins, a hematoma should be strongly suspected. A flap hematoma may cause loss of a flap; its evacuation may salvage the flap. A few sutures along the flap margin opposite the entrance of the vascular pedicle into the flap should be cut immediately. This may allow some dissipation of the pressure induced by the hematoma, but formal evacuation of the hematoma should be done in the operating room as soon as possible after the hematoma is detected (see Figure 45.2, *C*).

Exploration in the Operating Room

If none of these maneuvers rapidly improves the appearance of the flap, the patient should be returned to the operating room immediately for exploration of the pedicle; if this is done quickly, it can be very successful (see Figure 45.5). The situation is almost always worse than it appears. Chen and colleagues reported a 9.9% reexploration rate in 1142 free flaps and an overall salvage rate of 63.7%. Of the failing flaps, 96% presented within 72 hours and 85% of them could be salvaged.[17]

1. Initially, only the incision that provides access to the pedicle is reopened. If all the sutures around the flap are removed, the edematous flap will be very difficult to control during inspection of the pedicle and it will be impossible to replace

the flap back into the primary defect with the precision achieved in the first surgery.
2. Any hematoma should be gently removed with warm irrigation and the gloved finger. Suction should only be used with extreme care.
3. The pedicle and recipient vessels proximal to the anastomoses should be examined for obvious kinks, occlusions, or thrombosis. The point of occlusion in a vein will usually be obvious, the upstream segment being turgid and the downstream segment collapsed. Arterial occlusion is usually less evident and can be detected by lack of a pulse on palpation or with a sterile Doppler probe. Testing of arterial flow by the "milking" or "sweeping" test should not be done until a microsurgical clamp has been placed across the artery downstream distal to a side branch through which emboli, which would otherwise wash into the flap microcirculation, can be safely diverted. After placement of the clamp, the side branch can be opened to determine the presence or absence of flow across the anastomosis.
4. Do not hesitate to open an anastomosis between clamps to assess flow and if necessary redo the anastomosis. If a clot is present in a patient with a normal clotting mechanism, remember that blood flow only stops if arterial inflow is poor, if "runoff" through the flap is impeded, or if the anastomosis is technically imperfect. If the anastomosis looks good, inspect the downstream segment for an unrecognized injury to the pedicle. If none is found and inflow through the recipient artery is strong, excise the anastomosis and do it again. There is usually enough redundancy in the recipient artery and arterial pedicle to allow a second end-to-end anastomosis. If not, a short interposition vein graft may be necessary. Revision of an end-to-side anastomosis is more difficult unless a "T"-graft[40,79] has been used or can be harvested. With a "T"-graft, three cuts and three anastomoses can save the situation.
5. Do not hesitate to excise a redundant segment and perform another anastomosis.
6. The patient should be kept in the operating room for a period of time after reexploration and revision of the anastomoses to ensure that further thrombosis does not occur.

Other Salvage Techniques

There are as many publications in the literature concerning experimental methods of enhancing flap survival as there are of monitoring, possibly more, but there are no prospective clinical trials documenting the efficacy of any pharmacologic agent to enhance flap survival. However, medicinal leeches and various thrombolytic agents may play an occasional role in the salvage of a failing free flap, either as an adjunct intraoperatively, during reexploration of the microsurgical anastomoses, or if the patient or the flap is not deemed suitable for surgical reexploration.

Leeches

It is well established that leeches can be used to salvage a failing replanted digit if venous outflow is compromised or if a suitable vein is not available for anastomosis. In an extension of this technique, leeches have been used to relieve venous congestion in pedicled flaps and free flaps.[7,28,131] The success of flap salvage after leech therapy has been reported to be as high as 60 to 70%. Just as in the replant situation, there is one report of a successful free flap performed with only an arterial anastomosis in which leeches provided venous drainage of the flap for 8 days until neovascularization was reestablished.

Hirudo medicinalis may ingest an amount of blood almost 10 times its own weight; however, the therapeutic effect of leeches is not due to the volume of blood ingested but due to continued bleeding from the bite after detachment of the leech. Several pharmacologically active substances are secreted by the leech, including hyaluronidase, an antihistamine, a vasodilator, and hirudin, which is the most potent natural anticoagulant known. Hirudin is a 65-amino acid polypeptide with a molecular weight of 9000 daltons and inhibits the conversion of fibrin to fibrinogen.

The most significant risk of leech therapy is infection[28] with *Aeromonas hydrophila*, which may cause a major necrotizing soft tissue or muscle infection with an incidence estimated at between 7 and 20%. Consequently, it may be prudent not to use leeches for a failing free muscle flap. *A. hydrophila* infections may be prevented or treated secondarily with a second- or third-generation cephalosporin or an aminoglycoside antibiotic. The second major risk of prolonged leech therapy is blood loss and the eventual need for blood transfusion. Leeches must also be prevented from "wandering" or attaching to normal better perfused tissues.

Thrombolytic Agents

Several thrombolytic agents have been used for the treatment of various arterial and venous thromboses, including myocardial infarction, pulmonary embolism, deep venous thrombosis, and thrombotic-embolic problems in the upper and lower extremities. However, there are only a few reports of thrombolytic therapy for salvage of a failing free flap.[3,20,24,37,77,83,97,106]

Heparin may prevent anastomotic thrombosis by blocking the conversion of prothrombin to thrombin and by decreasing platelet adhesiveness. Systemic intravenous infusion of heparin is sometimes used by some microsurgeons to prevent thrombosis of the arterial and venous anastomoses in replanted or revascularized digits, especially when these injuries have been associated with a crushing mechanism or after repeated revision of the anastomoses. However, systemic heparin may be complicated by bleeding and the development of hematomas. Local infusion of heparin through a tiny silicone catheter inserted into one of the venae comitantes of a free gracilis muscle flap was successful in preventing thrombosis of a revised end-to-side anastomosis of the other vena comitans. Heparin was infused at a rate of 250 U/hour for 6 days, and the flap was successfully salvaged after revision venous anastomosis was performed without inducing systemic anticoagulation.[83]

Streptokinase is an enzyme isolated from group C β-hemolytic streptococci that converts plasminogen into the enzyme plasmin, which in turn sequentially degrades fibrin in a thrombus. Successful salvage of a failing free flap due to either arterial or venous thrombosis has been reported, either by infusion of streptokinase into the totally isolated free flap[97] or by selective arterial infusion of streptokinase into the flap by direct arterial puncture proximal to the arterial anastomosis using a fine 30-gauge needle.[77] By avoiding return of streptokinase to the systemic circulation, very high doses of intraarterial streptokinase infusion can be used, up to 60,000 U in 1 hour.

Urokinase is a naturally occurring enzyme derived from human kidney cells and probably has significant advantages over streptokinase.[106] Unlike streptokinase, urokinase does not cause allergic reactions and can be used at very high concentrations with less risk of hemorrhage and without inactivating plasminogen. One of the authors (NFJ) has successfully salvaged two radial forearm flaps and one toe transfer that were failing due to venous thrombosis or combined arterial and venous thromboses by expedient reexploration and intraarterial infusion of urokinase into the recipient artery proximal to the arterial anastomosis. Serletti and associates[106] reported the successful salvage of five free flaps that were failing due to thrombosis of the venous anastomosis by infusion of 250,000 U of urokinase over 30 minutes through a 25-gauge catheter inserted into the recipient artery proximal to the arterial anastomosis.

There are two case reports of the use of an intravenous infusion of tissue plasminogen activator (t-PA)[37] in conjunction with an intravenous infusion of heparin to successfully salvage a free flap compromised by a presumed arterial thrombosis. The optimal dose of t-PA to achieve therapeutic thrombolysis has not been determined. Intravenous infusion of t-PA was begun at 12 mg/hour but was discontinued after 15 minutes because of hemorrhage from the flap donor site.

In summary, reexploration of the microsurgical anastomoses is the best solution to salvage a failing free flap, but leeches and the newer thrombolytic agents[20] may occasionally be indicated either before reexploration or in conjunction with surgical reexploration.

CRITICAL POINTS *The Failing Free Flap*

Nonoperative Measures

- Check the volume status of the patient, oxygenation, hematocrit.
- Release or remove constricting dressings.
- Reposition the patient's arm (up or down).
- Release sutures at the margin of the flap to release pressure and/or hematoma.

Operative Measures

- Return to the operating room for exploration.
  - Remove any hematoma.
  - Check the status of the vessels (e.g., for clotting or kinking).
  - Open the vessel between clamps (avoid distal embolization of clot).
  - Revise the anastomosis.
  - Add a vein graft if necessary.
  - Observe the flap closely in the operating room after revision for re-thrombosis.

Other Measures

- Use leeches for venous congestion (but not instead of returning to the operating room for revision of the thrombosed anastomosis).
- Anticoagulation (heparin)
- Thrombolytic agents
  - Streptokinase/urokinase/t-PA for disseminated thrombosis

INFECTION

Should infection develop beneath a flap, it should be treated just like any wound infection. In a patient who is not compromised systemically, infection invariably means that débridement of the original wound has been inadequate or perfusion to part of the flap has failed. Antibiotics may be used as a supplement, but expeditious surgical exploration is the best guarantee of flap survival. If exploration is delayed, thrombosis of the pedicle may result in complete loss of the flap. The flap should be elevated on the side opposite to the pedicle and reflected to the extent necessary to reveal the source of infection. If the source is an infected hematoma, evacuation with subsequent catheter irrigation for 2 days should suffice. Any suspicious areas of infection in the bed or in the flap itself should be radically débrided, followed once again by catheter irrigation for 2 days.

SPECIFIC FREE FLAPS

Lateral Arm Flap

First described by Song and associates, the lateral arm flap and its vascular anatomy were popularized by Katsaros and colleagues.[66,67] In many respects, it is ideal for upper extremity reconstruction because it can be harvested from the same limb using the same tourniquet.[124] The flap can be made as small as 10 cm^2 (Figure 45.6 and see Figure 45.4) and as large as virtually the entire circumference of the upper arm or extended onto the proximal forearm. It is thin and pliable and can be innervated. A segment of vascularized humerus (up to 10 cm long and 25% [1.5 cm] of the circumference) can also be harvested with the flap,[124] as can a vascularized segment of triceps tendon.[136]

For special contouring, the flap can be divided along the midline of its long axis or transversely from side to side, provided that the lateral intermuscular septum is preserved. This permits the proximal and distal portions to be laid side by side to cover a wider defect or to be placed on both sides of a hand that has sustained a major penetrating wound or requires coverage of both the palmar and dorsal aspects of the thumb/index finger web space (Figure 45.7). One drawback, which precludes its use in some young female patients, is that the donor site scar is very noticeable, whether it is closed directly or with a skin graft. Another is that the flap may be bulky: in one series of lateral arm flaps used for reconstruction of the upper extremity, 50% were considered bulky by the surgeon and required defatting.[44] These two disadvantages of the lateral arm skin flap can potentially be avoided by harvesting only lateral arm fascia[136] and covering this lateral arm fascial flap with a split-thickness or full-thickness skin graft.

Anatomy

The arterial supply to the lateral arm flap is the posterior radial collateral artery, one of the two terminal branches of the profunda brachii artery. The profunda brachii arises from the brachial artery in the distal axilla and accompanies the radial nerve in the spiral groove until both penetrate the lateral intermuscular septum, just distal to the deltoid insertion. Here the artery divides, with the anterior radial collateral artery continuing with the radial nerve anterior to the brachioradialis origin from the humerus and the posterior radial collateral artery passing posterior to the origin of the lateral intermuscular septum. The vessel becomes closer to the humerus and supplies bone via the overlying periosteum as it proceeds down to the lateral epicondyle, to which it is adherent.

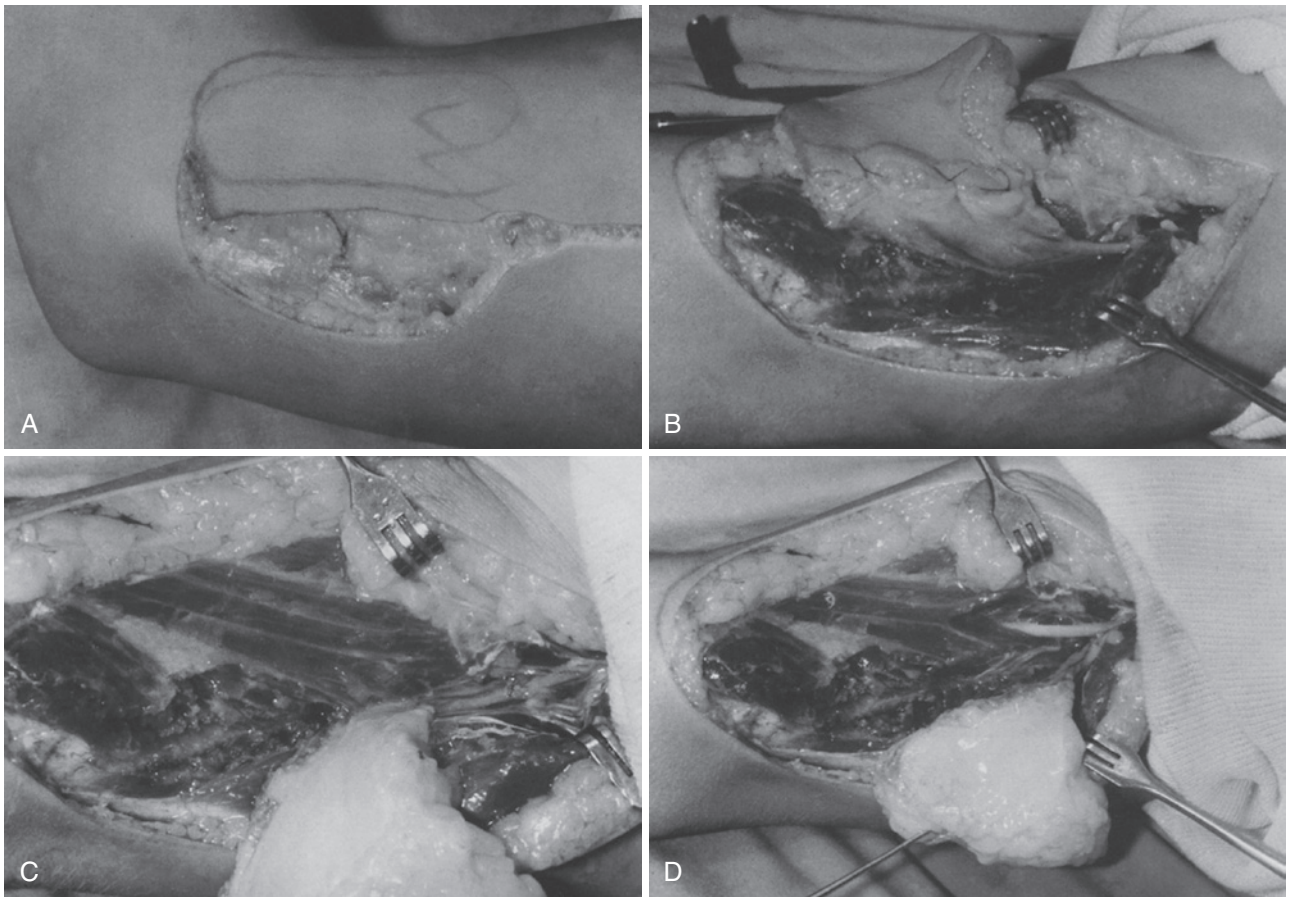

FIGURE 45.6 Lateral arm flap dissection. **A,** The posterior incision has been made, and the fascia overlying the triceps is seen. This must be divided to gain access to the correct plane for further dissection. **B,** The dissection has been completed to the point of releasing the lateral intermuscular septum from the underlying bone. The humerus can be seen in the distal third of the wound with the muscles of the mobile wad anteriorly and the triceps posteriorly. The sutures between the fascia and the skin prevent any shearing force from developing between these tissues. **C,** On a close-up view, the humerus is seen more clearly. The oozing is from the muscular branches that have been divided. The more proximal course of the pedicle is seen to the right of the incision. **D,** The pedicle has been dissected more proximally, and the radial nerve is now clearly seen as the white structure passing forward between the brachialis and the brachioradialis.

Between the point at which it leaves the radial nerve and the lateral epicondyle, the posterior radial collateral artery provides branches to bone, to muscles in both anterior and posterior compartments, and to the fascia and overlying skin. The main branches to fascia and skin therefore arise between these two points, which roughly demarcate the lower half of a line between the deltoid tubercle and the epicondyle.

The posterior radial collateral artery anastomoses distally with a rich vascular plexus composed of the olecranon anastomosis and branches of the radial recurrent artery, so that the territory of the lateral arm flap can be extended up to 12 cm distal to the lateral epicondyle onto the proximal forearm. Alternatively, only the proximal forearm skin can be harvested, thereby increasing the length of the posterior radial collateral artery pedicle.

The artery of the flap is usually accompanied by two venae comitantes and by two nerves, the posterior cutaneous nerve of the arm and forearm and both branches of the radial nerve. The posterior cutaneous nerve of the arm can be used to innervate the flap, whereas the posterior cutaneous nerve of the forearm should be preserved but can be harvested with the flap as a vascularized nerve graft. If the flap is designed on its distal skin territory as the lateral arm/proximal forearm flap, the posterior nerve of the forearm is used to innervate the flap.

Operative Technique

A sterile tourniquet is applied high on the upper arm after preparation up to the axilla. A line marking the lateral intermuscular septum is drawn from the deltoid tubercle to the lateral epicondyle and defines the midline axis of the flap (see Figure 45.4, *A*). The flap template is laid over this line marking the septum and in most instances, should be centered over the distal half of the line, although if a longer pedicle is required, the template can be moved more distally until it is centered over the epicondyle. If more skin cover over the pedicle is desired, the template should be moved proximally.

The skin is incised around the posterior margin of the flap and the incision extended proximally along the axial line as far as the deltoid tubercle. The incision is carried down to fascia. The posterior margin of the incision is elevated with skin hooks and the dissection continued posteriorly, superficial to the fascia until the midline of the triceps tendon is reached. The

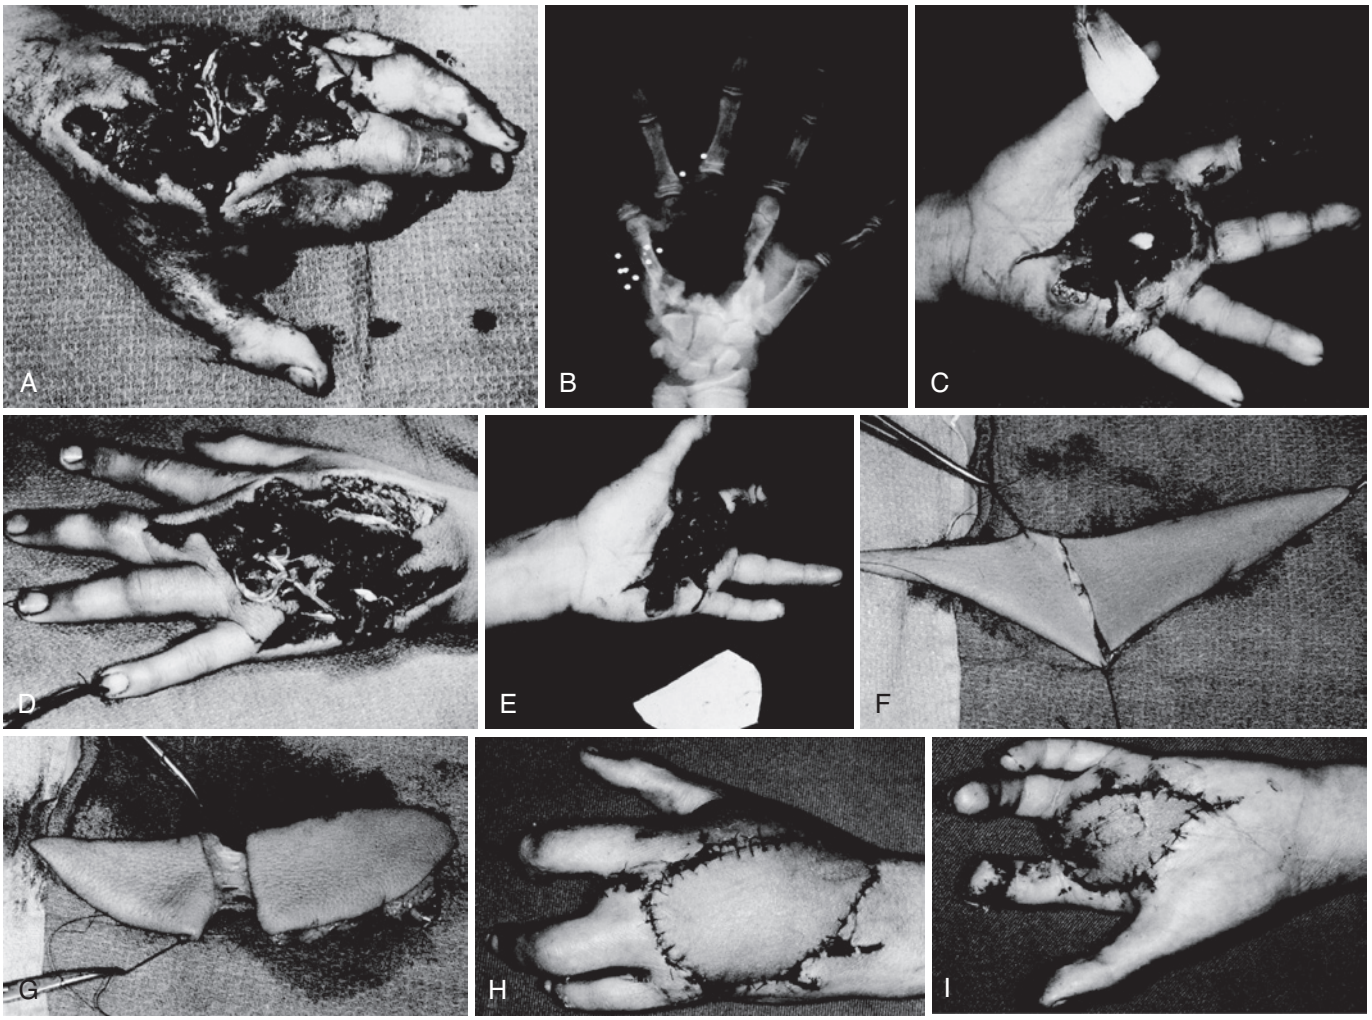

FIGURE 45.7 Lateral arm flap. **A,** This 14-year-old right-handed youth sustained a close-range shotgun injury to his left hand. **B,** Radiographs show significant metacarpal loss. Distraction displayed the **(C)** palmar and **(D)** dorsal defects. The middle finger was nonviable and had no metacarpal and was therefore amputated. The index finger was transposed into the position of the middle finger metacarpal. Length was restored by inserting the middle phalanx from the middle finger as an intercalated bone graft. The bony defect in the ring metacarpal was restored by using the proximal phalanx from the middle finger in a similar fashion. Significant palmar and dorsal defects remained. **E** and **F,** Templates were taken and placed end to end in designing a lateral arm flap taken from the same arm. **G,** After the lateral arm flap was raised, it was divided transversely through skin and subcutaneous tissue down to the level of the intermuscular septum containing the pedicle. The vessels of the flap were anastomosed to the radial artery and cephalic vein, placing the proximal portion of the flap on the dorsal defect and the distal portion of the flap on the palmar defect. The intervening pedicle was accommodated between the heads of the ring finger and now translocated index finger. **H** and **I,** Complete viability of the flap 14 days postoperatively when the patient started on a passive and active exercise program.

fascial vessels can be clearly seen running over the tendon (see Figure 45.6, *B*). The fascia is incised along the midline of the tendon and elevated from the tendon and muscle by dissecting in an anterior direction with the fascia elevated under some tension, at the same time retracting the triceps muscle in a posteromedial direction. The fascia and skin can be sutured to one another using the long ends of the ties as stay sutures. The dissection proceeds easily, with few if any small vessels to cauterize, until the septum is reached, at which point the pedicle vessels will be seen with muscular branches diving into the triceps. The posterior-to-anterior dissection is completed at this point.

The anterior margin of the flap and the underlying fascia over the brachialis and brachioradialis muscles should now be incised. The fascia here is more flimsy than that posteriorly but can be readily defined and managed in precisely the same way as previously described for the posterior portion of the flap, dissecting this time in a posterior direction beneath the fascia until the muscular vessels are encountered. The distal margin of the flap should now be raised, dissecting right up against the aponeurosis of the extensor origin in a proximal direction until the epicondyle is reached. The fascia here is very ill defined. There is no need, however, to incise the aponeurosis as one is tempted to do, only a need to dissect hard against it up to the epicondyle.

After raising all three margins, the flap can be elevated away from the lateral humerus. The assistant should retract the anterior and posterior muscle bellies away from the septum. With

traction applied to the flap in an upward direction with the nondominant hand, the surgeon should now elevate the septum from the periosteum of the humerus with a knife or bipolar cautery, taking care to ensure that all periosteal and muscular branches are cauterized. Although initially difficult, the further proximal one proceeds, the more easily the flap is raised (see Figure 45.6, *C* and *D*).

When the radial nerve is first seen leaving the field anteriorly between the brachialis and brachioradialis muscles, those vessels passing forward with the nerve should be ligated. The dissection is continued as far proximally as necessary to achieve a pedicle length of approximately 6 cm (see Figure 45.6, *D*). The two posterior cutaneous nerves will be encountered here: the deeper posterior cutaneous nerve of the forearm can be dissected out of the septum to avoid anesthesia in the forearm; the more superficial posterior cutaneous nerve of the arm can be divided high and later used to innervate the flap. The more proximal the dissection proceeds, the more difficult it becomes, because one is now pursuing the profunda brachii in the spiral groove beneath the lateral head of the triceps. This requires strong retraction with heavy rakes. A further impediment is the overlying tourniquet, but to release it at this stage will only make the situation worse. If necessary, an additional 6 to 8 cm of pedicle length can be gained by splitting the lateral and long heads of the triceps to expose the entire length of the profunda brachii vessels in the spiral groove. A tunnel can be developed beneath the lateral head of the triceps, and either the flap can be delivered proximally through this tunnel or the pedicle can be divided and the pedicle vessels delivered distally. This extended pedicle also increases the mean diameter of the artery from 1.5 mm up to 2.45 mm.

The authors adopt the convention of placing metal clips on the veins and silk ligatures on the artery, thus avoiding any potential confusion later. After dissection of a free tissue transfer has been completed, it is customary to release the tourniquet to reperfuse the flap before dividing the pedicle, but the lateral arm flap is an exception. It is completely reliable and the inevitable bleeding from adjacent muscles will obscure the important step of dividing the pedicle at its highest point.

The secondary defect can be closed directly if the flap is less than 6 to 8 cm wide, but otherwise a split-thickness skin graft is applied with confident expectation of full take, because the bed is well vascularized. The only complications associated with the harvest of a lateral arm flap are permanent hypoesthesias in the distribution of the posterior cutaneous nerve of the forearm if it is divided and temporary radial nerve palsy. The authors have never encountered this serious problem in their practice, but it has been reported after an Esmarch bandage was used as a tourniquet or when careful monitoring of cuff pressure was not followed.[44] A study of donor-site morbidity and aesthetic outcomes revealed that 90% of patients had decreased sensation after harvest of a lateral arm flap, but 85% of patients would still choose a lateral arm flap again.[71]

CRITICAL POINTS *Lateral Arm Flap*

Indications
- Soft tissue defects of the hand (smaller areas)
- Defects of the first web space

Preoperative Evaluation
- Doppler examination of the pedicle

Pearls
- A sterile tourniquet is placed as high as possible.
- The flap axis is a line from the deltoid tubercle to the lateral epicondyle.
- Avoid damage to the radial nerve during pedicle dissection.

Technical Points
- Begin dissection posteriorly on the skin.
- Elevate the skin and fascia toward bone.
- Elevate the anterior skin and fascia.
- Dissect the pedicle off the humerus in a distal-to-proximal direction.
- The artery can be quite small; the vein is fragile.
- Beware of the radial nerve running with the pedicle proximally.
- It may be necessary to remove the tourniquet to get added length on the pedicle as it spirals around the humerus.

Pitfalls
- Elevating skin and fascia without vessels
- Injury to radial nerve

Donor Site Management
- Small defects (<7 cm) can be closed primarily.
- Defects of 7 cm or larger will need skin grafting.

Radial Forearm Flap

The radial forearm flap[35,87,112,134] certainly offers unrivaled quality of thin, mobile skin, similar in its characteristics to the skin over the dorsum of the hand. Most dorsal and palmar defects of the hand can be covered by a pedicled reverse radial forearm flap[81] (see Chapter 44), but occasionally the size and shape of the defect may necessitate using a free radial forearm flap either from the contralateral forearm (Figure 45.8) or even from the ipsilateral forearm.[64] In any of these variations, the radial forearm flap depends on the availability of good flow through the ulnar artery and the palmar arches into the digital vessels. The radial artery may occasionally be the only patent vessel to the hand when there has been a penetrating or crushing injury to the forearm or palmar surface of the hand. Even when this is not the case, the radial artery has been shown to be the dominant artery in 12% of hands. Harvesting a radial forearm flap may potentially result in acute ischemia of the hand or postoperative symptoms of cold intolerance. However, digital temperature and Doppler flow studies have shown that loss of the radial artery does not cause any significant compromise to the circulation of the hand. Therefore, most surgeons no longer reconstruct the radial artery with a reversed interposition vein graft. The appearance of the donor defect, which has to be skin grafted, remains the major drawback of this flap for some surgeons.

Anatomy

The radial artery pursues a relatively superficial course down the forearm, from its origin at the bifurcation of the brachial artery to just distal to the radial styloid, where it passes deep to the abductor pollicis longus and extensor pollicis brevis tendons through the anatomic snuffbox. In the proximal forearm, it lies on the superficial surface of the pronator teres, just beneath the medial margin of the brachioradialis muscle. More distally, it comes to lie in turn on the radial head of the flexor digitorum

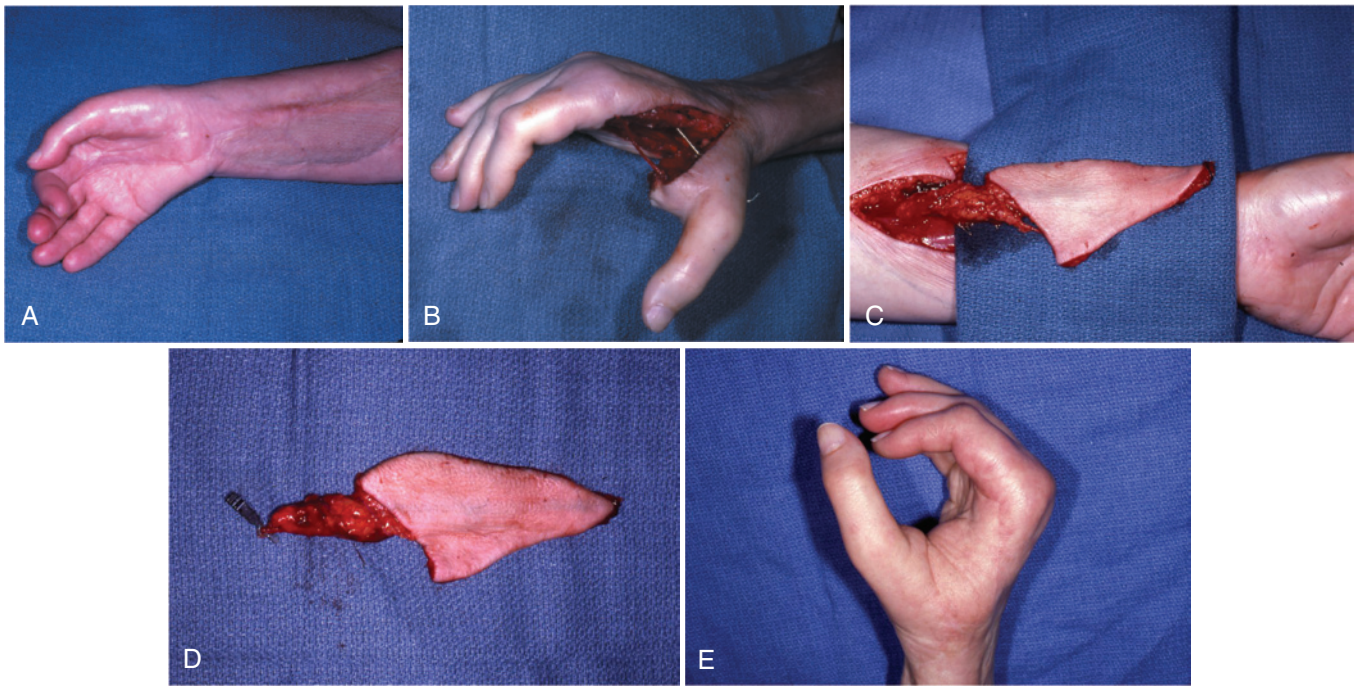

FIGURE 45.8 Radial forearm flap. **A,** This woman sustained a severe crushing injury of her right dominant forearm which required fasciotomies and vein graft revascularization. **B,** She later developed a severe adduction contracture of the thumb/index finger web space which necessitated a radical release of the first web space. **C** and **D,** A reverse radial forearm flap was not an option for coverage of the radical web space release, because the forearm had been previously skin grafted and the radial artery reconstructed with a vein graft. Therefore a contralateral left radial forearm flap was harvested. **E,** This provided thin pliable skin for the widened thumb/index finger web space.

superficialis and flexor pollicis longus, where it is palpable through the skin. The artery is accompanied by two venae comitantes.

Throughout its course, the artery gives off branches to a plexus of vessels in the overlying deep fascia, which supplies the skin of the anterior and radiodorsal surfaces of the forearm. Similarly, deep fascial branches also supply the periosteum of the distal half of the radius between the insertions of the pronator teres and brachioradialis. This allows a segment of vascularized bone to be harvested from the radius up to 10 cm in length and up to 30% of the cross-sectional area of the radius as an osteocutaneous flap.[35]

The minimal precaution that should be taken before raising a forearm flap is an Allen test to ensure that flow will be adequate through the remaining ulnar artery. Noninvasive vascular studies to determine arterial dominance are probably unnecessary.

Operative Technique

The course of the radial artery should be mapped out with a Doppler probe and marked on the skin, as should the course of the largest superficial vein in the forearm proximal to the flap (Figure 45.9, *C*).

The pattern of the defect is placed on the forearm with the marked course of the radial artery close to the radial border of the template. The radial artery should not be used as the midaxis of the flap; otherwise, if the flap extends around the radial border of the forearm, the skin-grafted defect becomes much more noticeable.[64] The flap is usually designed over the middle or distal third of the forearm. However, if the radial artery is to be used in a "flow-through" situation to reconstruct an associated arterial defect in the wound (see Figure 45.9),[9,93] the length of radial artery required proximal and distal to the flap to restore arterial inflow to the distal limb will predetermine the proximal-distal location of the flap on the forearm.

If pedicle length is not a consideration, the flap can be raised with its distal margin 3 to 5 cm proximal to the wrist crease. This avoids skin grafting over the more distal flexor tendons, especially the flexor carpi radialis, and the chances of the skin graft not taking over this critical area are reduced.

The radial margin of the flap is incised as well as a short longitudinal incision extending distally from the flap margin over the course of the radial artery. In elevating the radial skin margin from the underlying deep fascia, the cephalic vein should be identified and preserved, because very occasionally it may be needed to reconstruct the radial artery. Great care should be taken to preserve branches of the superficial radial nerve. Once the skin has been elevated for about 1 cm from the flap margin, the deep fascia should be incised to enter the plane of dissection radial to the radial artery pedicle.

The distal, ulnar, and proximal margins of the flap are now incised and the deep fascia can be sutured to the skin at several points around the flap to prevent shearing between the two during elevation of the flap. If the ends of these sutures are left long, they can be grasped with hemostats to provide the necessary tension during dissection. The flap is now raised by dissecting in the loose areolar tissue beneath the deep fascia in an ulnar-to-radial direction. Wherever a tendon is encountered in elevating the flap, care must be taken to preserve the overlying paratenon.

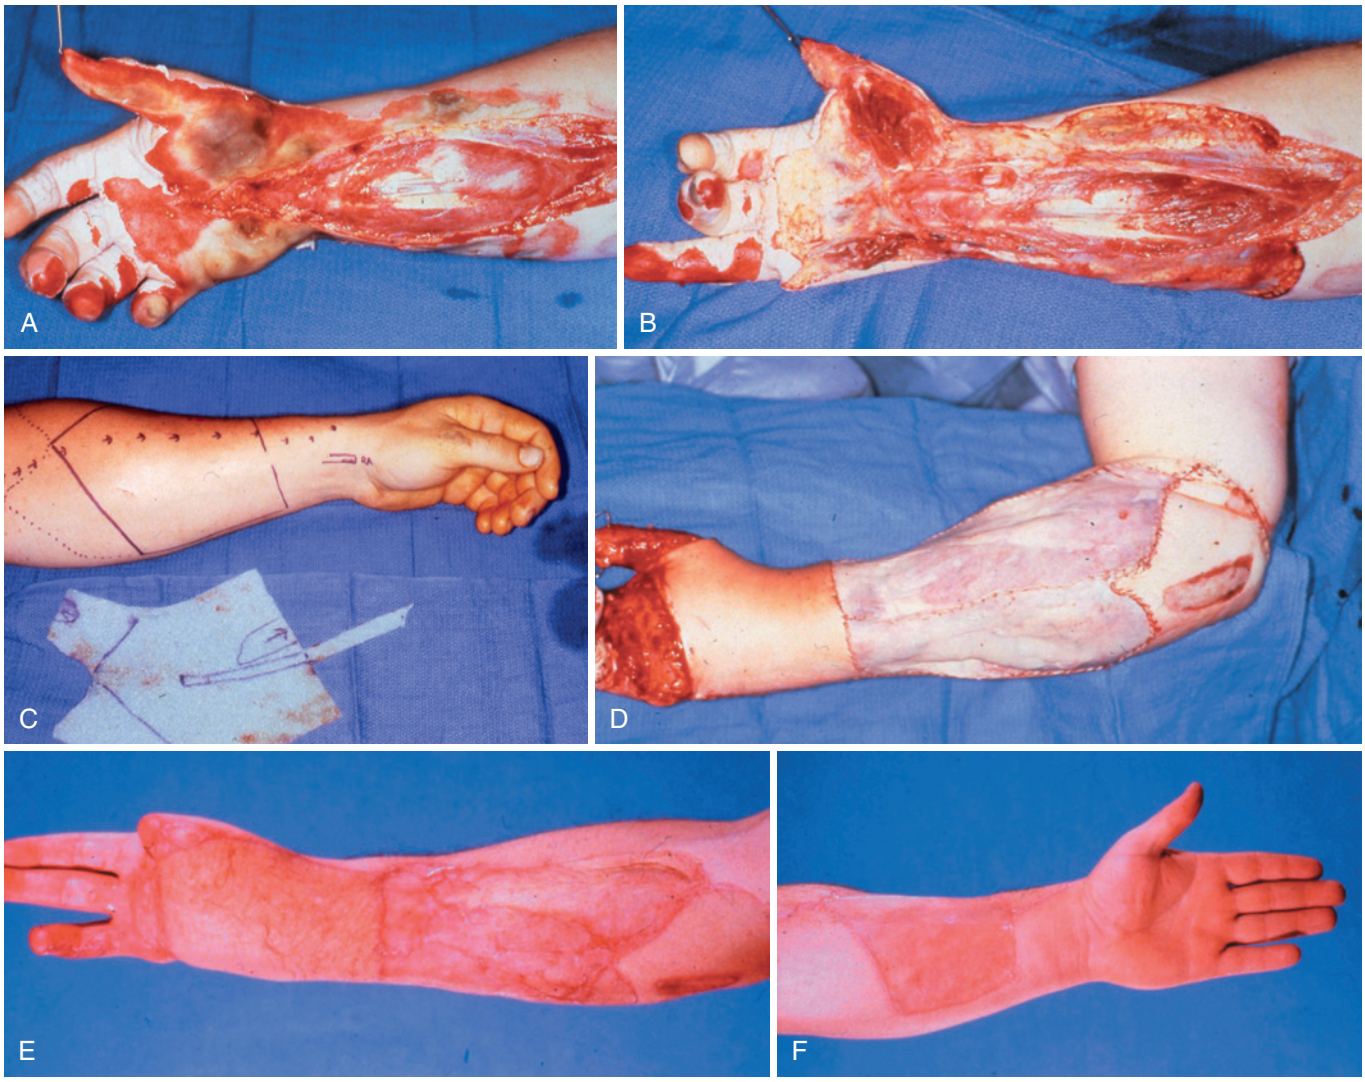

FIGURE 45.9 Radial forearm flap. **A,** This extensive thermal crush injury of the right hand required extensive débridement **(B)** with excision of the thrombosed ulnar artery, the small finger, the flexor retinaculum, and the distal portion of the flexor carpi ulnaris. Circulation to the digits was deemed to be marginal. **C,** A contralateral left radial forearm flap was designed based on the radial artery and the cephalic vein. The flap was to be applied in retrograde fashion to provide not only cover for the structures of the carpal tunnel but also to restore blood flow to the superficial palmar arch from the proximal ulnar artery. Fascial extensions of the radial forearm flap to be used to cover the palm of the hand are shown by the *dotted outline*. A pattern has been taken with plastic foam. **D,** The appearance immediately after application of the radial forearm flap, the skin grafts, and a transposition flap of the flexor carpi ulnaris. **E,** The result before thumb reconstruction. **F,** The defect of the donor forearm covered with a split-thickness skin graft. (From Chick LR, Lister GD, Sowder L: Early free-flap coverage of electrical and thermal burns, *Plast Reconstr Surg* 89:1013–1019, 1992, with permission.)

Once the flap has been raised from the ulnar margin across to the flexor carpi radialis tendon, traction on this muscle in an ulnar direction will reveal the radial artery and its venae comitantes. Similarly, dissection from the radial margin of the flap will reveal the vessels as the fascia is lifted from the brachioradialis. This muscle conceals the artery beneath its anterior border, the more so the farther proximal the dissection. Strong traction on the brachioradialis in a radial direction and dissection hard against the muscle and tendon are required. Distally, the two venae comitantes are ligated and divided. The radial artery is also divided between a ligature proximally and a microvascular clamp distally. Working from the radial and ulnar aspects, the lateral intermuscular septum containing the radial artery and venae comitantes can be visualized at all times and the portion of the septum passing inferiorly from the artery down to the flexor pollicis longus and radius can be divided to allow elevation of the vascular pedicle in continuity with the overlying flap. Small perforating vessels passing downward to supply the radius and flexor pollicis longus muscle can be coagulated. Dissection now progresses in a distal-to-proximal direction, and the vascular pedicle is elevated in the plane between the flexor carpi radialis and brachioradialis muscles. A longitudinal or gently curving incision proximal to the skin flap allows elevation of the proximal radial artery and any subcutaneous veins, if necessary, all the way to the bifurcation of the brachial artery just distal to the antecubital fossa. Usually, the two venae comitantes drain via a communicating branch into the superficial venous system so that a single large cubital vein can be

used as the proximal venous anastomosis.[120] The tourniquet is deflated, and this should reveal immediate reperfusion of the flap and the hand.

The microvascular clamp is removed from the distal stump of the radial artery, and this allows subjective evaluation of retrograde flow from the radial artery provided by inflow through the ulnar artery and palmar arches. If this flow is adequate, the distal radial artery is ligated. The proximal radial artery and venae comitantes or superficial vein are ligated and divided in the antecubital fossa, and the flap is transferred to the recipient defect.

The radial artery is reconstructed only if there is poor retrograde flow through the distal stump of the radial artery after release of the tourniquet. If this is necessary, either the cephalic vein, if it has not been incorporated in the flap, or the greater saphenous vein can be harvested, reversed, and used as an interposition vein graft with two end-to-end anastomoses to the proximal and distal ends of the radial artery. If bone has been taken from the radius in its distal third for a radial forearm osteocutaneous flap, contour can be restored by transposing the pronator quadratus muscle on the anterior interosseous vascular pedicle. The strength of the radius can be augmented by prophylactic anterior plating of the radius from proximal to distal of the bony defect. Any exposure of the flexor carpi radialis tendon is covered by imbrication of the flexor digitorum superficialis muscle. The margins of the flap donor defect are sutured to the underlying muscles to provide a shallow contour over which a nonmeshed split-thickness skin graft is placed (see Figure 45.9, *F*).[6,64,121] Some surgeons believe the donor defect to be cosmetically unsightly, but most patients are not embarrassed by the appearance of the forearm in long-term follow-up. To improve the "take" of a split-thickness skin graft over the donor site, a suprafascial radial forearm flap can be harvested above the level of the deep fascia, with only a cuff of fascia around the radial artery. The appearance of the donor defect can also be potentially eliminated by raising a radial forearm fascial flap with fascia alone (Figure 45.10).[14,36,51] However, a potential disadvantage is that split-thickness skin grafts may not "take" completely over a fascial flap and the fascial flap may not be sufficiently robust to provide coverage of the primary defect.

CRITICAL POINTS *Radial Forearm Free Flap*

Indications
- Soft tissue defect of hand and wrist
- May provide fascia, skin, tendon, and bone if needed
- Wound with need for distal revascularization (flow-through flap)

Preoperative Evaluation
- Allen test for patency and adequacy of ulnar artery inflow to hand
- Scars on forearm from prior injury or surgery

Pearls
- "Best" flap to place on hand but donor site may be cosmetically ugly
- May use as fascia-only flap to avoid skin graft on forearm

Technical Points
- Design the flap 3 to 5 cm proximal to wrist if possible.
- Do not center the flap on the radial artery, but make the radial artery the radial border of the flap.
- Dissect the pedicle as a "unit"; do not divide the veins from the artery.
- Preserve the cephalic vein; avoid damage to the superficial branch of the radial nerve.
- The palmaris longus may be included in the flap if vascularized tendon reconstruction is required.

Pitfalls
- Damage to superficial branch of radial nerve
- Inadvertent division of the septum between the skin and vascular pedicle, when dissecting from radial side

Donor Site Management
- All but very small flaps will require skin grafting.
- The flexor carpi radialis tendon may be covered by imbrication of the superficialis muscle "up and over."
- A nonmeshed split-thickness graft is fine; the donor site is somewhat better with a full-thickness graft.
- Use a splint until the graft has taken.

Scapular Flap

Anatomy

The scapular flap, a cutaneous flap, is based on the vascular territory of the cutaneous branch of the circumflex scapular artery.[39,46] The circumflex scapular artery is the first branch of the subscapular artery, arising 2 cm from the origin of the subscapular artery from the axillary artery. The external diameter of the circumflex scapular artery is 1.72 mm. The circumflex scapular artery passes posteriorly through the triangular space between the long head of the triceps laterally, the teres major inferiorly, and the subscapularis medially and superiorly. It then divides into a number of branches deep to the teres minor. The cutaneous branch continues posteriorly between the teres minor above and the teres major below. It turns sharply medially over the lateral border of the scapula and divides into two branches: one branch runs transversely, superficial to the deep fascia overlying the teres minor and the infraspinatus, and the other branch runs obliquely downward parallel to the lateral border of the scapula. Flaps based on the transverse branch of the circumflex scapular artery have by convention been described as scapular flaps, whereas those based on the descending branch are described as parascapular flaps (Figure 45.11, *B*).[89] A thin circumflex scapular artery perforator flap based on a perforator vessel arising within 1.5 cm of the bifurcation of the circumflex scapular artery has recently been described.[25]

Injection studies have shown that the vascular territory includes all of the skin inferior to the scapular spine, extending medially toward the spine and laterally over the deltoid. The lateral border of the scapula can be harvested with either the scapular or parascapular flaps as a vascularized bone graft[114] and could potentially be considered as an option for simultaneous reconstruction of a combined dorsal hand defect and an underlying metacarpal bony defect. A combined scapular osteocutaneous flap and latissimus dorsi flap can also be harvested on their common vascular pedicle.

Operative Technique

The patient is placed in the lateral position with padding beneath the opposite axilla. The arm that is uppermost should be prepared and draped with a stockinette, so that the arm can be abducted as required. With the arm abducted, the triangular space through which the pedicle passes can be convincingly

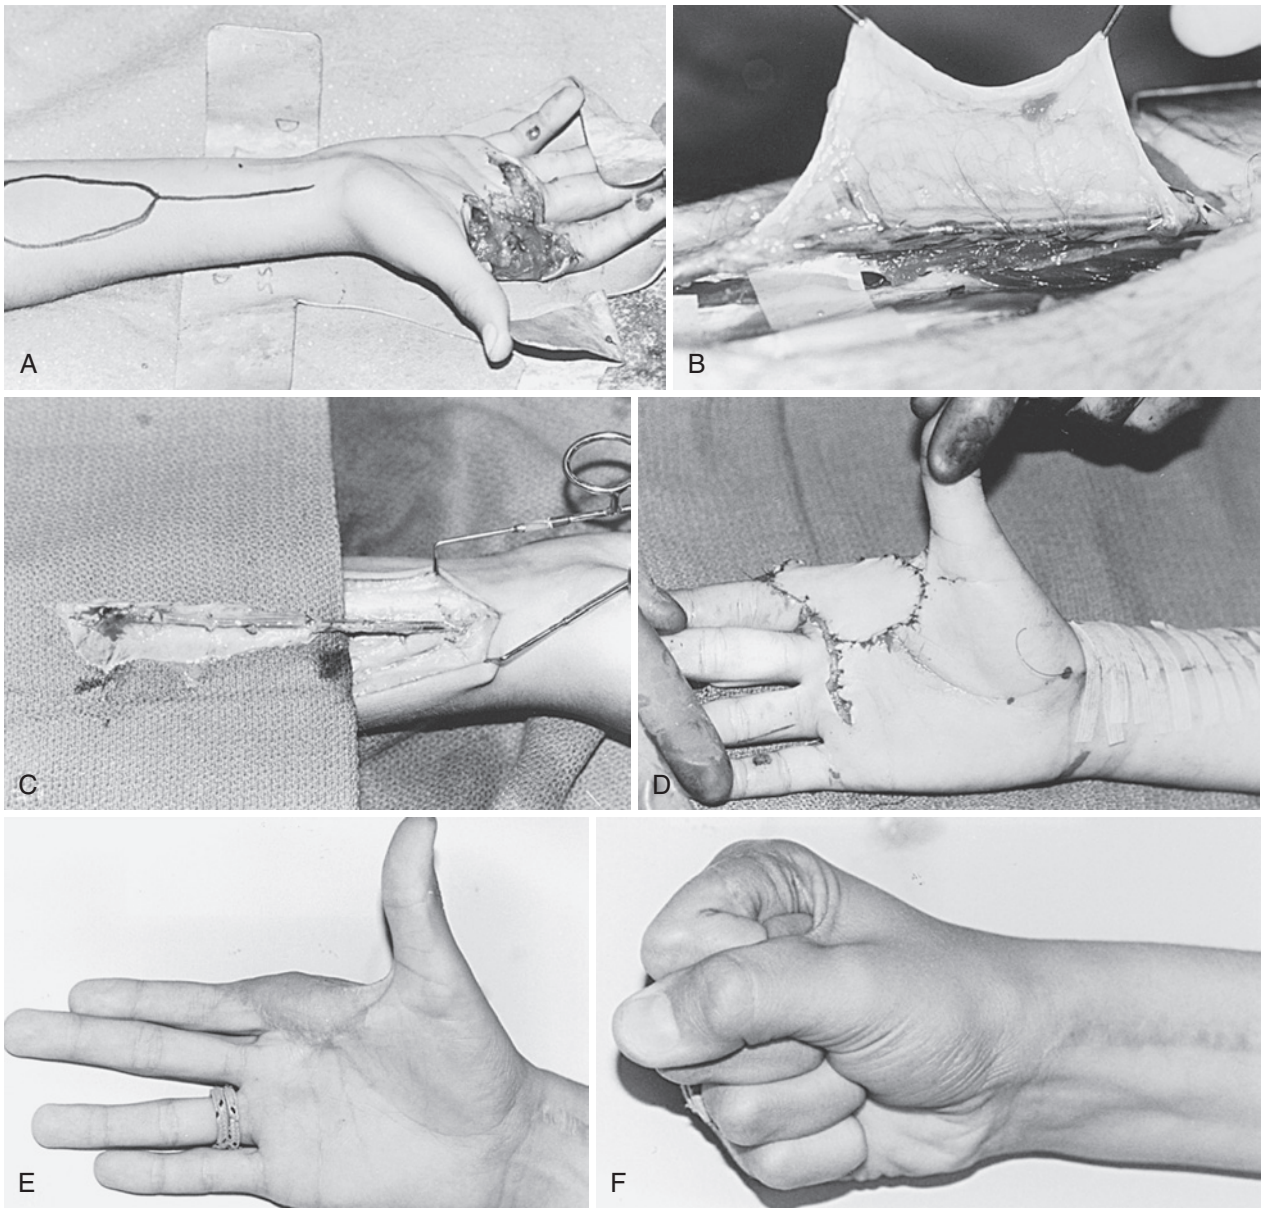

FIGURE 45.10 Reverse radial forearm fascial flap. **A,** Palmar defect from a shotgun injury with the area of fascia to be harvested outlined on the forearm. **B,** Fascia elevated off the muscle. Note the rich vascularity of the fascia. **C,** The fascia with its radial artery pedicle after harvest. **D,** Fascia placed in the palmar defect and covered with a full-thickness skin graft. **E** and **F,** Late result with stable coverage and good motion. Note the forearm scar from primary closure of the donor site.

palpated by gripping the posterior axillary fold between the finger and thumb (see Figure 45.11, *A*). The defect into which the thumb intrudes is formed by the teres major, the deltoid, and the combined scapula and teres minor.

A sterile Doppler probe may be used to trace the cutaneous vessels across the back, and the axis of the transverse and descending branches should be drawn. The flap template should now be placed over either axis, taking into account the orientation of the pedicle to the primary defect and the laxity of the skin with regard to primary closure. A transverse scapular flap may extend medially as far as the spine and can be extended farther across the midline or laterally over the deltoid if required. Scapular and parascapular flaps should not be designed as more than 10 cm wide, because such width would make it impossible to directly close the secondary defect, and this is not a good site for a skin graft.

The margins of the flap are incised down to the thick fascia overlying the infraspinatus. The plane superficial to this deep fascia is well defined and relatively avascular. The flap can be swiftly raised proceeding from medial to lateral for a scapular flap or from inferior to superior for a parascapular flap. As the triangular space is approached, the cutaneous branch of the circumflex scapular artery can be displayed by transilluminating the flap. The triangular space should be approached by splitting the aponeurotic teres minor away from the muscular teres major. As dissection proceeds into the space, the surgeon should be very careful because there are several large, short, and comparatively fragile branches that supply the muscles and

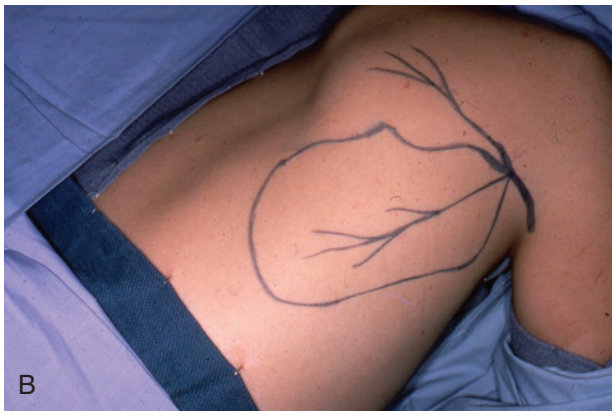

FIGURE 45.11 Scapular flap. **A,** Using the finger and thumb to grip the posterior axillary fold, the triangular space is readily detected lying between the triceps (T), the teres minor (TMn), and the teres major. **B,** A pencil Doppler probe can be used to trace the transverse and descending branches of the circumflex scapular artery. In this patient, a parascapular flap is to be harvested based on the descending branch of the circumflex scapular artery.

CRITICAL POINTS *Scapular Flap*

Indications
- Moderately sized soft tissue defects of upper extremity (Figure 45.12)
- Defects with short segmental bone loss (using vascularized lateral border of scapula)

Preoperative Evaluation
- Perform Doppler imaging of the pedicle as it exits the triangular space.
- Mark the lateral border of the scapula, teres major, and teres minor.

Pearls
- A very large "parascapular" flap can be harvested to cover very large defects.

Technical Points
- Flaps should be designed over a vessel defined by Doppler imaging.
- Do not design flaps wider than 10 cm because this is a difficult area for a split-thickness skin graft to take.
- Raise the skin with fascia from medial to lateral (scapular flap) or inferior to superior (parascapular flap).
- Watch for multiple branches from the pedicle to muscles and lateral scapula in the triangular space.
- The pedicle can be lengthened by dissecting subscapular vessels up to axillary vessels.

Pitfalls
- Dissection should proceed with caution when one is approaching the triangular space.

Donor Site Management
- Limit the flap width to 10 cm and close primarily over drains.
- Skin grafting of this donor site is unwise.

lateral border of the scapula. The assistant should apply traction to the borders of the space, so that the surgeon can visualize and ligate these branches.

To obtain the longest possible pedicle, the incision should be extended into the axilla. The thoracodorsal artery should be located on the undersurface of the latissimus dorsi muscle and traced proximally so that the "T"-bifurcation of the subscapular artery into the thoracodorsal and circumflex scapular arteries can be completely defined. Either the circumflex scapular artery can be divided just distal to the thoracodorsal artery, or the subscapular artery can be divided just below its origin from the axillary artery, thereby incorporating the "T"-junction that will facilitate two end-to-end anastomoses rather than an end-to-side anastomosis using the circumflex scapular artery. A pedicle some 15 cm in length from the axillary artery to the flap can be achieved.

After completion of the dissection, the secondary defect can be closed primarily. This should be done with strong sutures because dehiscence can occur with abduction of the shoulder. After harvest of a parascapular flap, 45% of patients complained of sensory abnormalities, but 100% said they would choose a parascapular flap again.[71]

A "fascial" version of the scapular flap has been described with the advantages that its width can be greater than 10 cm and that the donor scar is less likely to widen and become hypertrophic.[27,70] Strictly speaking, this scapular fascial flap should probably be termed a subcutaneous flap or adipofascial flap. If the surgeon has decided that a fascial flap is the optimal flap, the scapular fascial flap may be a better selection in men in order to avoid the potential alopecia seen after harvesting a temporoparietal fascial flap, but it requires a change from the lateral position to the supine position during surgery.

Groin Flap

Anatomy

The groin flap (Figure 45.13, *A*) is an axial-pattern cutaneous flap. Its axial vessel is the superficial circumflex iliac artery,[110] which is a relatively constant vessel, present in 96% of a series of angiograms. The vessel arises from the femoral artery in the femoral triangle, which forms a vascular "hub"[118] for the axes of several flaps that converge in this location (Figure 45.14).

The superficial circumflex iliac artery emerges from the femoral triangle by passing over the medial border of the sartorius immediately after giving off a deep muscular branch. Initially below the deep fascia, the vessel emerges upward through the fascia as it crosses the sartorius. It passes laterally, parallel to, and 2 cm below the inguinal ligament (see Figure 45.13, *A*).[22,48,54] At a point below the anterior superior iliac spine, the vessel divides and supplies the skin immediately below the iliac crest. The vascular territory of the superficial circumflex

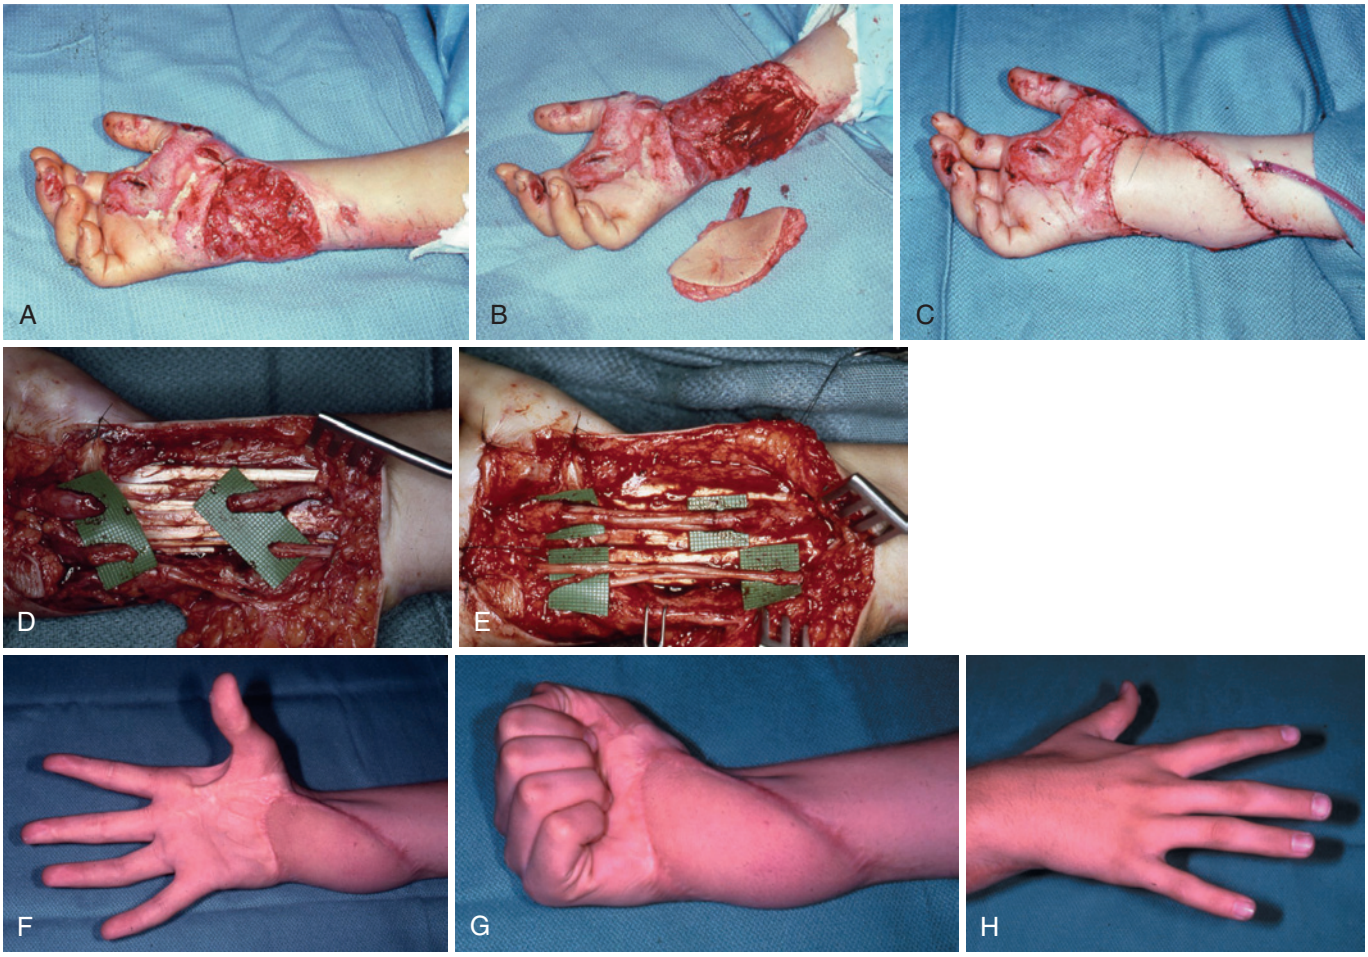

FIGURE 45.12 Scapular flap. **A,** This 5-year-old boy sustained a degloving injury of the palmar aspect of his right wrist with segmental defects of both the median and ulnar nerves and several flexor tendons, when he was thrown out of a car. **B** and **C,** After serial débridements, the flexor tendons were reconstructed and the soft tissue defect covered with a free scapular flap, with end-to-end anastomosis of the circumflex scapular artery to the already transected distal ulnar artery. **D** and **E,** Three months later, the flap was re-elevated and the segmental defects of the median and ulnar nerves were reconstructed with sural nerve grafts. At 9 years after operation, without any tenolyses or tendon transfers, the patient has regained excellent palmar abduction of the thumb **(F)** and full flexion **(G)** and extension of the fingers without any clawing **(H)**. The flap developed some hypertrophy of the subcutaneous fat as the patient went through puberty and would benefit from minor debulking.

iliac artery ends at some point lateral to the anterior superior iliac spine. Practical experience has demonstrated that the flap can be safely extended beyond the anterior superior iliac spine by a distance at least equal to the width of the flap.

The venous drainage, which is as important as the arterial supply, and the lymphatic outflow of the flap have both been studied in detail. Variations in venous anatomy in the femoral triangle are important to the microsurgeon. Usually, the groin flap is not reinnervated, but the lateral cutaneous branch of the subcostal or 12th thoracic nerve consistently crosses the iliac crest 5 cm posterior to the anterior superior iliac spine. This nerve could potentially be dissected, divided, and sutured to any available cutaneous nerve in the hand. If a relatively large block of bone is required in the hand in association with a soft tissue defect, a segment of vascularized bone can be taken from the iliac crest immediately beneath the flap (see Figure 45.13, *B*).[91]

The groin flap can be designed up to 12 cm wide and still allow primary closure of the donor defect (Figure 45.15, *D*). Because the donor site scar can be readily hidden, it is an ideal flap for use in young women when aesthetic considerations are important. It requires a more demanding dissection compared with most other free flaps, but the free groin flap has been advocated in children for repair of congenital differences, tumor resection, and trauma repair. Despite a higher reexploration rate of 24%, there were only 2 failures in a series of 33 children.[54]

Operative Technique. The midline axis of the flap should be drawn 2 cm inferior and parallel to the inguinal ligament (see also Chapter 44). A planning template of the defect should be laid on the skin immediately below the anterior superior iliac spine. This allows for a relatively long vascular pedicle by incorporating the more medial inguinal dissection (see Figure 45.13, *C*). The lower margin of the flap is incised down to the superficial surface of the deep fascia. The deep fascia should be incised and retracted proximally to reveal the sartorius, the tensor fasciae latae lateral to it, and the intervening intermuscular septum. While maintaining traction on the flap superiorly

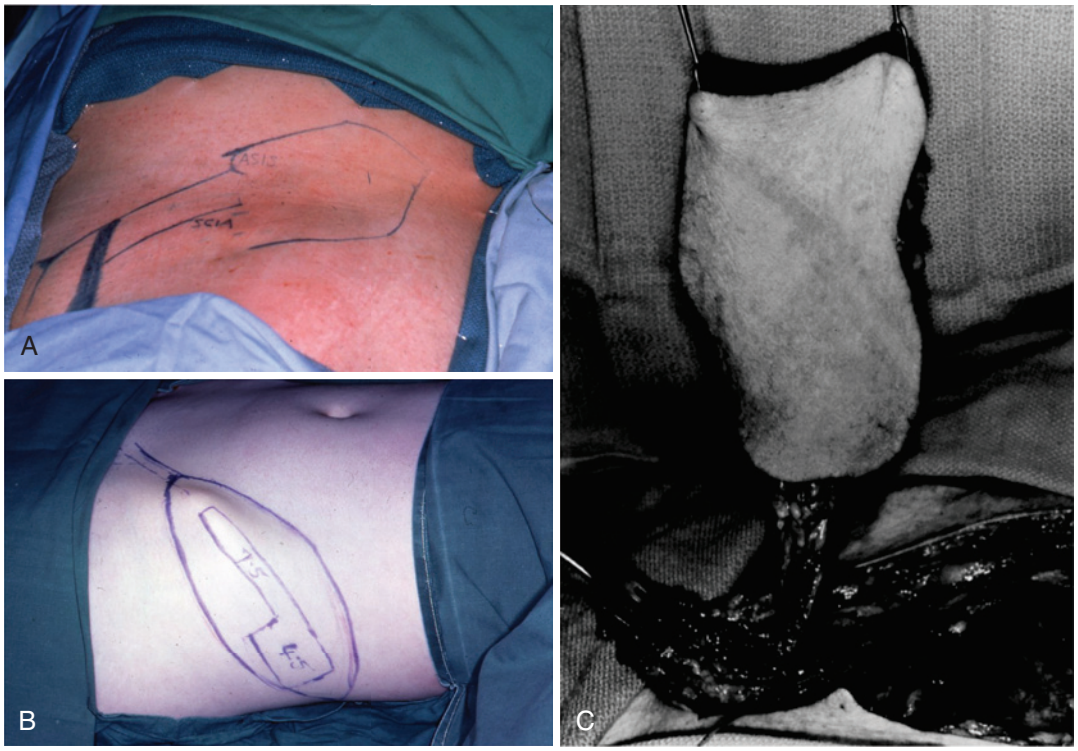

FIGURE 45.13 Groin flap. **A,** The superficial circumflex iliac artery pedicle of a free groin flap lies 2 cm below and parallel to the inguinal ligament passing from the pubic tubercle to the anterior superior iliac spine. **B,** Vascularized bone from the iliac crest can be incorporated into a free groin flap, but is better based on the deep circumflex iliac artery rather than the superficial circumflex iliac artery. **C,** The long pedicle that can be achieved in harvesting a free groin flap is demonstrated.

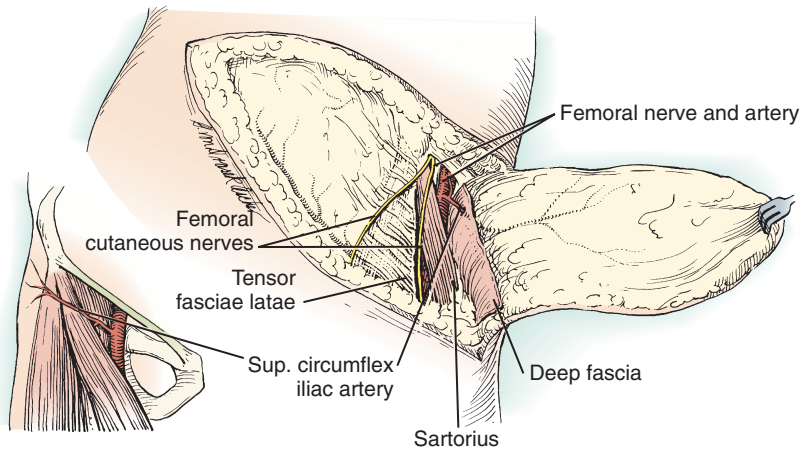

FIGURE 45.14 Groin flap. The groin flap is based on the superficial circumflex iliac artery, which runs parallel to and approximately 1 inch inferior to the inguinal ligament. It emerges through the deep fascia as it crosses the sartorius and breaks up into branches at the level of the anterior superior iliac spine. When the flap is raised, the lateral femoral cutaneous nerve should be preserved or, in certain instances (see text), divided and repaired. The fascia that is divided at the lateral margin of the sartorius can be seen. (From the Christine M. Kleinert Institute for Hand and Microsurgery, with permission.)

and away from the thigh, the deep fascia should be divided in a superior direction in the line of the fibers of the sartorius and at its lateral border just medial to the intermuscular septum.

The superficial circumflex iliac artery will be seen in the deep fascia as it is lifted from the sartorius. Incision of the fascia proceeds beyond the artery as far as the origin of the sartorius from the anterior superior iliac spine. Once it has been confirmed that the vessel is present, the remainder of the incision outlining the upper margin of the flap is made. As the upper incision is carried down to the external oblique aponeurosis, a significant artery passing superiorly will be encountered in the majority of cases. This should not cause alarm, because this is the superficial inferior epigastric artery, which must be divided. Furthermore, division of the superficial inferior epigastric

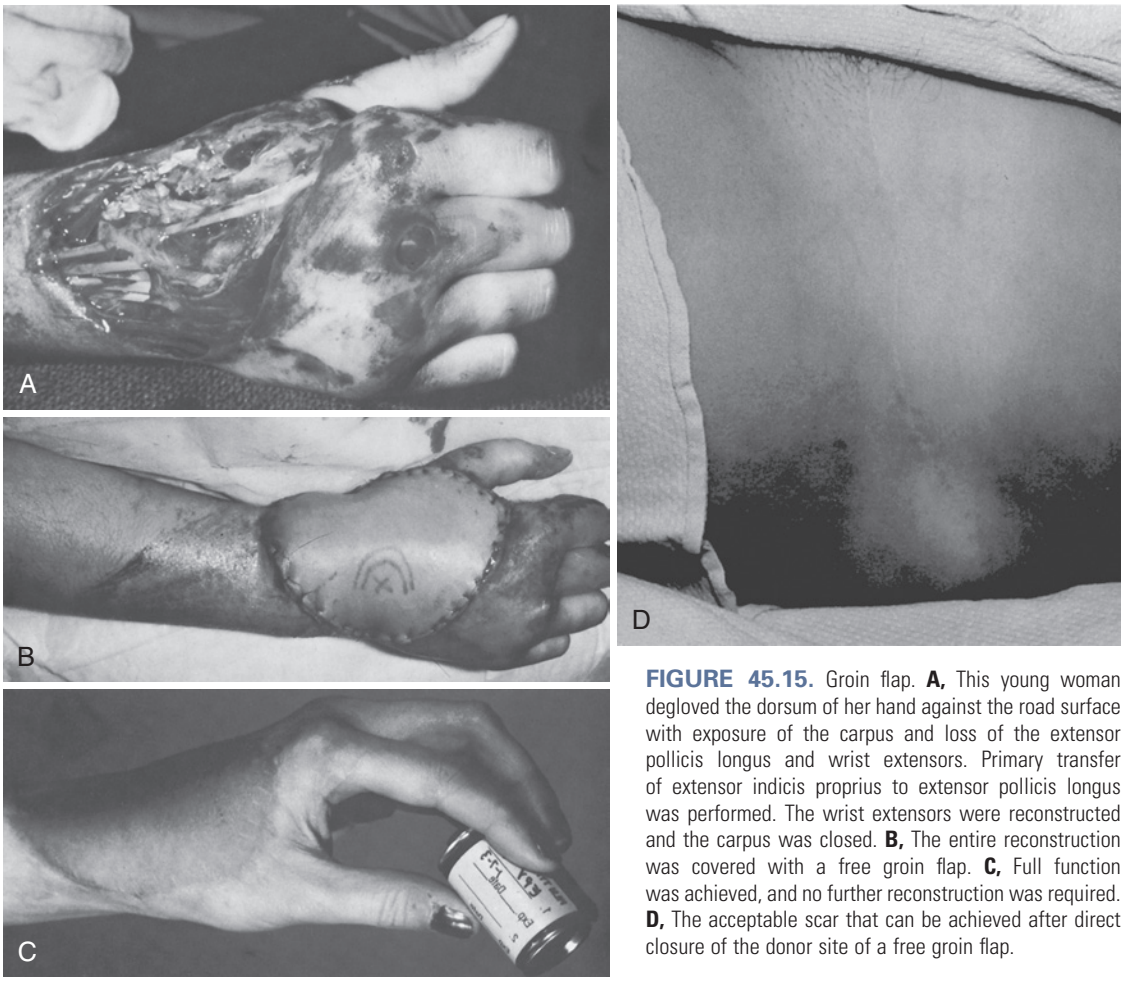

FIGURE 45.15. Groin flap. **A,** This young woman degloved the dorsum of her hand against the road surface with exposure of the carpus and loss of the extensor pollicis longus and wrist extensors. Primary transfer of extensor indicis proprius to extensor pollicis longus was performed. The wrist extensors were reconstructed and the carpus was closed. **B,** The entire reconstruction was covered with a free groin flap. **C,** Full function was achieved, and no further reconstruction was required. **D,** The acceptable scar that can be achieved after direct closure of the donor site of a free groin flap.

artery indicates that the level of dissection is in the correct plane.

The flap is retracted inferiorly off the external oblique aponeurosis until the level of the anterior superior iliac spine is reached. The incision made previously in the sartorius fascia is located and turned medially to free the deep fascia of the thigh from the inguinal ligament. In the course of this incision, the lateral cutaneous nerve of the thigh will be encountered. Care must be taken not to injure this nerve; otherwise, *meralgia paresthetica* may result. Whereas the nerve usually passes deep to the flap vessels and can be freed by dissection, on occasion it or one of its usual two branches may be superficial to the vessels. In this situation, the vascular pedicle should be dissected medially, divided, and passed beneath the nerve.

By applying upward traction to the flap, the fascia can be dissected off the underlying fibers of the sartorius muscle as far as its medial border, paying careful attention to the vessel, which can usually be seen passing down through the superficial fascia to lie on the muscle itself. The main hazard to further dissection of the pedicle is the muscular branch of the superficial circumflex iliac artery. This should be isolated by retracting the sartorius laterally with instruments on either side of the pedicle, superiorly and inferiorly. Once the muscular branch has been dissected free under loupe magnification, it can be divided. The superficial circumflex iliac artery can be mobilized all the way to its origin from the femoral artery. If the vessel is of small caliber, a cuff of the femoral artery can be taken. This is especially advantageous if an end-to-side anastomosis is to be performed. The venous drainage of the flap will be encountered as the medial border of the flap is incised. All veins emerging from the flap should be preserved and traced medially. They will usually join before draining into the termination of the long saphenous vein, providing at most two veins, of suitable caliber, for anastomosis.

The flap can now be thinned by having an assistant hold the flap vertically with hooks or stay sutures and the surgeon using forceps and curved tenotomy scissors with their concave surface uppermost. The flap can be thinned quite radically at the margins by trimming away fat. In the middle of the flap, the surgeon must be more cautious; otherwise, the pedicle may be damaged. Lobules of fat between the flap margins and midline can be lifted with the pickups and trimmed away. The deep fascia that has been lifted must not be transgressed; any fat that lies between it and the skin must be left alone.

Closure should commence at the lateral end of the donor defect. It may be difficult, but the surgeon should not undermine the margins in an attempt to facilitate closure. This only increases the area of potential dead space and does little to relax the skin. Rather, the surgeon should flex the thigh and use heavy sutures, knowing that primary closure is always possible if the width of the flap was less than 12 cm when first outlined. The tension created will inevitably result in postoperative

inflammation along the suture line. Even if this inflammation becomes pronounced, do not remove sutures! To do so would open the entire cavity, and if the cavity becomes infected, as would almost be inevitable, one has created a disaster similar to a pressure sore.

More recently, the superficial circumflex iliac artery perforator (SCIP) flap has evolved from the conventional free groin flap.[56,74] The potential advantages of this flap are possible thinning of the flap by primary defatting, harvesting of a purely adipofascial flap, and minimal concealment of the donor site. However, the disadvantages are the dissection of a smaller perforator and supermicrosurgical anastomosis of vessels less than 1 mm in diameter.

A similar perforator flap may be designed and harvested on the superficial inferior epigastric artery system (SIEA).[88]

Anterolateral Thigh Flap

Anatomy

After the vascular anatomy of the anterolateral thigh (ALT) flap was first described by Baek[4] in 1983 and Song in 1984,[113] it has been increasingly used over the past decade for microsurgical reconstruction in Asia[73,129] but has not really achieved the same popularity in North America and Europe.[1,59,127] A large skin island over the anterior and lateral aspect of the thigh can be harvested supplied by either the septocutaneous or musculocutaneous perforators of the descending branch of the lateral circumflex femoral artery.[133] The lateral femoral circumflex artery is a branch of the profunda femoris artery and passes downward between the rectus femoris and vastus lateralis muscles. Xu and colleagues[133] reported that the perforators to the skin passed through the vastus lateralis muscle, and Wei and associates[129] found that 87% of the skin perforators were musculocutaneous and only 13% were septocutaneous in a study of 672 anterolateral thigh flaps. The continuation of the descending branch can be used as a flow-through artery for simultaneous revascularization of the forearm or hand.[55] Fascia lata can be harvested with the flap for tendon or ligament reconstruction, and a portion of the vastus lateralis muscle can be harvested to fill any dead space. Potentially, this flap can be harvested as a sensate flap by including the lateral femoral cutaneous nerve of the thigh.

Operative Technique

The flap is designed over a line drawn between the anterior superior iliac spine and the midpoint of the lateral border of the patella with the patient in a supine position.[101] The main cutaneous perforators are detected with a pencil Doppler probe and are centered primarily within a 3- to 5-cm radius of the midpoint of this longitudinal axis and 1.5 cm lateral to this line[137] (Figure 45.16, *C*). The descending branch of the lateral circumflex femoral artery passes downward in the fascia between the rectus femoris and the vastus lateralis muscles. The medial margin of the skin flap is incised down through the deep fascia overlying the rectus femoris muscle. The flap is elevated posteriorly in the subfascial plane until the intermuscular space between the rectus femoris and vastus lateralis muscles is exposed. If septocutaneous perforators from the lateral circumflex femoral artery are seen, the lateral border of the flap is incised, the flap is elevated in an anterior direction toward the intermuscular septum, and the flap is harvested as a septocutaneous flap. However, if septocutaneous perforators are absent, the flap is harvested with a small cuff of vastus lateralis muscle as a musculocutaneous flap or as a perforator flap by intramuscular dissection of the musculocutaneous perforators.[73] After the perforators have been dissected and included, the descending branch of the lateral circumflex femoral artery is ligated distally and the pedicle elevated in a distal-to-proximal direction up to the ascending branch. If more pedicle length is required, the pedicle can be dissected further up to the profunda femoris artery. Either the descending branch of the lateral circumflex femoral artery or the lateral circumflex femoral artery itself may serve as the vascular pedicle with a length of 8 to 12 cm.

The main advantage of the anterolateral thigh flap is that the patient does not need to be turned in a lateral position as might be the case with harvesting a latissimus dorsi or scapular flap. Specifically for upper extremity reconstruction, the anterolateral thigh flap can be radically thinned to a thickness of 2 to 4 mm (see Figure 45.16).[1,73,127,129] Extra fascia can be harvested to wrap around exposed tendons. The anterolateral thigh flap has numerous advantages compared with other free flaps for upper extremity reconstruction: a large skin paddle of up to 20 × 15 cm even for thinned flaps; a long vascular pedicle; the possibility of restoring sensation by incorporating the lateral femoral cutaneous nerve; harvesting part of the vastus lateralis muscle to fill any dead space; the ability to harvest the flap simultaneously in a supine position; and minimal morbidity at the donor site because the donor site can be closed directly if the width does not exceed 6 to 8 cm (otherwise, a split-thickness skin graft is necessary). Potential disadvantages of the anterolateral thigh flap include a lateral thigh scar, especially if a skin graft has to be used (this may preclude its use in women); hairiness of the lateral thigh skin in men; decreased sensation over the lateral thigh; and variability of the vascular anatomy. In a study of 220 patients undergoing anterolateral thigh flap transfer, Hanasono and colleagues[47] found a low incidence of wound-healing problems, but 84% of patients had numbness in the lateral femoral cutaneous nerve distribution. Even though 37% of patients had a significant amount of vastus lateralis muscle harvested as part of the flap, all patients returned to their preoperative level of activity. Klinkenberg and associates[71] found altered sensation in 90% of patients after harvesting an anterolateral thigh flap compared with 45% of patients after harvesting a parascapular flap. Only 75% of patients said they would choose an anterolateral thigh flap again, compared with 100% of patients who said they would choose a parascapular flap again. However, it is likely that in the future, the anterolateral thigh flap may become one of the top choices for reconstruction of extensive defects of the upper extremity.

Latissimus Dorsi Muscle and Musculocutaneous Flaps

The latissimus dorsi was first described as an axial-pattern regional flap for breast reconstruction by Tansini in 1906. It was used only sporadically until Olivari reintroduced it for coverage of radiation defects of the anterior chest wall in 1976. The muscle is supplied primarily by the thoracodorsal artery from which perforators pass through the muscle to supply the overlying skin as a musculocutaneous flap (Figure 45.17, *B*). The diameter of the thoracodorsal artery (1 to 2.5 mm) and the

FIGURE 45.16 Anterolateral thigh flap. **A** and **B,** After serial radical débridements and amputation of the index and middle fingers for severe necrotizing fasciitis following a spider bite, soft tissue coverage of both the dorsal and palmar aspects of the left hand was required. **C,** Most of the septocutaneous perforators of the descending branch of the lateral circumflex femoral artery lie within 3 to 5 cm of the midpoint of the axis of the flap, which lies between the anterior superior iliac spine and the midpoint of the lateral border of the patella. **D,** This flap may be thinned to a thickness of 2 to 4 mm away from the vascular pedicle. **E,** Intraoperative appearance of the thinned anterolateral thigh flap. The flap can be monitored postoperatively by surface Doppler monitoring of a perforator marked by the suture. **F** and **G,** Two years following operation, the anterolateral thigh flap provides thin supple coverage of the palmar and dorsal aspects of the hand and maintains the web space between the thumb and ring finger.

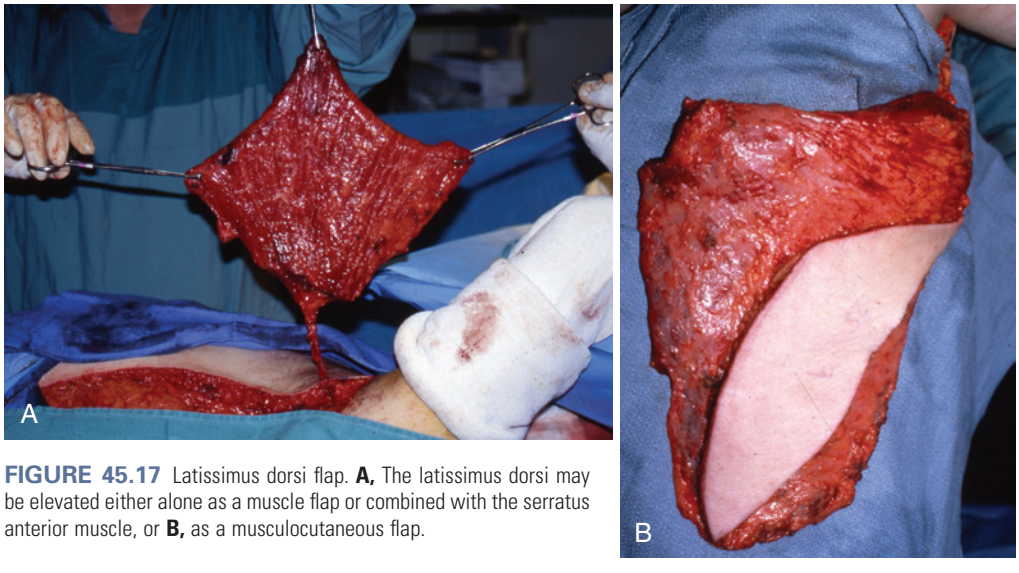

FIGURE 45.17 Latissimus dorsi flap. **A,** The latissimus dorsi may be elevated either alone as a muscle flap or combined with the serratus anterior muscle, or **B,** as a musculocutaneous flap.

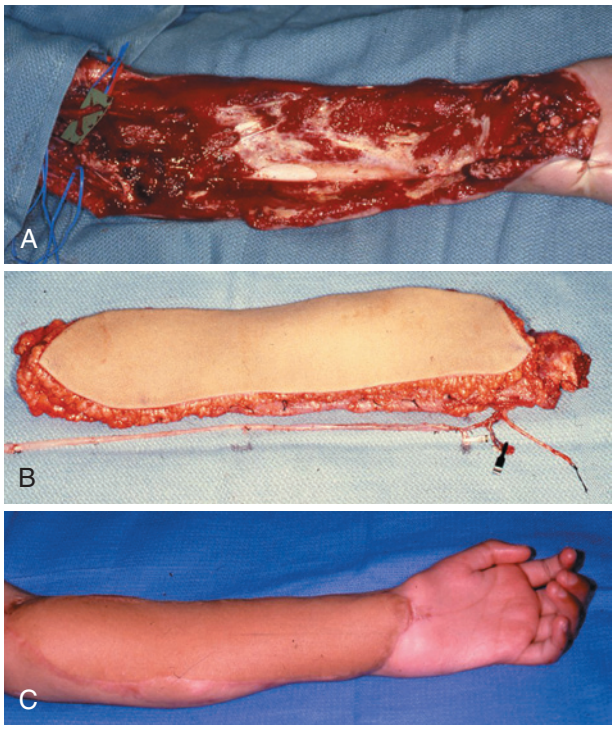

FIGURE 45.18 Latissimus dorsi musculocutaneous flap. **A,** This 9-year-old girl sustained a degloving injury of the entire volar forearm, including the median and ulnar nerves, the radial and ulnar arteries, and all of the flexor musculature. **B,** A very large contralateral right latissimus dorsi musculocutaneous flap was harvested with dissection of the vascular pedicle all the way to the origin of the subscapular artery from the axillary artery. A long interpositional vein graft was anastomosed end-to-end to the circumflex scapular artery. The subscapular artery was anastomosed end-to-end to the stump of the radial artery at the elbow, and the interpositional vein graft was anastomosed end-to-end to the distal ulnar artery to augment the vascular supply to the hand. The thoracodorsal nerve was coapted to the stump of the anterior interosseous nerve, and the distal latissimus muscle fascia was sutured to the flexor digitorum profundus tendons at the wrist to act as a functioning free muscle transfer, as well as to provide soft tissue coverage of the forearm. **C,** The latissimus dorsi musculocutaneous flap provides a very satisfactory appearance of the reconstructed forearm 1 year postoperatively.

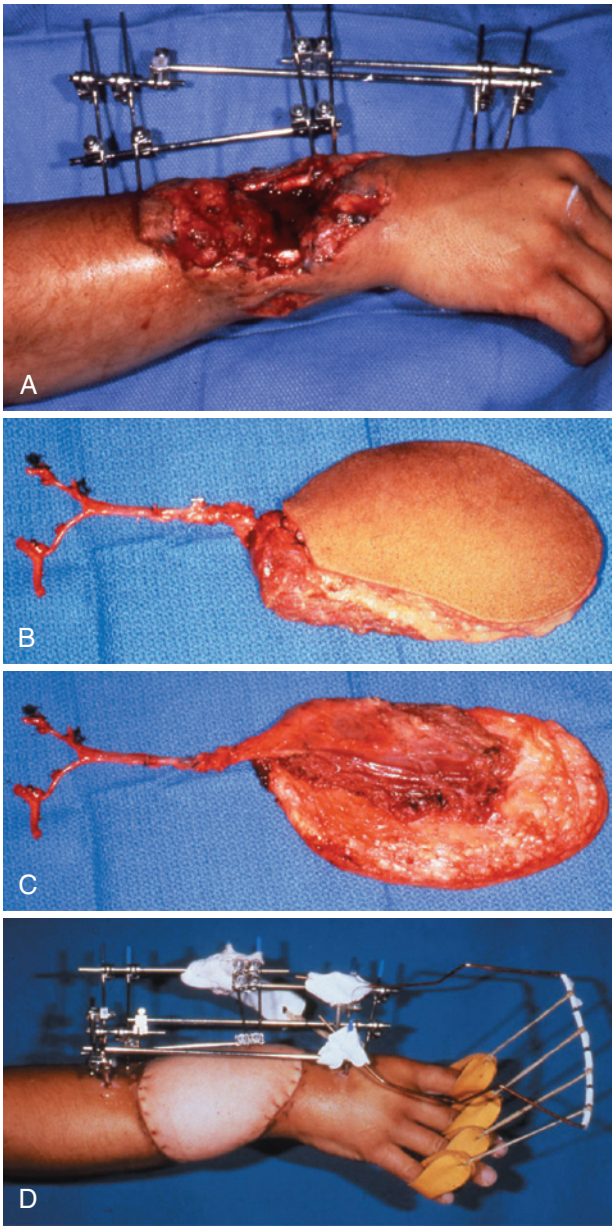

FIGURE 45.19 Tailored latissimus dorsi musculocutaneous flap. **A,** Radical débridement and external fixation of a high-velocity gunshot wound. **B,** The long pedicle and limited bulk of the tailored latissimus dorsi musculocutaneous flap is displayed. **C,** The small portion of latissimus muscle required to vascularize this musculocutaneous flap is demonstrated. The "T"-segment obtained by harvesting both the subscapular and the circumflex scapular arteries in continuity with the thoracodorsal artery can be seen to the left side of the figures. **D,** The tailored latissimus dorsi musculocutaneous flap has been anastomosed to the ulnar artery in the midforearm. An extension outrigger has been fitted to allow immediate motion. (**B** and **C** from Lister GD, Arnez AO: The anterior T and Y grafts. *Plast Reconstr Surg* 88:319–322, 1991, with permission.)

length of the pedicle (11 to 16 cm) have made it the most robust and, therefore, popular flap for free tissue transfer, especially to the extremities (Figures 45.18 and 45.19).[31]

Harvested as a free muscle flap (Figure 45.20 and see Figure 45.17, *A*),[43] the latissimus has the advantages of its easy draping into the interstices of a complex convoluted wound and of easy closure of the donor defect. Minor disadvantages include the appearance of the split-thickness skin graft on the muscle and the decreased perfusion in the most distal part of the muscle. The musculocutaneous flap has the advantages of appearance and excellent flow (see Figure 45.18). If the defect contains deep isolated pockets, these can be filled with a combined serratus anterior and latissimus dorsi muscle flap (Figure 45.21).[49]

Anatomy

The latissimus dorsi muscle arises from the lower six thoracic vertebrae, from the thoracolumbar fascia, and from the posterior iliac crest. From this extensive origin the muscle fibers converge to wrap around the lower border of the teres major and end in a quadrilateral tendon that inserts into the intertubercular sulcus of the humerus. Together with the teres major it forms the posterior axillary fold.

The blood supply of the muscle is supplied primarily by the thoracodorsal artery, which is the continuation of the subscapular artery after it gives off its circumflex scapular branch some 2 cm distal to its origin from the axillary artery. The

FIGURE 45.20 Latissimus dorsi muscle flap. **A,** This 62-year-old woman sustained a severe crushing-degloving injury to her left wrist and hand with multiple carpal and metacarpal fractures in a rollover accident. After Kirschner wire fixation of the fractures, she unfortunately developed secondary fungal infection of the dorsal soft tissues and was advised to undergo a below-elbow amputation. **B,** Radical débridement of the infected skin and soft tissues all the way down to the dorsal aspect of the carpus and metacarpals, but with preservation of some of the extensor tendons. **C** and **D,** The entire defect was covered immediately with a free latissimus dorsi muscle flap and a nonmeshed split-thickness skin graft. **E,** Two years later, the patient has maintained a sensate functional hand with satisfactory appearance of the forearm, wrist, and hand.

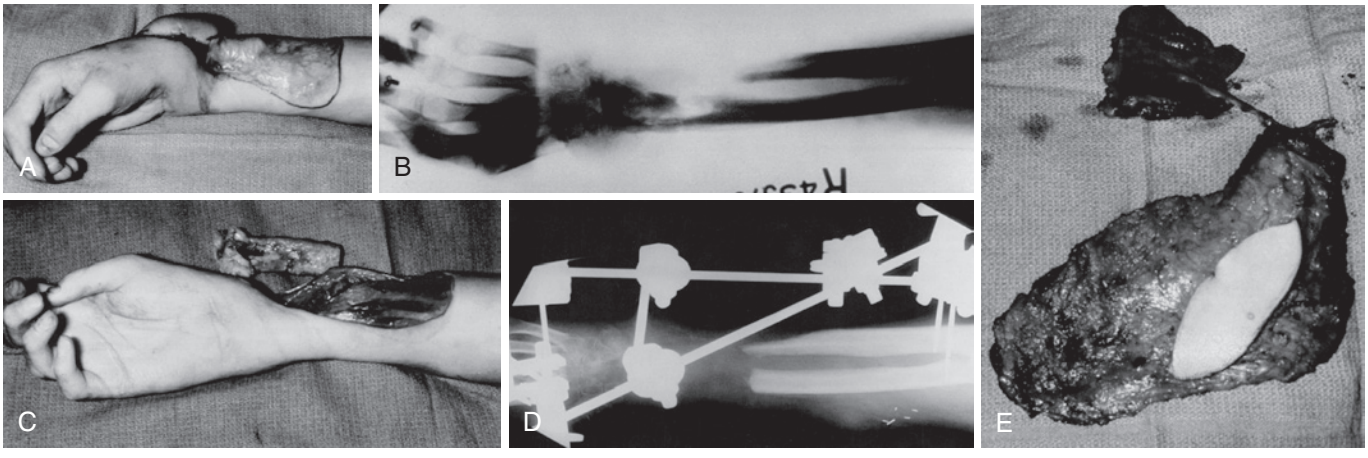

FIGURE 45.21 Combined latissimus dorsi and serratus anterior muscle flaps. **A,** This patient, who had sustained a crushing injury, had previously been treated with a skin graft and a pedicled groin flap and now presents with a sinus discharging pus. **B,** A radiograph reveals absence of the distal ulna and osteomyelitis of the distal radius. **C,** Radical débridement, including the portion of the radius that did not have adherent periosteum, has been performed. **D,** An external fixator has been applied. **E,** A combined latissimus dorsi and serratus anterior muscle flap has been harvested. The serratus anterior was placed into the defect created by excision of the radius, and the latissimus covered the remaining defect. Six weeks later, when there was no evidence of recurrent infection, a vascularized fibular bone graft was used to reconstruct the distal radius.

thoracodorsal artery provides a variable number of branches to the chest wall, notably one to the serratus anterior muscle, before reaching the hilum of the latissimus dorsi muscle some 11 cm from the axillary artery (Figure 45.22). Immediately distal to the hilum the artery divides into two branches in 94% of specimens.[122] The upper branch runs parallel to, and 3.5 cm from, the upper margin of the muscle; the lateral branch runs parallel to, and 2.1 cm from, the lateral margin of the muscle. This arrangement allows the surgeon to split the muscle longitudinally as a hemi–latissimus muscle flap when a narrow flap is required,[122] with the additional advantage of preserving the thoracodorsal nerve innervation to the remaining muscle.

Preoperatively, it may be of some benefit to have the patient abduct the arm against resistance so that four or five points can be tattooed along the posterior axillary fold with methylene blue and a hypodermic needle.

Operative Technique

The patient should be placed in the lateral position with padding beneath the torso sufficient to protect circulation to the

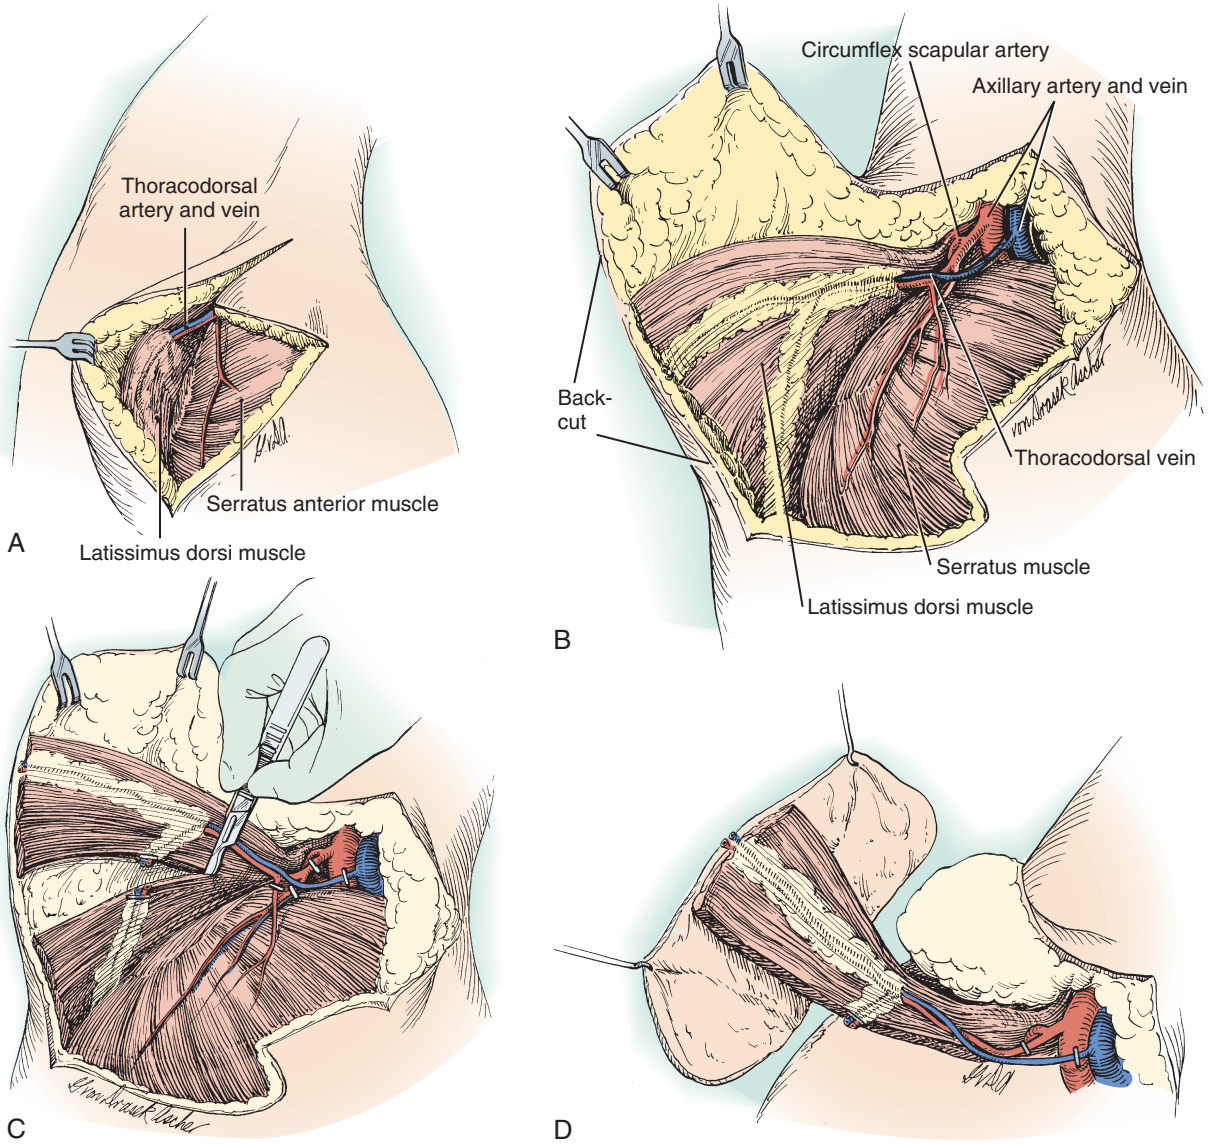

FIGURE 45.22 The vascular pedicle of the latissimus dorsi flap is displayed here in the course of its dissection. The subscapular artery arises from the axillary artery and soon gives off the circumflex scapular, which passes between the teres major and the latissimus dorsi. **A,** The next branch to arise is that to the serratus. The thoracodorsal artery passes beneath the epimysium of the latissimus dorsi and there divides into two branches. The upper branch runs parallel to and 3.5 cm from the upper margin of the muscle, and the lateral branch runs parallel to and 2.1 cm from the lateral margin of the muscle. **B,** The first, distal cut of the flap has been made through skin and muscle. **C,** The lateral or anterior portion of the muscle is being used alone in designing this small flap. The posterior, or upper, branch of the thoracodorsal has therefore been divided, and the muscle is split either with a knife, as shown here, or better with cutting diathermy through both muscle and skin as required. **D,** The proximal margin of the flap has been divided here through skin and will be divided through muscle just proximal to the point at which the thoracodorsal artery passes beneath the epimysium of the latissimus dorsi. In this way, a thin, well-tailored latissimus dorsi is created. (The clips shown here on the artery and vein of the pedicle would not, of course, be applied in using the latissimus as a regional flap.) (Modified from Godina M: The tailored latissimus dorsi flap. *Plast Reconstr Surg* 80(2):304–306, 1987.)

contralateral arm on the operating table. Easy exposure to the axilla is provided by wrapping the forearm with soft padding and then applying upward traction to a ceiling fixture to achieve 100 degrees of abduction. A similar position can be achieved, although less satisfactorily, by taping the forearm to a sterile Mayo stand. In either case there is considerable danger of a brachial plexus neurapraxia with consequent paresis. Checking the radial pulse regularly is no guarantee that all is well. This complication can only be avoided by a strict practice of returning the arm to the patient's side for 5 minutes every hour, a practice that should be monitored by the anesthesiologist.

An inverted "L"-shaped incision should be made skirting the axillary hair-bearing area and extending down toward the previously tattooed points marking the posterior axillary fold. Through this incision, the anterior border of the latissimus is located and everted using retractors or heavy stay sutures placed in the muscle margin.

The thoracodorsal pedicle can best be found where it approaches the muscular hilum. This is approximately at the nipple line in the male or the child. With good retraction and light, the vessel can be traced proximally, identifying first the serratus branch, a branch to the teres major, and then the circumflex scapular artery. These should be ligated and divided.

With a template of the primary defect, the cutaneous component of the flap can be marked out over the posterolateral thorax, distal to the level of the hilum, which has already been identified. The flap template can be designed either anteriorly or posteriorly with respect to the anterior border of the muscle. Placing the skin pattern more posteriorly gives more muscle to fold into a deep defect, whereas moving the skin pattern anteriorly, relative to the muscle, produces a thinner flap.[42] The flap margins are incised and extended down to the underlying muscle with cutting diathermy. Depending on the requirements for extra muscle anterior or posterior to the skin flap, either the anterior or posterior margins of the incision will need to be elevated off the latissimus dorsi muscle. After the anterior border of the muscle is elevated off the underlying serratus anterior muscle, the entire muscle and skin flap are dissected in an anterior-to-posterior direction. Care should be taken to ligate any large secondary perforators entering the muscle posteriorly. The requisite amount of muscle is cut with the diathermy and the flap swung superiorly away from the trunk to allow clear definition of the proximal thoracodorsal artery. Careful isolation of the thoracodorsal artery and its two venae comitantes up to their origin from the subscapular artery and vein completes the axillary dissection (see Figure 45.17, *A* and *B*).

If an end-to-side anastomosis is to be performed or if the flap is being transferred into an atherosclerotic vessel or into a single-vessel limb, it may be advantageous to take the subscapular artery and as much as needed of the circumflex scapular artery as a "T"-segment (see Figure 45.19, *B* and *C*). By interposing the subscapular-circumflex scapular portion of the "T"-segment into the atherosclerotic vessel, a difficult end-to-side anastomosis is avoided. By saving the "T"-segment of the subscapular/thoracodorsal/circumflex scapular arteries and performing the end-to-side anastomosis using the thoracodorsal artery, the "T"-segment can later be used to salvage the end-to-side anastomosis should it be required.[79]

"Tailored" Latissimus Dorsi Musculocutaneous Flap and Thoracodorsal Artery Perforator Flap

If only a narrow flap is needed, the lateral branch of the thoracodorsal artery should be located and the anterior and inferior borders of the flap carefully incised, avoiding the lateral branch. The medial branch should be ligated and divided and the thoracodorsal artery dissected off the latissimus dorsi, working from the axilla as far distally as possible. The pedicle can be lengthened by dividing muscular branches that turn in a proximal direction toward the axilla within the muscle. The proximal margin of the flap can be incised while the pedicle is retracted anteriorly to protect it. Raising the flap in this manner, rather than taking the whole muscle as in the past, provides a flap tailored exactly to the primary defect (see Figure 45.19).[42] Use of the tailored flap avoids the bulky proximal portion of the latissimus muscle that is inevitable when the whole muscle is taken.

Recently, Angrigiani and colleagues[2] have described harvesting the latissimus dorsi skin flap without the underlying muscle based on a single muscle perforator. The thoracodorsal artery perforator (TDAP) flap may be designed either vertically, based on a proximal perforator of the descending branch of the thoracodorsal artery,[19] or transversely, based on perforators from both the descending and transverse branches of the thoracodorsal artery.[75] TDAP flaps based on multiple perforators (identified with a handheld Doppler probe) are more reliable than flaps based on a single perforator.[65,135]

CRITICAL POINTS *Latissimus Dorsi Muscle Flap*

Indications
- Large and small defects of the hand and arm
- Complex defects requiring more tissue
- Untidy wounds after débridement or management of osteomyelitis

Preoperative Evaluation
- Presence of scars or a prior mastectomy with axillary dissection may contraindicate use (pedicle may have been damaged or ligated).

Pearls
- "Best" free flap for most surgeons
- May take a portion of the muscle or "tailor" flap to defect

Technical Points
- Approach muscle from the anterior border first.
- Elevate the muscle and identify the pedicle with the descending branch to the serratus anterior.
- Once the pedicle has been identified, elevate the muscle off the chest wall.
- Once an adequate portion of the muscle is elevated, divide it distally and medially and continue the dissection from distal to proximal.
- Carefully dissect the pedicle in the axilla.
- Abduction of the arm helps with pedicle dissection.
- The pedicle may include the subscapular artery up to the axillary artery.

Pitfalls
- Damage to the pedicle may occur during dissection.
- Do not divide any branch until the main pedicle is identified proximally.
- Seromas may occur at the donor site.

Donor Site Management
- Primary closure is performed over drains.
- Leave drains in for 10 to 14 days to prevent seromas.
- Morbidity from loss of muscle is minimal.

The donor defect should always be closed directly, because a skin graft in this location presents a very difficult nursing problem. Large defects may require transposition of loose tissue from the waistline anteriorly, using a rhomboid design (see Chapter 44). Suction drains should be left for several days because this donor site is associated with a higher incidence of seroma formation. No significant loss of function has been shown after harvesting the latissimus dorsi.

Serratus Anterior Muscle Flap

The serratus anterior free muscle flap was popularized by Buncke as the flap of choice for small to moderate-sized soft tissue defects in the upper extremity.[10] It is a remarkably reliable free muscle flap because of its consistent long vascular pedicle and large-diameter vessels and is associated with minimal donor site morbidity.

Anatomy

The serratus anterior muscle arises from the first nine ribs medial to the anterior axillary line and inserts into the medial border of the scapula. The lower three slips of the muscle arising from the seventh, eighth, and ninth ribs are supplied by a large branch of the thoracodorsal artery, whereas the upper six slips are supplied by branches of the lateral thoracic artery (Figure 45.23, *A*). The dual vascular supply allows elevation of the lower three slips of the muscle with simultaneous preservation of the vascular supply to the upper two thirds of the muscle. If necessary, a very long vascular pedicle, up to 15 cm in length, can be obtained by dividing the thoracodorsal artery and vein distal to the origin of the branch to the serratus muscle and elevating the thoracodorsal pedicle all the way up to its origin from the subscapular artery and vein, just as in the dissection of the latissimus dorsi vascular pedicle (see Figure 45.23, *B*). The serratus muscle is innervated by the long thoracic nerve that lies directly anterior to the vascular pedicle on the chest wall. Under magnification, the branches of the long thoracic nerve to the lower three slips of muscle can be dissected. This ability to separate the motor innervation and blood supply to the lower three slips of the serratus muscle while still preserving the motor nerve and blood supply to the upper six slips minimizes the morbidity of harvesting the entire serratus muscle. In a series of 100 consecutive serratus anterior free muscle flap transfers, winging of the scapula did not occur and all patients retained full range of motion of the shoulder. Occasionally, this separate motor nerve to the lower three slips can be reinnervated as a functional free muscle transfer for functional restoration of thenar muscle loss.

Operative Technique

The patient is placed in the lateral position with the arm included in the operative field. Through a long midaxillary incision, the anterior border of the latissimus dorsi muscle can be elevated and retracted to reveal the thoracodorsal vessel pedicle and its branch to the serratus muscle. The small branches to the upper six muscle slips can be divided, but all branches to the lower three slips are preserved. With the use of loupe magnification, the nerve branches to the lower three slips are carefully divided from the main branch of the long thoracic nerve. Starting inferiorly and working in a superior direction, the lower three slips of the serratus muscle are divided at their origin from the seventh, eighth, and ninth ribs and elevated in the loose areolar plane between the muscle and the chest wall, taking care not to penetrate the intercostal muscles and pleura. Posteriorly, the insertions of the three slips into the scapula are divided. This allows the vascular pedicle to be lifted off the upper six slips of the muscle, and the pedicle can then be easily mobilized up to its origin from the thoracodorsal artery and vein. If a long vascular pedicle is not required, the muscle is allowed to perfuse and then the pedicle is divided just distal to its origin from the thoracodorsal vessels. If a longer vascular pedicle is required, the thoracodorsal vessels are divided distal to the origin of the serratus vessels and the entire thoracodorsal-subscapular system is dissected up to its origin from the axillary artery and vein (see Figure 45.23, *B*). If the serratus muscle is also to be used as a functioning free muscle transfer, interfascicular dissection will allow the branches to the lower three slips to be split off from the main long thoracic nerve for several centimeters as a separate group fascicle.

Hemostasis is achieved over the lower chest wall. The distal stump of the lower three slips of the serratus muscle attached to the angle of the scapula can be resutured to the remaining upper six slips of the serratus muscle and the incision closed directly over a suction drain.

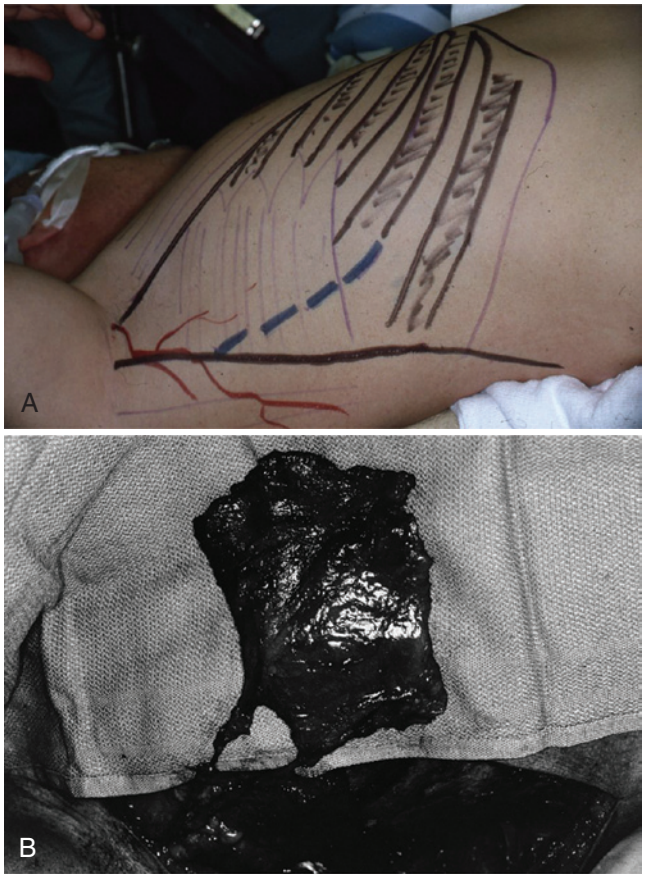

FIGURE 45.23 Serratus anterior muscle flap. **A,** Preoperative marking of the midaxillary incision used to harvest a right serratus anterior muscle flap. The descending serratus branch from the thoracodorsal artery passes anteriorly down to supply the lower three slips of the muscle. **B,** This small muscle flap can be isolated on a very long vascular pedicle by dividing the thoracodorsal artery and vein distal to the origin of the serratus branch and mobilizing the thoracodorsal artery and vein all the way proximally to their origin from the subscapular artery and vein.

Rectus Abdominis Muscle Flap

The rectus abdominis muscle flap is a distant second choice for coverage of large soft tissue defects of the upper extremity after the optimal choice of the latissimus dorsi muscle flap.[95,96,98] The rectus abdominis muscle is long and thin and can therefore be considered for coverage of longitudinal defects of the dorsal or palmar surfaces of the forearm and wrist and may be spiraled in "barber pole" fashion around the radial or ulnar borders of the forearm.

Anatomy

The rectus abdominis muscle has two vascular pedicles: the superior epigastric artery and the deep inferior epigastric artery arising from the external iliac artery. As a free flap for upper extremity reconstruction, it is isolated on the inferior pedicle, the deep inferior epigastric artery, and two accompanying venae comitantes.[117] The vascular anatomy is very reliable with a pedicle length of 5 to 7 cm and an arterial diameter of approximately 2.5 mm.

Operative Technique

The muscle can be harvested through a paramedian or transverse Pfannenstiel abdominal incision. A longitudinal or transverse ellipse of overlying skin perfused by musculocutaneous perforators can be incorporated in a rectus abdominis musculocutaneous flap, and this has become the optimal choice for microsurgical breast reconstruction. However, for upper extremity reconstruction, the rectus abdominis is usually harvested as a muscle flap and resurfaced with a split-thickness skin graft. One advantage of the rectus abdominis muscle flap is that it can be harvested with the patient in a supine position, compared with the lateral position used for harvesting a contralateral latissimus dorsi muscle flap. Relative disadvantages include the shorter length of the vascular pedicle and the possibility of abdominal bulging or even herniation of the lower abdomen after harvest of the rectus muscle.

An intriguing potential spin-off is the use of a flap of posterior rectus sheath and peritoneum supplied by the deep inferior epigastric vessels to provide a gliding peritoneal surface for coverage of exposed extensor tendons in dorsal hand degloving injuries.

Massive defects of the upper extremity have been reconstructed using a combination latissimus dorsi and rectus abdominis musculocutaneous flap based on the intact vascular pedicle of the thoracodorsal vessels and microsurgical anastomoses of the deep inferior epigastric vessels to the radial or ulnar arteries at the wrist.

Temporoparietal Fascial Flap

The ultrathin and highly vascular tissue of the temporoparietal fascia is ideal for coverage of small defects of the hand and wrist[8,14,52,53,126] when a skin graft would be preferable to a bulky flap but the recipient bed is poorly vascularized, as in circumstances where periosteum has been stripped to expose bone or where tendons have been denuded of paratenon.

Anatomy

The temporoparietal fascia is the superior extension of the submuscular aponeurotic system, which supports the muscles of facial expression. It is located between the scalp and the fascia overlying the temporalis muscle and is supplied by the superficial temporal artery and vein, which emerge from beneath the parotid gland in front of the ear to pass superiorly into the temporal and parietal scalp (Figure 45.24, *A*).[126] The superficial temporal artery measures 1.8 to 2.2 mm in diameter in front of the ear and provides a pedicle length of 4 to 5 cm. The superficial temporal vein lies posterior and superficial to the artery

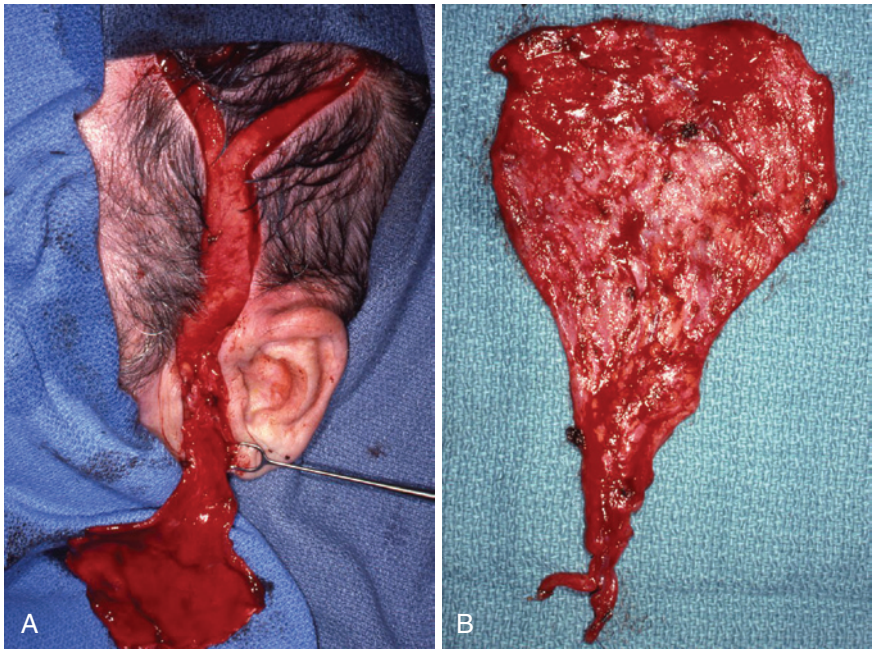

FIGURE 45.24 Temporoparietal fascial flap. **A,** The temporoparietal fascia can be harvested through a preauricular incision extending up into the temporal hair-bearing scalp as a "Y"- or "T"-shaped extension. **B,** This thin fascial sheet can be used to wrap around exposed tendons to preserve their gliding and can then be covered either primarily or secondarily with a split-thickness or full-thickness skin graft.

and gives off multiple branches to the subcutaneous tissue of the scalp. Most temporoparietal fascial flaps have not exceeded 13 cm in length and 9 cm in width (see Figure 45.24, *B*). The superficial and deep fascias investing the temporalis muscle are vascularized by the deep middle temporal branch of the superficial temporal artery, and consequently this fascia can also be transferred together with the temporoparietal fascia to provide a "double" fascial flap[53] that can be used to "sandwich" exposed flexor or extensor tendons and preserve gliding.[8]

The auriculotemporal nerve follows the course of the superficial temporal vessels and is divided during flap dissection. A segment of the outer table of the skull vascularized by the temporoparietal fascia has been reported for craniofacial reconstruction, but vascularized bone transfer to the hand using the temporoparietal fascial flap has not been described.

Operative Technique

The patient is positioned supine with the head turned to the side. The contralateral side of the head is used to allow simultaneous donor and recipient site dissection (two-team approach). The vascular axis of the superficial temporal artery is determined either by palpation or by using a pencil Doppler probe. A 1- to 1.5-cm strip of scalp is shaved over this vascular axis beginning just above the ear. Narrow temporoparietal flaps can be harvested through this single incision, but for larger flaps an inverted "L"-shaped or a "T"-shaped extension may be required within the hair-bearing scalp skin (see Figure 45.24, *A*). The preauricular part of the incision extends down to the earlobe. The temporoparietal fascia can also be harvested endoscopically. The superficial temporal artery and vein are identified in front of the ear and traced in a superior direction. The vessels are quite fragile, and great care must be taken to use bipolar coagulation of all the small branches. Scalp flaps are elevated in the plane between the subcutaneous tissue and the temporoparietal fascia. The proper plane is sometimes difficult to find, but the hair follicles should be kept in the subcutaneous tissue of the elevated scalp flaps. Dissection continues anteriorly and posteriorly from the incision but should not be extended too far anteriorly from the axis of the superficial temporal artery because of injury to the frontal branch of the facial nerve. The superficial temporal vessels lie above or within the fascia, whereas the motor branches of the facial nerve lie below the fascia. A nerve stimulator may be helpful in identifying these facial nerve branches at the level of the zygoma and lateral orbital rim. The template of the recipient defect is either centered over the axis of the superficial temporal vessels or positioned a little more posteriorly, again to avoid damage to the frontal branches of the facial nerve. The superior and posterior margins of the outlined fascial flap are incised to enter the loose areolar plane between the temporoparietal fascia and the fascia overlying the temporalis muscle. The anterior margin of the flap is incised in a distal-to-proximal direction up to the point where the frontal branch of the superficial temporal artery passes anteriorly to the forehead. After division of this branch, further dissection proceeds just anterior to the superficial temporal vessels to taper the pedicle down to the axial vessels at the top of the ear. The temporoparietal fascial flap is now completely isolated as an island based on the vascular pedicle in front of the ear. Additional length to the vascular pedicle can be obtained by more proximal dissection, but this may be both tedious and bloody because of large branches from the artery and vein. After ligation of the superficial temporal artery and vein, the fascia is transferred to the hand and covered with either a split-thickness or full-thickness skin graft.

After hemostasis of the scalp incision has been achieved, the incision is closed over a small suction drain. The preauricular incision is closed with fine 5-0 nylon sutures, and these are removed within 5 days to prevent conspicuous scarring. The temporoparietal fascia probably produces one of the most inconspicuous donor sites of any free flap, but alopecia may sometimes occur. Patients may occasionally have diminished sensibility within the distribution of the auriculotemporal nerve, but this is usually not painful.

CRITICAL POINTS *Temporoparietal Fascial Flap*

Indications
- Need for thin soft tissue coverage in hand
- Potential need for "gliding" surface over tendons

Preoperative Evaluation
- Doppler examination/palpation of superficial temporal artery

Pearls
- Very thin flap for reconstruction, particularly on the dorsal hand over and around the extensor tendons

Technical Points
- This tissue lies directly underneath the hair follicles, and getting in the right plane can be difficult.
- Elevate scalp carefully off fascia; beware of vein branches into scalp.
- Superficial and deep fascia may be taken.
- Artery and vein are small and fragile.
- Avoid deep dissection proximally in the parotid to prevent damage to the facial nerve!

Pitfalls
- Alopecia common, particularly around incision
- Damage to thin-walled veins when elevating flap

Donor Site Management
- Close primarily over drain.

Sensory Flaps From the First Web Space of the Foot

Either the great toe or the second toe can be transferred for reconstruction of the thumb or fingers (see Chapter 47), but for reconstruction of digital pulp defects or crucial areas of the hand that require sensation, there is unanimity regarding the appropriate donor site, namely, the first web space of the foot. Depending on the requirements of the primary defect, this flap may vary from a single pulp alone[12,45,72,76] to the fibular aspect of the great toe together with all or part of the nail combined with the tibial aspect of the second toe.[82,86] Such sensory flaps can be used to reconstruct critical areas of the hand, including pulp defects of the thumb and fingers, pulp defects of adjacent digits, and the thumb/index finger web space. Reconstructed digits in the hand develop a sensory threshold similar to the contralateral donor toe with an average static two-point

discrimination of 3 to 7 mm[45] and an average moving two-point discrimination of 6 to 8 mm.[72]

Anatomy

All the tissues in the first web space of the foot are supplied by the lateral digital artery to the great toe and the medial digital artery to the second toe, which arise from a variable "arterial complex" in the web space. This arterial complex receives its blood supply from two sources: the first dorsal metatarsal artery, arising from the dorsalis pedis artery, and the first plantar metatarsal artery, arising from the plantar arch (Figure 45.25, *A*). This first plantar metatarsal artery is supplied not only by the posterior tibial artery but also by the dorsalis pedis artery through a deep communicating branch that passes downward through the first intermetatarsal space at the point where the first dorsal metatarsal artery arises from the dorsalis pedis artery. The two feeding arteries and the two digital arteries have a varying relationship in the first web space, hence the term "arterial complex".

The nerve supply to the first web space likewise comes from two sources: (1) the lateral digital nerve to the great toe and the medial digital nerve to the second toe, both originating from the first common plantar digital nerve, and (2) the deep peroneal nerve dorsally (see Figure 45.25, *B*).

Operative Technique

The fibular aspect of the great toe provides an ideal donor site because its structure is identical to that of the pulp of an important digit, such as an avulsed thumb (Figure 45.26). Preparation for harvest commences with examination of the foot with a pencil Doppler probe to identify the presence and course of the first dorsal metatarsal artery as it originates from the dorsalis pedis artery to pass distally. It is possible to make some estimate of the depth of the vessel by angling the probe in different directions. Detection of a pulse suggests that the vessel lies superficial in its most common location along the dorsal surface of the interosseous muscle.

The venous drainage on the dorsum of the foot should be mapped out before exsanguinating the limb and inflating the tourniquet (see Figure 45.25, *A*). There are two venous systems on the dorsum of the foot. One drains the medial aspect of the great toe and metatarsal region and lies superficial to the second, larger system, which forms an arch extending from side to side across the dorsum of the foot and drains into the greater saphenous vein. The deeper system is less pronounced on inspection but clearly has veins of larger caliber and should be selected for harvest.

An incision should be marked out on the dorsum of the foot overlying the first intermetatarsal space to provide access to the most promising vein and should pass distally to reach the outline of the flap, which should be marked on the fibular aspect of the great toe. A second incision extends proximally on the plantar surface of the foot between the weight-bearing areas of the first and second metatarsal heads.

Only the distal portion of both dorsal and plantar incisions should be opened initially and should be sufficient to dissect the contents of the first web space. Although there are some fibrous septa in the web, the tissues are relatively loose. The most distal structure of importance in the web is likely to be the arterial complex. Loupe magnification and delicate scissor dissection are required immediately. As soon as an artery is encountered (and it may lie as far as 1 cm proximal to the free margin of the web), it should be dissected distally into both the great toe and second toe and proximally onto the dorsal and plantar aspects, until all the ramifications of the "arterial complex" are displayed and understood. If the dorsal artery

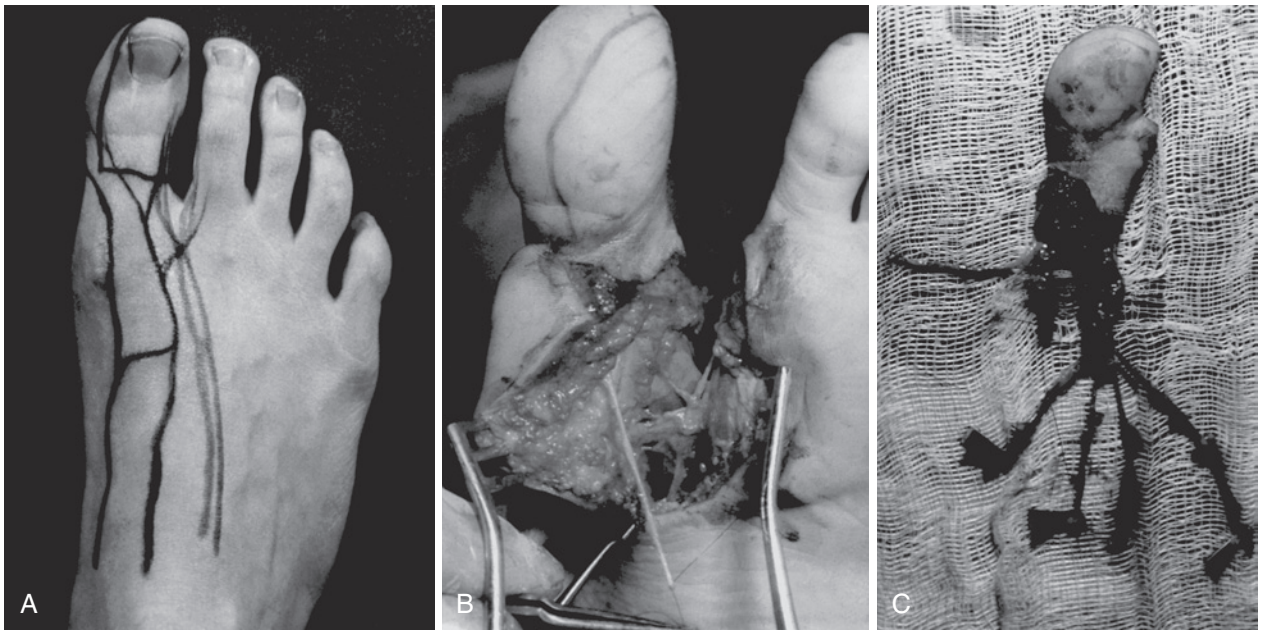

FIGURE 45.25 Sensory flap from the first web space of the foot. **A,** Using a pencil Doppler probe, the first dorsal metatarsal artery has been marked *(double pale line).* The major veins have been marked after temporary elevation of the tourniquet *(dark lines).* **B,** Dissection of the first web space. The plantar digital nerve to the fibular aspect of the great toe has been divided and marked with a suture. **C,** After dissection, the veins and first dorsal metatarsal artery are marked with microvascular clamps.

FIGURE 45.26 Sensory flap from the first web space of the foot. **A** and **B,** Palmar and dorsal views of the defect resulting from avulsion of the pulp of the dominant thumb. **C,** The partial toe flap designed on the fibular aspect of the left great toe. **D** and **E,** Postoperative result.

appears large and seems to communicate with the first dorsal metatarsal artery, it should be chosen because it provides a longer pedicle. The dorsal incision is extended proximally and the medial flap reflected until a suitable vein is located over the first metatarsal. The vein does not need to be dissected distally all the way to the flap, because it will probably have several fragile tributaries. Instead, the medial dorsal flap, which will remain on the foot, should be dissected off the venous system on the dorsum of the great toe. A monobloc of subcutaneous tissue between the toe flap and the selected proximal vein can be defined by cutting down onto the extensor tendons on either side of the venous pedicle and elevating it by bipolar dissection directly off the extensor tendons. This relatively bulky tissue will be readily accommodated by the loose skin of the thumb/index finger web space. The vein is dissected proximally, until sufficient length is obtained to reach a recipient vein of satisfactory caliber in the hand.

The first dorsal metatarsal artery is dissected in a distal-to-proximal direction from its initial identification in the web space to its origin from the dorsalis pedis artery.[130] The deep communicating branch from the dorsalis pedis artery to the plantar arch should be ligated and divided. Dissection of the dorsalis pedis artery is continued as far proximally as is necessary to reach the site of arterial anastomosis in the hand, which is usually a branch of the radial artery just distal to the anatomic snuffbox at the base of the index and middle finger metacarpals. The dorsalis pedis artery passes beneath the extensor hallucis brevis tendon, which courses from proximal lateral to distal medial and can either be preserved or divided to improve access. In circumstances in which the first dorsal metatarsal artery is judged to be too small or absent, the surgeon will have to decide whether to dissect the shorter first plantar metatarsal artery to the great toe/second toe web space and whether, if necessary, to elongate this plantar pedicle by harvesting an interposition graft, either an arterial graft from the subscapular, superficial temporal, or interosseous systems[40,79] or a venous graft from the saphenous system.

During this dissection of artery and vein, the surgeon will encounter the deep peroneal nerve, which lies just superficial to the artery. The branch of the deep peroneal nerve passing to the great toe should be dissected proximally, splitting it away from the other branches and transecting it with sufficient length so that it can be coapted to the "unsatisfied" radial digital nerve of the thumb ("unsatisfied" because the lateral digital nerve of the great toe will be coapted to the more important ulnar digital nerve of the thumb).

The plantar incision should be opened, and surgical access can be facilitated by externally rotating the patient's hip and flexing the knee and tilting the table as far toward the operative side as necessary to afford a comfortable view of the operative field. Initially, the incision should be made just long enough to obtain the necessary length of the lateral digital nerve of the

great toe; the length required should have been first determined from dissection of the ulnar digital nerve in the thumb. In contrast to the artery and vein, the lateral digital nerve should be as short as possible to allow early return of sensibility. Once sufficient nerve has been exposed, the lateral digital nerve should be mobilized as far distally as the proximal edge of the flap. The nerve should be gently separated proximally from the common digital nerve to obtain the required length, while the medial and lateral digital nerves are retracted apart with nerve hooks (see Figure 45.25, *B*).

The pulp flap, which has been left undisturbed throughout the previous dissection, can now be elevated. If pulp alone is to be taken, the pattern should be outlined almost to the lateral eponychial fold, leaving a rim of only 1 to 2 mm. The dorsal and plantar margins of the flap should be incised directly down to the underlying distal phalanx. The already dissected digital artery, vein, and digital and peroneal nerves should be retracted away from the skeleton with vessel loops, so that the flap can be elevated from proximal to distal beneath these protected structures, using bipolar cautery to raise the flap directly off the underlying bone and lateral collateral ligament of the interphalangeal joint.

If the nail plate is to be incorporated with the pulp flap, the dorsal cortex of the distal phalanx beneath the nail should also be harvested by making a coronal cut, which avoids the vessels passing through the rima ungulae, the aperture that lies between the neck of the phalanx and the lateral collateral ligament. Access for this cut is made through the distal part of both the plantar and dorsal incisions.

CRITICAL POINTS *First Web Space and Toe Pulp Flaps*

Indications
- Loss of thumb or digital pulp
- Reconstruction of sensation in other complex reconstructions

Preoperative Evaluation
- Pencil Doppler examination of great toe/second toe web space
- Mark superficial veins on the foot before tourniquet elevation.

Pearls
- Use the fibular aspect of the great toe for thumb pulp.
- Inspect the vascular anatomy distally in the web space first.

Technical Points
- Dissection may be done in a distal-to-proximal direction, or vice versa.
- The artery is deep to the veins in the first web space.
- Proper digital arteries may branch proximal to the web.
- Dissection of vessels in the web space must be done very carefully to avoid damage and/or later spasm.
- Base the flap on the dorsal arterial system (first dorsal metatarsal artery) if available.
- The flap may need to be based on the first plantar metatarsal artery system if the dorsal artery is small, and this may require vein grafting to reach recipient vessels.

Donor Site Management
- Close the dorsal foot incision.
- Use a split-thickness skin graft for the toe donor site with a bolster dressing.
- Place the foot in a walking cast with a toe pad for protection.

The most distal attachment of the flap should be left attached, the tourniquet is released, and reperfusion is confirmed without the risk of torsion of the pedicle, which might occur if the flap were totally detached. Once satisfactory perfusion to the flap is confirmed, the artery and vein can be ligated and the flap transferred to the hand (see Figures 45.25, *C* and 45.26). Closure is achieved by suturing the access incisions and applying a split-thickness skin graft to the secondary defect. If the graft is secured in place with a bolster dressing, the patient can ambulate on the first postoperative day. A walking cast is desirable to ensure undisturbed healing of the foot.

❖ AUTHORS' PREFERRED METHOD: Flap Selection

Soft Tissue Defects Alone

The selection of local, regional, distant, or free flaps for coverage of specific defects of the upper extremity has been detailed in Chapter 44. In choosing a specific free flap, the following factors should be considered: the health, comfort, and cosmetic demands of the patient; the size, thickness, and special needs of the defect; and the skill and experience of the surgeon. Patients with respiratory problems require full lung expansion after long surgical procedures. Therefore, latissimus dorsi or scapular flaps from the chest wall should probably be avoided in these circumstances. In a patient with an upper extremity wound who has suffered multiple traumas, other injuries may dictate a period of prolonged bed rest. Flaps from the back might create a nursing problem. In these patients, the radial forearm flap[51,64,87,112] may be an appropriate substitute for medium-sized defects. Female patients in particular are likely to be distressed enough by the primary wound without adding a disfiguring scar on the upper arm or forearm or over the scapula. Although attempts have been made to improve the secondary donor defect of such flaps by prior tissue expansion, the free groin flap[22,48,54] remains the optimal choice where cosmesis is a consideration (see Figure 45.15, *D*).

Large defects involving the entire anterior or posterior surface of the forearm, wrist, and hand require a latissimus dorsi flap harvested either as a musculocutaneous flap, a muscle flap resurfaced with a split-thickness skin graft,[31,43] or an anterolateral thigh flap.[1,59,73,127,129] An alternative option may be omentum harvested through a conventional laparotomy or a laparoscopy and covered with a split-thickness skin graft.[58,105]

Medium-sized defects can be covered with either the "tailored" latissimus dorsi musculocutaneous flap or TDAP flap,[2,19,42,75] the scapular flap,[39,46,89] or the anterolateral thigh flap.[1,59,73,127,129] The "tailored" latissimus dorsi flap or TDAP flap offers a long pedicle without the disadvantage of the bulky proximal portion of the muscle close to its insertion (see Figure 45.19). The scapular flap[39,46,89] offers remarkably tough skin with no underlying muscle (see Figure 45.12). This flap is therefore well suited for large dorsal or palmar defects of the hand and wrist,[13] except in the overweight patient, where such a flap would be very thick.

Small defects for which no local flap is available or suitable can often be covered with either a lateral arm free flap[66,67,124] or a fascial flap. The lateral arm flap can be made small enough to provide coverage of one phalanx in a single finger (see Figure 45.4). It can also be contoured to be thick in a slim patient or thin in an obese patient. Thickness is achieved by harvesting a larger area of fascia than of skin and folding the fascia into the

primary defect; thinness is achieved by taking fascia alone without skin[136] and later applying a split-thickness skin graft.

Free fascial flaps[14,32] based on the temporoparietal fascia,[8,52,53,126] radial forearm fascia,[36,51] dorsal thoracic fascia,[27,70] and serratus fascia[11] can also provide coverage of small defects in the hand and fingers. These free fascial flaps can be covered by a split-thickness skin graft primarily, but skin graft "take" may be better if the skin graft is applied a few days later. Free fascial flaps have also been advocated for coverage of small wounds with exposed flexor or extensor tendons or even to wrap around the tendons to maintain their gliding function and prevent their adherence to exposed bone.

Composite Defects

Traumatic injuries and surgically created defects of the upper extremity frequently involve the underlying tendons, sensory nerves, and bony skeleton. Even though one-stage reconstruction of all the tissue components of a composite defect would be ideal, composite reconstruction of associated defects of bone, tendon, artery, and nerve is indicated only occasionally.[78,104]

In the future, it may become possible to prefabricate composite flaps having the exact requirements of each tissue component required to reconstruct a specific defect.

Bone

Vascularized bone can be included in an overlying free flap as an osteocutaneous flap, as with the iliac crest with the groin flap,[91] the lateral border of the scapula with the scapular flap,[114] a rib with the serratus anterior muscle flap,[57] the radius with the radial forearm flap,[35] the second metatarsal with the dorsalis pedis flap,[91] the humerus with the lateral arm flap,[124] and the fibula with the fibular osteocutaneous flap.[128] Small bone defects can be reconstructed with conventional nonvascularized bone graft, either as a corticocancellous block for structure or as cancellous chips. This can be performed primarily at the same time as free flap coverage of the defect or secondarily once the soft tissues have healed. Large segmental defects of the humerus, radius, and ulna or composite soft tissue and bony defects are best reconstructed with the fibular osteocutaneous flap.[128] See also Chapter 46.

Tendon

Vascularized tendon grafts can be transferred with the dorsalis pedis flap[84,107] or the radial forearm flap.[51,99] Such tendocutaneous flaps may occasionally be indicated for one-stage reconstruction of a degloving injury of the dorsum of the hand with loss of skin and extensor tendons. The donor defect in the foot is troublesome after harvest of a dorsalis pedis flap. There is also no evidence that extensor tendon function is any better than with conventional tendon grafting as a secondary procedure beneath a healed skin flap.

Artery

Arterial reconstruction in the upper limb can also be performed using the same arterial system that supplies the free flap. Thus the subscapular arterial system has been used to restore arterial continuity via the circumflex scapular branch, while the thoracodorsal branch supplies the overlying latissimus flap. The distal end of the inflow artery to a flap can also be anastomosed to a distal artery in the limb as a "flow-through" flap to restore flow to the distal limb. The radial artery of a contralateral radial forearm flap has been used in such a "flow-through" fashion to replace segmental defects of the radial or ulnar arteries and so restore flow to the hand.[9,93] Similarly, the continuation of the posterior radial collateral artery supplying a lateral arm flap to cover a defect over the anatomic snuffbox and first metacarpal can be anastomosed to a digital artery to restore flow to the thumb. The descending branch of the lateral circumflex femoral artery of an anterolateral thigh flap,[55] the peroneal artery of a fibular osteocutaneous flap, the medial plantar artery flap,[132] and a flap harvested from the amputated upper extremity have also been reported as "flow-through" flaps.

Sensation

Modest sensibility can be restored to some free flaps by coapting the sensory nerve of the flap, such as the superficial peroneal nerve of the dorsalis pedis flap,[84,92,100] the posterior cutaneous nerve of the arm of the lateral arm flap,[66] the medial or lateral antebrachial cutaneous nerves of the radial forearm flap, and the T12 branch of the groin flap to a sensory nerve in the vicinity of the defect. No such donor sensory nerves exist for scapular or latissimus flaps.

However, for restoration of critical sensation in the thumb or fingertips, a free neurovascular flap from the fibular aspect of the great toe or the tibial aspect of the second toe is the optimal choice (see Figure 45.26).[12,45,72,76,82,86]

CONCLUSION

The practicing hand surgeon should have a limited repertoire of highly reliable free flaps that can be used to reconstruct the majority of defects encountered in the upper extremity. The lateral arm flap or various fascial flaps can be used for reconstruction of small defects; the scapular, tailored latissimus, or radial forearm flaps for medium-sized defects; and the latissimus muscle flap, anterolateral thigh flap, or omental flap for large defects. The free groin flap or superficial circumflex iliac artery perforator flap, although more difficult to dissect, should be considered if cosmesis of the donor site is especially important. A contralateral radial forearm flap is especially indicated for coverage of the forearm or wrist if simultaneous revascularization of a segmental radial or ulnar arterial injury is also required. The fibular osteocutaneous flap is the optimal choice for composite reconstruction of associated bone and soft tissue defects involving the humerus, radius, and ulna. Finally, the fibular aspect of the great toe, the tibial aspect of the second toe, or the entire first web space flap is the preferred sensory flap for reconstruction of the thumb or finger pulp or for restoration of critical areas of sensibility in the hand.

Vascularized Bone Grafting

Allen T. Bishop and Alexander Y. Shin

Bone grafts have been used since the first decade of the twentieth century to fuse joints and repair defects. The desirability of a living bone graft was recognized by several early investigators who used pedicled fibular grafts for tibial defects as early as 1905.[59] The concept of pedicle grafting has been widely applied since that time, using rib, clavicular, iliac crest, scapular, radial, greater and lesser trochanter, medial femoral condylar, pisiform, second metacarpal, and humeral grafts.

The microsurgical transfer of autogenous living bone awaited the development of techniques and instruments for microvascular anastomosis. With appropriate microsurgical instruments and techniques, development of free vascularized bone flaps was rapid. This included the first free bone transfer, of an osteocutaneous composite rib flap,[91] followed with use of rib, fibula, and iliac crest transfers. The fibula remains the mainstay for most large extremity defect reconstructions. Many variations have been described that allow tailoring of the graft to meet specific needs, including reconstruction of combined bone and soft tissue loss in one setting. In recent years, smaller bone grafts, as well as periosteal and osteochondral free flaps, have provided additional choices better suited for some specific applications than the fibula, rib, or iliac crest.

GENERAL CONSIDERATIONS IN VASCULARIZED BONE GRAFTING

Pedicle Flap Versus Free Flap

Vascularized bone grafts allow living bone tissue to be transplanted to an adjacent or remote location and survive by maintenance or restoration of blood flow. Free vascularized bone grafts require microvascular anastomoses to a recipient site artery and vein, whereas pedicle grafts are moved with their blood supply undisturbed to an adjacent area. Pedicle flaps may have orthograde or retrograde flow through a distally based pedicle with satisfactory results.

Biology of Conventional Bone Grafts

A bone graft obtained without a blood supply is termed a *conventional graft*. It may be obtained from the patient (autograft), another individual (allograft), or another species (xenograft). Cancellous conventional autografts are commonly used to encourage healing of fractures, arthrodeses, or allograft/host junctions in reconstructive surgery. Structural autografts are used to span significant defects in the axial or appendicular skeleton. Autografts are superior, in general, to allogeneic or xenogeneic material.

For most bone defects of less than 6 cm with a well-vascularized bed, adequate soft tissue cover, and absence of infection, a conventional cancellous or corticocancellous autograft is generally recommended. Cancellous bone has greater inductive capacity than cortical bone and should be used unless mechanical stability is required.

The process of bone graft incorporation is by *creeping substitution*, a process of gradual vascular ingrowth, resorption, and replacement of necrotic bone. Creeping substitution results in rapid revascularization of small cancellous grafts but is slow and incomplete in cortical bone. As much as 40 to 50% of lamellar bone remains necrotic, and the revascularization process that does occur causes significant mechanical weakening because of resorption of necrotic bone. Large structural allografts, like autografts, must also be replaced by living bone. Despite the reduction in immunogenicity resulting from cryopreservation, they invoke a local and systemic immune response that diminishes the stimulus of new bone formation and are replaced more slowly and less completely than similar grafts of autograft bone. This effect may be diminished by freezing, freeze drying, irradiating, or decalcifying the bone, or eliminated with the use of immunosuppressive drugs. Conventional (nonvascularized) bone grafts of all types have substantial problems with fatigue fracture, even years after the surgical procedure. Successful grafting requires a well-vascularized bed, adequate immobilization, and protection from excessive stress by rigid internal fixation.

Biology of Vascularized Bone Grafts

Unlike conventional bone grafts, vascularized bone remains alive and dynamic in its new site. Viable bone does not undergo creeping substitution; thus, significant osteopenia does not occur. The result is improved strength, healing, and stress responsiveness as compared with nonvascularized conventional bone grafts. The incidence of stress fracture is lower than in massive structural autografts or allografts. Further, union is more rapid, and bone hypertrophy in response to applied stress may occur with time.[24] Bone healing is more likely in difficult circumstances, including scarred or irradiated beds, or in avascular bone. Vascularized grafts have superior material properties. These include strength, toughness, and an elastic modulus two to four times greater than these factors in conventional structural grafts.

The ability of vascularized grafts to adapt to applied stress by hypertrophy is a frequently observed phenomenon. Hypertrophy does not invariably occur, however. It is less likely when the graft is significantly stress-shielded by extensive internal fixation, or in the absence of weight bearing.[24] Other important factors include age, extent of bone vascularity, and the source of the bone graft. The fibula is more likely to undergo hypertrophy than the iliac crest or rib.

Other Advantages of Vascularized Bone Grafts

In addition to superior cell survival, maintained circulation, and useful mechanical properties, vascularized grafts have other significant advantages over conventional grafts. These include the possibilities of restoring longitudinal growth by inclusion of the growth plate, revascularizing adjacent necrotic bone, improving local blood flow in scarred soft tissue beds, and reconstructing composite tissue loss in one procedure by inclusion of skin, muscle, tendon, nerve, and other tissues with the bone graft.

INDICATIONS FOR VASCULARIZED BONE GRAFTING

Based on the information reported above, it would seem that vascularized autografts would be ideal for grafting under most circumstances. Their use as free tissue transfers is technically demanding, however, and pedicle grafts are often more limited in location, dimension, pedicle length, and, hence, indications. Prolonged operative times and extensive dissection increase the risk of complications, and donor site morbidity may be significant. For bone defects under 6 to 8 cm with normal soft tissues, conventional techniques remain the method of choice under many circumstances.

Segmental Bone Loss

Vascularized transfer is indicated in segmental bone defects larger than 6 to 8 cm that are due to tumor resection, traumatic bone loss, osteomyelitis, or infected nonunion.[149]

Biologic Failure

The use of vascularized grafts in smaller defects is reasonable in cases where "biologic failure" of bone healing is likely or has already occurred. Examples include persistent nonunion after conventional graft treatment, poorly vascularized bone and/or surrounding soft tissue, avascular necrosis of bone, and congenital pseudarthrosis. Other indications include composite tissue loss requiring composite bone/soft tissue flap reconstruction, joint arthrodesis in exceptional circumstances, and a need for longitudinal bone growth requiring physeal transfer.

Avascular Necrosis of Bone

Vascularized grafts have been used to treat osteonecrosis in many areas, including the femoral head, scaphoid, talus, and lunate. Experimental models of avascular necrosis have demonstrated that vascularized bone or arteriovenous pedicle grafts can be used to repair necrotic bone by neovascularization and new bone formation extending from the vascularized graft into the damaged area.[131,151] In the clinical setting, symptomatic improvement and direct evidence of revascularization on imaging studies have been reported in these locations. Vascularized bone or corticoperiosteal flaps also optimally treat nonunions of long bones due to osteoradionecrosis.

Complex Tissue Loss

Many vascularized bone flaps may be harvested to include other tissues. Examples include osteomuscular or osteocutaneous fibular flaps, composite groin flaps including skin and/or muscle, and scapular flaps based on the thoracodorsal pedicle that may include skin and serratus anterior or latissimus dorsi muscle (Figure 46.1). Flow-through fibular flaps permit simultaneous transfer of a second free flap, allowing simultaneous coverage of large soft tissue defects in a single stage. The unique ability of free tissue transfer to solve complex tissue defect problems with a single-stage reconstruction makes them highly desirable in these difficult circumstances.

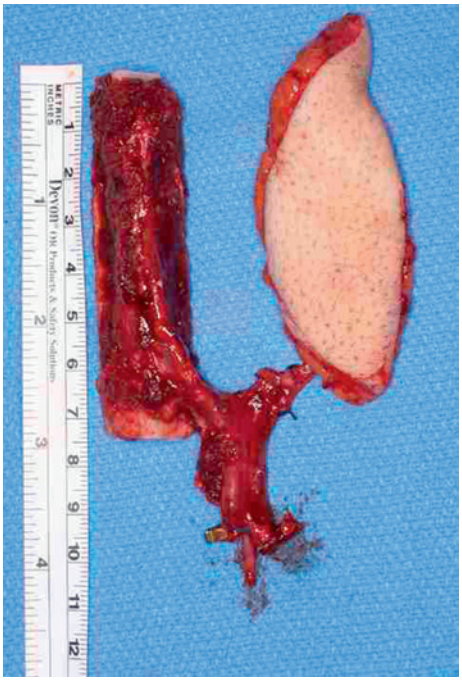

Figure 46.1 Osteocutaneous fibula. The fibula may be harvested as a composite flap including skin for coverage or monitoring purposes.

Physeal Arrest

Transfer of vascularized epiphyses may allow continued growth of a limb.[60] This is currently practical only for fibular grafts with inclusion of the entire proximal fibula, or with toe flaps including bone or joint.

Osteomyelitis

Infections represent a particularly difficult problem. Application of systemic or local antibiotics and aggressive débridement of necrotic bone and soft tissue must be carried out until the infection is deemed inactive or eradicated. Criteria commonly used to determine inactive sepsis include an absence of sinus tracts, negative bacterial cultures, a negative C-reactive protein level, and a sedimentation rate of less than 15 mm/hour, maintained for at least 1 month.[96] When strict criteria for determining quiescence are used, recurrent infection will occur infrequently.

Carpal Defects or Disorders

Vascularized bone or osteochondral flaps may be applied to defects of the carpal and hand to aid or accelerate fracture healing or replace deficient bone. However, they have most widely been indicated for revascularization of ischemic bone. The most common instances are scaphoid fractures resulting in

proximal pole avascular necrosis, osteonecrosis of the lunate (Kienböck disease), or osteonecrosis of the scaphoid (Preiser disease). They are also indicated when previous conventional surgery has failed or is deemed likely to fail. Bone-only flaps must be used with some caution once subchondral fracture results in damage to the articular surface, or in very small or fragmented scaphoid proximal fragments. In such instances, partial replacement of both deficient bone and a damaged or nonfunctional articular surface has been recently demonstrated in scaphoid nonunions with small or fragmented proximal segments[11] and in avascular necrosis of the lunate.[12] In both circumstances, replacing the proximal half of the lunate or scaphoid to include the radial articular surface may prove to be a viable technique.

VASCULARIZED BONE GRAFT SELECTION

Selection of the optimal donor for a vascularized bone graft depends on consideration of a number of factors, including whether material taken from the donor site will match not only the size and shape of the defect but also its material properties. Other considerations include the proximity to the donor area, adequacy of the vascular pedicle for microvascular anastomosis at the recipient site, and donor site morbidity. The most important source of vascularized grafts for large upper extremity bone defects (>6–8 cm) is the fibula. Historically, the iliac crest has been used as well, but its membranous nature, curved shape, and relatively weak mechanical properties make it a secondary consideration in most such instances. Smaller defects, particularly in the hand and wrist, continue to benefit from vascularized bone flaps, as well. Distal radius pedicle grafts taken from either the dorsal or palmar surface have been extensively used for carpal nonunion or avascular necrosis based on well-defined anatomy and flap design. In recent years, the medial femoral condyle (MFC) flap variants, including bone,[18,29,68] periosteum,[25,36,114] and articular cartilage,[12,55] are finding increasing favor in difficult clinical situations. Corticoperiosteal flaps are superior to other methods in treating failed reconstructions and radiation-induced pathologic fractures of the clavicle.[36] The healing rate and time to union are significantly better in scaphoid nonunions with humpback deformity and dorsal intercalated segmental instability carpal collapse, when treated with a large MFC graft.[18] Previously unsalvageable lunates, with damaged proximal articular surfaces, may also be reconstructed with osteoarticular MFC segments.[12] Additional options may include pedicled flaps from the pisiform,[21,53] metacarpal head,[109] proximal second metacarpal metaphysis,[120] and ulnar or radial diaphysis.[46] Free microsurgical transfer is also possible from the iliac crest[106] and rib.[78]

Preoperative Planning

Recipient Site

Preoperative planning is vital for successful free tissue transfer. The bony, vascular, and soft tissue anatomy of a particular recipient site must be considered, along with factors related to the bone defect itself. For example, the length and location of the bone defect, infection status, amount of soft tissue loss or scarring, and condition of recipient vessels must be determined. The method of bone fixation should be planned in advance. If osteomyelitis is present, extensive débridement of all devitalized bone and adequate preliminary soft tissue coverage are prerequisites before vascularized grafting is considered.

The adequacy of recipient vessels is a paramount consideration. Clinical examination of pulses and the Allen test may be all that is required in nontraumatic cases. In many instances of traumatic or postirradiation bone deficiency, the extent of soft tissue injury extends well proximal and distal to the level of bony abnormality. Within the reactive zone, a patent vessel may be prone to spasm as well as friability due to surrounding scar or granulation tissue. This will render any anastomosis potentially flawed. In such situations, planning an anastomosis proximal or distal to the zone of injury is necessary. This may be performed with a sufficiently large flap or long pedicle, or at times by the use of vein grafts. Arteriography of the recipient site should be performed if there is any preoperative concern. This is most common in trauma indications, where vascular damage is likely. The probable need for vein grafting may be determined by preoperative arteriography, and by consideration of known factors such as pedicle length and distance of bone from available recipient vessels.

Vein grafting may be done as conventional arterial and venous interposition grafts, or by fabrication of a temporary arteriovenous fistula. In the latter circumstance, a reversed saphenous vein graft is anastomosed end to side to the recipient artery and end to end to the vein. End-to-side arterial anastomoses may have a higher patency rate in free tissue transfer and preserve distal circulation. The shunt is allowed to perfuse while the donor tissue is harvested.

The vascularized graft can be placed in either an orthograde or retrograde flow position, as dictated by the position of the best vascular anastomosis. A retrograde position has no effect on patency or rate of union.[23] Bony stabilization is performed, followed by vascular anastomosis. Use of stable internal fixation provides results superior to those of minimal internal or external fixation.[48,54] Plates spanning the entire reconstruction, or intramedullary fixation, are optimal. Stabilization may include the use of intercalary allografts.[14,17,82,103] In the upper limb, this is most generally considered for humeral shaft and shoulder arthrodesis reconstructions.[112] Addition of supplemental cancellous graft at junction sites increases the primary healing rate.

Donor Site

Selection of the best donor site is based on a consideration of the recipient site requirements and the characteristics of available donors. Larger defects in the upper limb are generally best reconstructed with fibular flaps, but smaller defects and bone with impaired vascularity or failure to heal with conventional methods may heal with smaller vascularized bone, corticoperiosteal, or osteocartilaginous flaps.

The donor site should be examined for evidence of previous injury or surgery, and an adequate history should be obtained to rule out systemic disease or local closed injury possibly affecting the surgical plan. A vascular examination should be performed, including peripheral arterial pulses. In the case of fibular harvest, vascular anomalies are rare, and adequate perfusion of the foot following harvest has been demonstrated to be nearly normal in most cases. We do not routinely perform angiography unless the examination suggests possible problems. Less invasive methods, such as computed tomography (CT)

scanning or magnetic resonance angiography, are proving to be of value.

Postoperative Monitoring

Thrombosis of the vascular pedicle in a vascularized bone graft results in conditions less favorable for vascular invasion and the usual process of bone graft incorporation than a conventional bone graft. Monitoring of graft viability in the immediate postoperative period is therefore desirable. A variety of methods have been used to assess viability on an intermittent basis, for the purposes of planning subsequent treatment and anticipating outcome. These include selective angiography, monitoring of healing and hypertrophy with serial radiographs, bone biopsy or observation of bleeding on subsequent surgery, or early 99m technetium bone scans, generally in the first postoperative week, as well as use of Doppler ultrasound scanning or single photon emission computed tomography scans.

Intermittent monitoring methods, however, will not detect acute thrombosis. Continuous monitoring is possible with the use of a surface or implantable laser Doppler velocimeter or a thermocouple probe, or, most practically, monitoring of a skin paddle serving as a "buoy flap." Detection of thrombosis allows revision of the anastomosis and salvage of a significant number of failing free tissue transfers.

Buoy Flap

By far the most feasible and easily interpreted continual monitor is a fasciocutaneous buoy flap. It enables direct observation of the transferred tissue, allowing immediate return to the operating room if loosening of the dressing, altering of the limb position, or trial of anticoagulation does not reverse the observed changes in 1 to 2 hours.[153] Cutaneous island monitoring is possible with most vascularized bone flaps, including the most common fibular, iliac crest, medial femoral condylar, and 1,2 intercompartmental supraretinacular artery (1,2 ICSRA) flaps.

Implanted Laser or Ultrasonic Probes

Although measurement of blood flow in an imbedded free flap is difficult, special probes have been used effectively for at least 48 hours postoperatively. In Schuurman's study of free fibular transfer, an occlusion rate of 10%, with 50% successful salvage, was seen with use of a laser Doppler probe.[121] A miniature Doppler ultrasonic probe is also available, designed to be secured to the outflow vein of the flap via a silicone rubber cuff.[132] The device was successful in salvaging 20 instances of thrombosis or spasm in 16 of 135 consecutive free flaps.[76]

Arteriogram

Arteriography allows assessment of bone viability at a single point in time. Angiography performed 6 to 8 weeks after surgery if positive is suggestive of likely clinical progress.

Bone Scan

Experimentally, positive bone scans correlate with vessel patency when done before the end of the first week, prior to the onset of creeping repair in both vascularized and nonvascularized autografts[122] (Figure 46.2). Use of dynamic imaging provides a more accurate, even semiquantitative, linear relationship between scan values and bone blood flow.

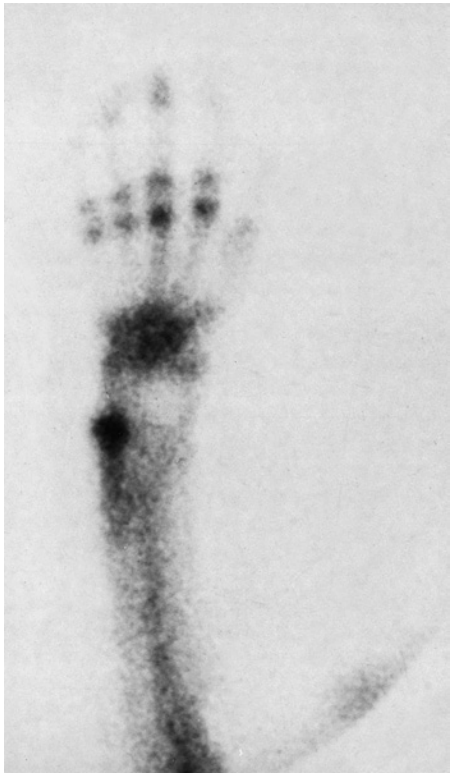

Figure 46.2 Bone scan 4 days following operation demonstrates excellent uptake in a fibular graft placed in the radius.

Bone scans obtained in the first 1 to 2 weeks following flap transfer have been demonstrably useful in clinical and experimental studies, correlating well with preserved circulation and clinical outcome.[158] In these studies, patients with a "hot" postoperative radionuclide were more likely to have a successful clinical outcome than those with negative or equivocal scans. In one series, only one of seven patients with poor scans healed primarily, and two cases (almost 30%) resulted in frank failure, necessitating removal of the transferred bone.[158]

COMPLICATIONS OF VASCULARIZED BONE GRAFTS

Impaired Vascularity

Vessel thrombosis occurs in a small percentage of free tissue transfers. If thrombosis occurs in a bone flap, it is likely that the surrounding cuff of necrotic soft tissue may impede neovascularization. Experimentally, the viability of thrombosed vascularized bone grafts is significantly less than that of conventional nonvascularized grafts as quantified by measurements of bone blood flow, new bone formation, and osteocyte counts.[125] Thus, the process of creeping substitution of necrotic bone is likely less extensive in failed vascularized grafts than in conventional grafts.

Delayed Union: Need for Secondary Bone Graft

Secondary bone grafting will be necessary in a substantial number of patients treated with structural vascularized bone grafts of the long bones. Primary healing occurs in roughly 68%

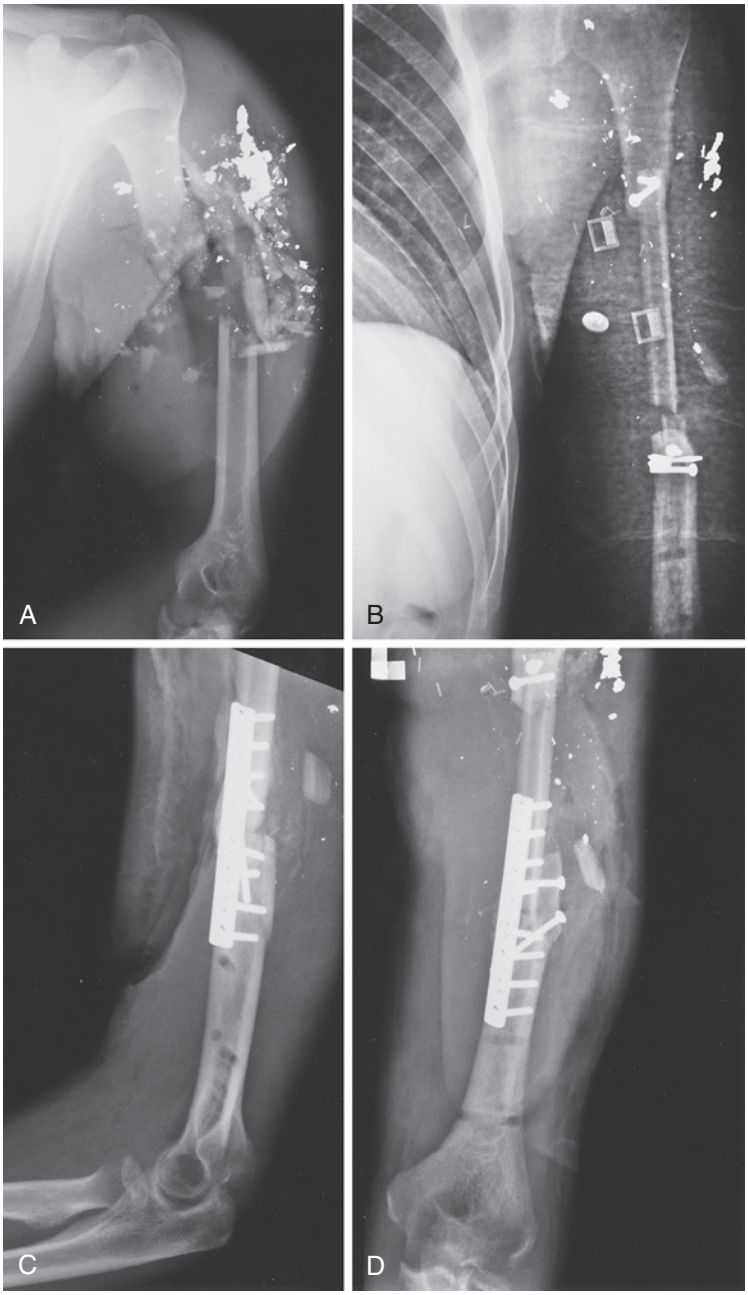

Figure 46.3 Gunshot wound in a 23-year-old man. **A,** Fragmentation of the humeral diaphysis before débridement. A large anterior wound was closed with a pedicled latissimus dorsi flap placed as an elbow flexorplasty to replace the missing biceps. **B,** A simultaneous fibular graft reconstructed the bone defect. A stress fracture occurred shortly after removal of a bridging external fixator several months later. **C** and **D,** Supplemental onlay bone grafting a plate fixation allowed healing of the fibula.

of vascularized fibular grafts, with poorer results in some locations and with a diagnosis of osteomyelitis.[48] Most that do not heal primarily will benefit from a secondary bone graft. Because the mean time to healing is 6 months for fibular grafts and 7 months for iliac crest grafts, timing of a secondary graft is generally somewhat longer, frequently at or before 12 months following the vascularized graft. A largely cancellous autograft at the ununited junction is usually sufficient. Problems associated with insufficient internal fixation may require revision at that time.

Stress Fracture

Stress fracture of a structural graft spanning a segmental defect may occur in both the upper and lower extremities (Figure 46.3, *A* to *D*).[112,135] Minami reported an incidence of 12 fractures occurring in 10 of 53 vascularized fibular transplant patients (23%).[98] Rigid stability provided by spanning plates or allograft replacement with intramedullary fixation on only fibular grafts results in a lower incidence of fracture.[112] Healing of stress fractures may occur with immobilization, provided the graft has adequate vascularity. Rapid formation of callus at the

fracture site and hypertrophy of the bone is observed thereafter, although displacement is common and requires stabilization.

The time of fracture occurrence may be significant because most occur within the first year after grafting. Fractures occurring in this time period generally have adequate circulation, as demonstrated by postoperative bone scanning[48] but have had insufficient time to undergo hypertrophy. Late fractures are uncommon and are associated with negative or equivocal bone scans. Most stress fractures occur through the transferred bone, rather than at its junctions.

When the fracture occurs in adults, union is often relatively easily obtained. Nondisplaced upper extremity fractures will heal in a cast alone, whereas displaced fractures require internal or external fixation with or without bone grafting.[48,98] A vascularized graft should be protected against fatigue fracture during the first year, allowing a gradual increase in mechanical loading, which enhances remodeling and hypertrophy.[24]

SPECIFIC VASCULARIZED GRAFTS: LONG BONE RECONSTRUCTION

Vascularized Fibular Grafts

ANATOMY

The fibula is the most used vascularized bone graft because its structure and shape are appropriate for diaphyseal locations. A long, straight segment of 26 to 30 cm in length may frequently be harvested, and osteosynthesis securely obtained to the recipient bone.

The blood supply to the fibula, as in other long bones, is derived normally from a nutrient artery via radially oriented branches, which penetrate the cortex and anastomose with the periosteal vessels. The source of the nutrient blood supply is a branch of the peroneal artery, generally entering the bone in its middle third. The resulting blood flow is centrifugal from medulla to cortex. This arrangement is the norm for the fibula, which has a single nutrient vessel entering its middle third from the peroneal artery. Additional periosteal branches from the peroneal and anterior tibial arteries also supply the diaphysis.

The proximal epiphysis is supplied by an arcade of vessels, including the lateral inferior genicular vessels and a recurrent branch from the anterior tibial artery.[61] Although some recommend use of the genicular blood supply, recent studies support the use of the anterior tibial vessels, which will also support the proximal two thirds of the diaphysis via the periosteal supply.[61] Such a pedicle supplies adequate vascularity to provide either longitudinal growth in children or viable articular cartilage for joint reconstruction. Although the genicular pedicle will provide periosteal blood flow, the peroneal vessels must be separately identified and supply the fibular shaft.

Transfer of a fasciocutaneous skin paddle of up to 10 by 20 cm is made possible by a series of fasciocutaneous or myocutaneous perforators from the peroneal artery, which typically pierces the soleus muscle adjacent to the lateral intermuscular septum (Figure 46.4). The location of the perforators may be determined in the operating room prior to skin incision by use of a Doppler ultrasound stethoscope. Osteomuscular flaps, including the flexor hallucis longus muscle and portions of the soleus or peroneal muscles, may also be raised using the same peroneal artery pedicle.

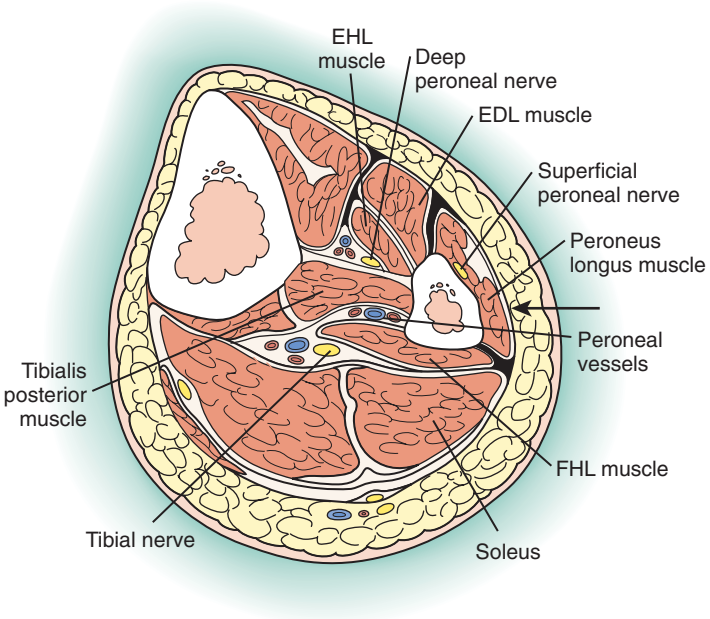

Figure 46.4 Harvest of a fibular free bone graft is performed from a lateral approach. The initial dissection is between the peroneus longus and the soleus. In this middle-third cross-sectional view, the peroneal vessels lie between the flexor hallucis longus and the tibialis posterior muscles. *EDL,* Extensor digitorum longus; *EHL,* extensor hallucis longus; *FHL,* flexor hallucis longus.

The peroneal pedicle has a length of 6 to 8 cm and an arterial diameter of 1.5 to 3 mm. Two venae comitantes lie on either side of the artery. Variations in the vascular anatomy of the leg are infrequent and include unusual deviations in the course of the peroneal vessels or its prominent contribution to the blood supply of the foot.

Technique

Osseous Fibular Flap. Two methods of fibular harvest have been described, including the original posterior approach developed by Taylor,[136] and the preferred lateral approach of Gilbert,[41] described below with some modifications. Exposure must protect the peroneal vessels, which lie between the tibialis posterior and flexor hallucis muscles (see Figure 46.4).

The patient is positioned supine, with a small sandbag beneath the ipsilateral buttock and another secured to the table near its foot to allow the patient's foot to rest securely with the knee flexed. The entire leg is draped free. Next, a pneumatic tourniquet is inflated. The fibula is measured, and its middle third identified. An incision is made directly along the fibular longitudinal axis laterally, extending through skin and subcutaneous tissue (Figure 46.5, *A*). The anterior border of a skin flap is incised at this step. This exposes the broad tendon of the peroneus longus, which is easily identified. A fat stripe posterior to the tendon identifies the interval between the peroneus longus muscle and the soleus muscle. This interval is developed with blunt dissection, beginning in the middle third of the bone (see Figure 46.5, *B*).The cutaneous vascular perforators supplying the skin may be visualized at this point passing either through the lateral intermuscular septum or, more commonly, through the adjacent anterior centimeter of the soleus. As the soleus is reflected posteriorly, one can identify the flexor hallucis

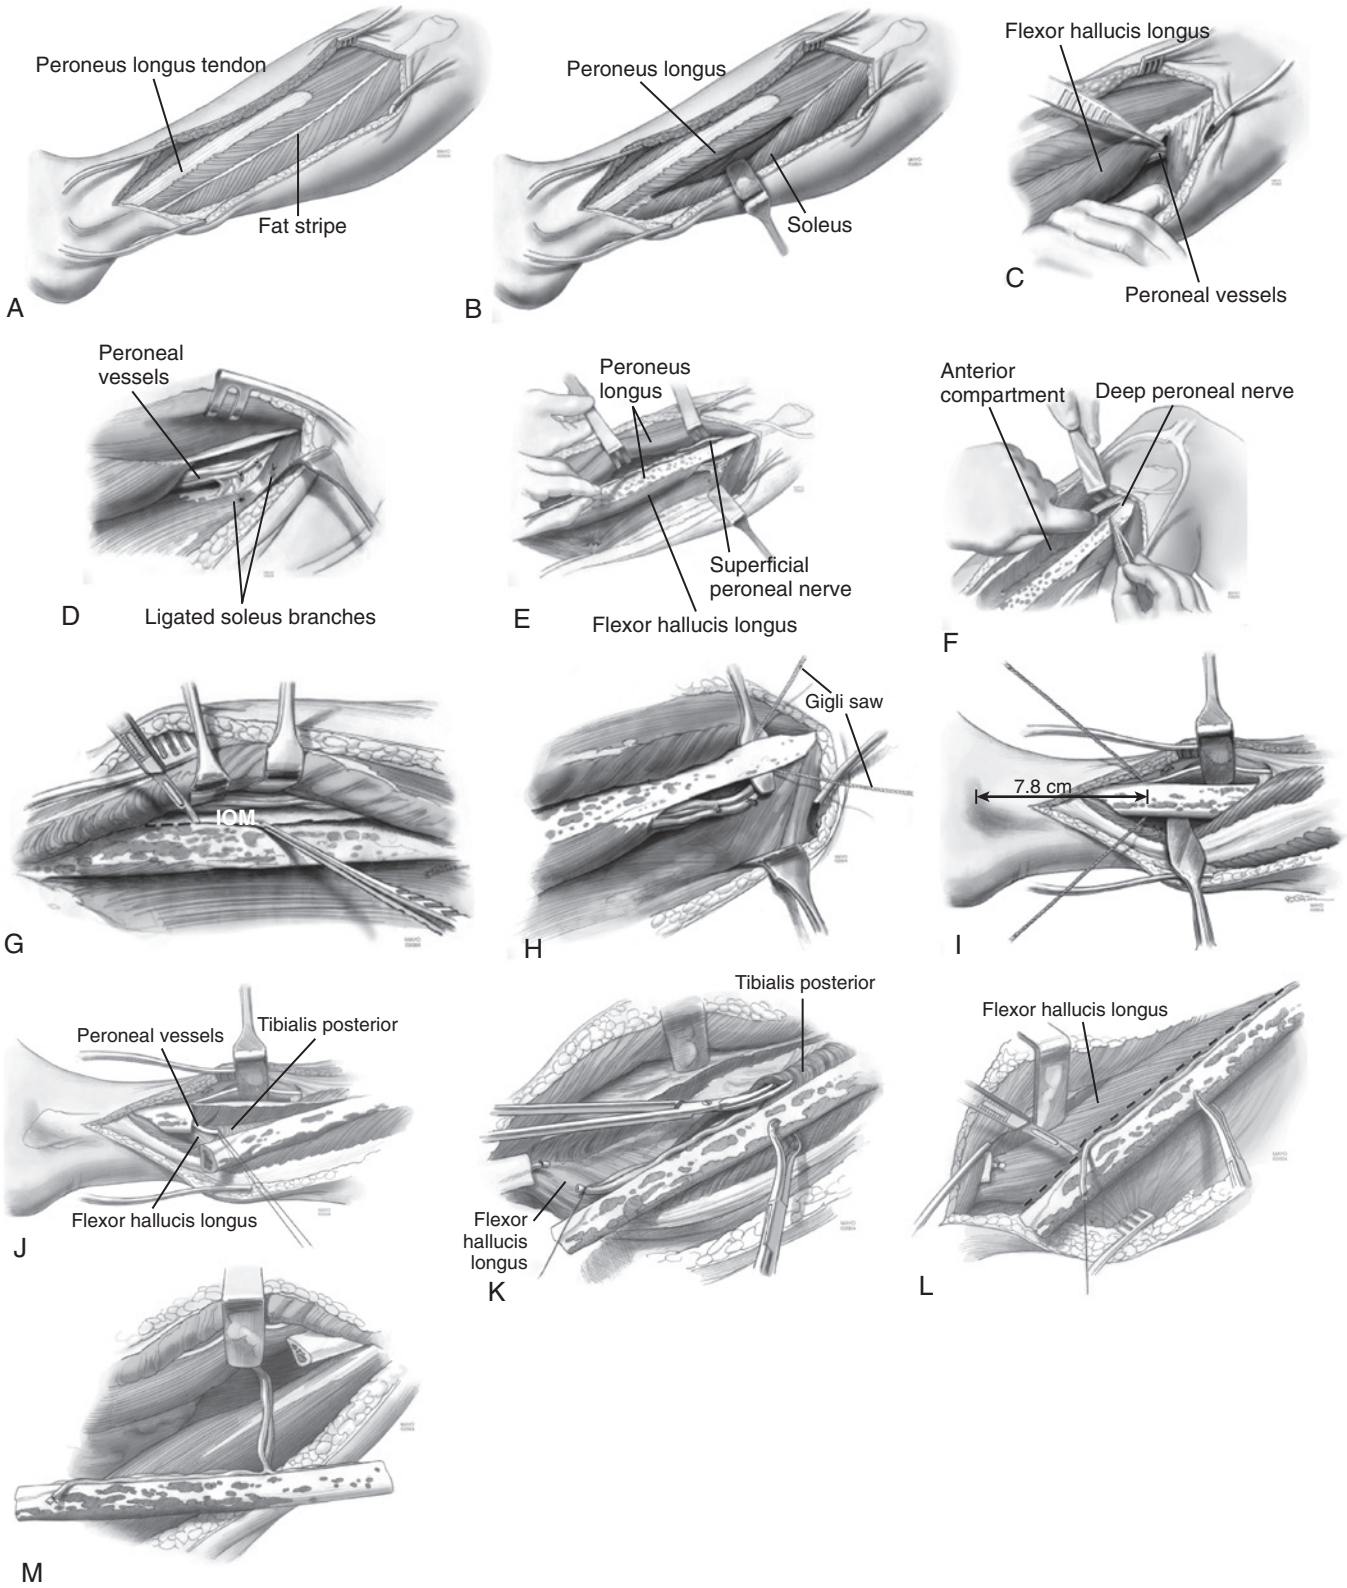

Figure 46.5 Technique of fibula harvest. See description in text. **A,** The *fat stripe* dorsal (posterior) to the peroneus longus tendon marks the plane of the initial dissection. **B,** Open the soleus/peroneus longus interval at midtibia. **C,** Follow the flexor hallucis longus (FHL) muscle on posterior surface of fibula to its proximal origin. The peroneal vessels will then be visualized passing anterior to the muscle. **D,** Ligate any muscular branches to the soleus, and complete the dissection of the soleus from the fibular neck. **E,** Dissect the lateral compartment muscles from the fibula, beginning *subperiosteally* proximally until the superficial peroneal nerve is identified and protected. Dissection proceeds above the periosteum distally. **F,** The deep peroneal nerve is identified, and the anterior compartment muscles are dissected from the fibula in a similar fashion. **G,** The interosseous membrane is divided from the anterior aspect. The tibialis posterior muscle is then visible. **H,** The proximal fibular cut is made, protecting the peroneal vessels and nerve. **I,** The distal fibular cut is made, preserving 7 to 8 cm of distal fibula. **J,** The peroneal vessels are visualized and ligated distally, located between the FHL and the tibialis posterior. **K,** The tibialis posterior muscle is divided from distal to proximal, exposing the peroneal vessels. It is necessary to identify and ligate multiple muscular branches. **L,** The FHL muscle is next removed from the fibula. **M,** The fibula is isolated on its proximal peroneal vessel pedicle.

muscle belly covering the posterior surface of the bone and obscuring the peroneal vessels from view.

The flexor hallucis longus muscle (FHL) origin lies well distal to the fibular neck. Proximal to the muscle, the peroneal vessels are identified as they pass deep to the FHL origin (see Figure 46.5, *C*). The vessels should be mobilized carefully from the posterior surface of the fibula, to prevent their inadvertent injury when the bone is divided.

Dissection is continued progressively proximally, elevating the soleus tendon of origin from its fibular attachment. Muscular branches of the peroneal vessels to the soleus will be visualized during the dissection and should be ligated and divided unless a composite osteomuscular flap with the soleus is desired (see Figure 46.5, *D*). The soleus is completely detached from the proximal fibula.

Next, the lateral compartment muscles are elevated from the fibula. Proximally, this must be done subperiosteally to avoid injury to the peroneal nerve. The nerve must be visualized and protected at this proximal level, lying directly on the bone of the fibular neck and proximal diaphysis. As the muscle is elevated in a distal direction, the superficial branch of the nerve lies further from the bone, and an extraperiosteal dissection plane will better preserve the bone blood supply. This dissection should leave small occasional wisps of muscle rather than a large muscular cuff on the bone surface because this will form a necrotic barrier to revascularization should the anastomosis fail (see Figure 46.5, *E*).

The anterior compartment is elevated similarly. Again, care is needed proximally to protect the deep branch of the peroneal nerve (see Figure 46.5, *F*). The anterior tibial artery will be identified, as will the interosseous membrane at the conclusion of this dissection. Depending upon ease of visibility, the interosseous membrane may be divided at this point (see Figure 46.5, *G*), or the bone divided proximally and distally first. Bone division is carried out with a Gigli saw, protecting neurovascular structures with careful circumferential retraction and blunt passage of the saw cable (see Figure 46.5, *H*). The middle third of the bone, at a minimum, must be raised to preserve the nutrient artery supply. Harvesting more of the proximal third will improve visualization of the peroneal artery pedicle at the conclusion of the graft elevation. Although the entire proximal fibula may be harvested if articular surface or physis is required, 7 to 8 cm of the distal fibula should be preserved to prevent valgus instability of the ankle (see Figure 46.5, *I*). In children, a distal tibiofibular syndesmotic fusion is necessary with an iliac crest interposition graft and screws to prevent ankle instability (see Figure 46.6). Fusion is not necessary in adults.

After the interosseous membrane and bone are divided, the peroneal artery is identified at the distal osteotomy and ligated (see Figure 46.5, *J*). A long suture tag is left on the proximal stump to facilitate proximal dissection of the vessel. Dissection proceeds from distal to proximal. Viewing the fibula from a dorsal direction, the muscle of the tibialis posterior muscle is now exposed after division of the interosseous membrane. The tibialis posterior muscle and posterior fascia must be divided to expose the peroneal vessels (see Figure 46.5, *K*). The muscle is teased away carefully first, ligating muscular perforators as they are encountered. A tissue plane is identified just anterior to the ligated peroneal vessel. This is the posterior fascia of the tibialis posterior, which is next divided to expose the artery. The dissection must be meticulous to identify and ligate multiple muscular perforators and protect the underlying vessels.

At this point, only the vascular pedicle and the FHL muscle belly remain attached to the bone. The FHL tendon may be divided at this point if the muscle is to be included with the fibula as an osteomuscular flap. In most cases, it is not, and the FHL is carefully incised at its fibular origin, protecting the peroneal vessels at all times (see Figure 46.5, *L*). Additional perforators will frequently require ligation.

Finally, the peroneal pedicle is dissected as far proximally as possible. Separation of the artery and venae comitantes from each other is desirable at this time. At this point, they form the sole remaining attachment of the fibula (see Figure 46.5, *M*). The tourniquet is released, and the bone is allowed to perfuse while careful hemostasis is obtained in the leg. The artery and veins are ligated proximally and divided to detach the flap. Two suction drains are placed, one between FHL and the soleus, and another subcutaneously. The FHL is loosely repaired to the peroneal muscle with a running absorbable suture. The skin is closed in layers.

Fibula With Skin Flap. Osteocutaneous flaps are often advocated because the skin serves as a visible and immediate monitor of peroneal vascular patency. At times, the skin is needed to enable wound closure without tension and provide coverage for the underlying fibula and vascular reconstruction. Inclusion of skin is made possible by several fasciocutaneous perforators from the peroneal artery, which supplies the skin at intervals, particularly along the middle third of the bone. If a cutaneous flap is elevated with bone, the locations of the major fasciocutaneous perforators are identified with a Doppler ultrasound stethoscope prior to tourniquet elevation because their exact position and number vary considerably between individuals. They may be readily identified midlaterally by an audible pulse using the probe, near the soleus/peroneal junction (lateral intermuscular septum). Alternatively, the exact placement of the skin island can be determined by visualization of the vessels directly after the anterior incision is made. The dissection proceeds exactly as for a conventional fibular graft, except that the peroneus-soleus interval is left undisturbed in the middle and distal thirds until the peroneal vessels are exposed anteriorly (after fibular osteotomies, and division of the tibialis posterior). Isolation of the perforating vessels is performed by division of the posterior skin flap at this point, and their mobilization back to the peroneal vessels. To avoid problems with excessively tight skin closure and compartment syndrome, the donor site at the skin paddle area should be closed by a split-thickness skin graft, unless a very small buoy flap only is taken.

Fibula With Physis. Inclusion of the proximal growth plate to allow for growth of the transferred bone is a reasonable procedure when no other options exist. In a leg with normal vascular anatomy, current opinion favors the use of the anterior tibial vascular pedicle, which will support the fibular head and neck with a nutrient vessel supply, and a periosteal supply to the diaphysis. The technique of harvest is well described by Innocenti.[61] It is most used in the upper limb for restoration of growth following resection of the distal radius in children,[3,60] but is also useful with resection of the proximal humerus[92] or distal ulna.[3]

A longitudinal incision centered between the tibialis anterior and extensor digitorum longus is prolonged proximally,

following the biceps femoris muscle. Dissection in the intermuscular plane between these two muscles, starting distally, exposes the tibialis anterior neurovascular bundle and preserves the delicate network of periosteal vessels supplying the diaphysis. During proximal dissection, many motor branches of the peroneal nerve cross the operating field, and they must be carefully preserved.

The common peroneal nerve is identified and protected at the level of the fibular neck. The origins of the extensor digitorum longus and peroneal muscles are incised and reflected laterally and inferiorly 2 cm distal to the proximal fibular tip, leaving a muscular cuff surrounding the fibular epiphysis. Once the vessels are isolated, the fibular head is released by division of the biceps femoris tendon and iliotibial band attachments and release of the lateral collateral ligament and tibiofibular joint capsule. The anterior tibial vessels may be ligated at their origin to complete the harvest.

Fibula With Muscle. The fibula may be harvested with inclusion of the lateral portion of soleus and/or the flexor hallucis muscle. The FHL provides only enough muscle to cover the distal fibular segment. It is easily harvested by dividing its distal tendon rather than by separating the FHL from the fibula at its origin.

A larger muscle, sufficient to obliterate dead space or provide coverage, may be preferred. In this instance, use of the lateral portion of the soleus is appropriate. This is also easily accomplished by sparing the soleus muscular branch(es) visualized during exposure of the peroneal pedicle early in the dissection, as described previously. Once one or more of the muscular branches is identified and spared, the dissection proceeds unchanged until the end of the elevation, when the soleus is divided longitudinally in its midsubstance. The tibialis posterior artery and tibial nerve are carefully protected during this process.

Double-Barrel Flap. Strength can be improved particularly for femoral applications, or two segments can be separated sufficiently to allow simultaneous reconstruction of the radius and ulna, by use of a *double-barrel graft*. Following harvest, the free fibula graft is osteotomized at its midpoint, the surgeon having first gently elevated and separated the peroneal vessels from the bone at the osteotomy point. This produces two vascularized bone grafts that require only one set of anastomoses. This folded fibula provides twice the cross-sectional area of a single fibula transfer when placed in a single bone. For forearm use, resection of a short intercalary segment of fibula will increase the separation of the proximal and distal segments of bone without tension on the spanning vascular bundle for reconstruction of both forearm bones. An effort should be made to ensure that one of the segments is vascularized by both a periosteal and an endosteal blood supply including the nutrient vessel. In most cases, this will be the proximal segment; the distal segment will therefore be vascularized by periosteal vessels alone.

Fibular Graft Complications

Donor site complications are unusual and mostly transient. A review of 132 free fibular grafts from the Mayo Clinic demonstrated donor site problems in 10 patients (8%).[48] These included transient peroneal nerve palsy (in five patients), FHL contracture (in three patients), stress fracture of the ipsilateral tibia (in one patient), and compartment syndrome (in one patient). Closure after harvest of an osteocutaneous fibula should include use of a split-thickness skin graft to minimize the risk of compartment syndrome postoperatively.

Figure 46.6 Fusion of the distal tibiofibular interval prevents the development of valgus instability of the ankle in children.

In children, valgus deformity of the ankle may occur unless a distal tibiofibular fusion is performed proximal to the physis (Figure 46.6). No similar sequelae have been seen at the knee when the fibular head is harvested for articular surface or physis.

Donor site morbidity, studied by Youdas and Wood[155] at two time points postoperatively, manifested itself as minimal alterations in knee and ankle-foot motion with gait analysis at less than 10 months postoperatively. After 10 months, no significant gait abnormalities were discernible, although impaired strength of ankle inverters and everters persisted.

Iliac Crest Flap

Although widely used in past decades, the iliac crest flap has been less commonly used in recent years, particularly in the upper limb. This is due to the development of alternative sources of smaller bone grafts, such as the medial femoral condyle, and the preferential use of fibular flaps in long bone reconstruction. Additional factors are its curved shape and relatively weak material properties when compared with the fibula. The donor scar is well hidden, however, and it can include a very large cutaneous component, permitting simultaneous reconstruction of large soft tissue defects. Its principal advantages are its largely cancellous nature and the large amount of soft tissue that may be raised with bone as a combined osteomusculocutaneous flap. The advantages of the osteocutaneous groin flap include (1) its use in supplying vascularized bone to what is frequently a poor recipient bed for a bone graft, (2) its

use in reconstruction of both soft tissue and bony defects simultaneously, and (3) the fact that it can be used in facilities without the capability for microvascular surgery when used as a pedicle flap for the upper extremity. As such, it remains a valuable reconstructive option in selected circumstances. Smaller grafts may certainly be taken. Excellent clinical outcomes have been reported for reconstruction of both scaphoid nonunions and Kienböck disease, for example.[2,38]

ANATOMY

The iliac crest receives a dual blood supply from the superficial circumflex iliac artery (SCIA) and deep circumflex iliac artery (DCIA). Of the two, the DCIA system is most important.[117,137] Musculocutaneous perforators penetrating the abdominal wall 1 cm proximal to the iliac crest provide its nutrition. The skin paddle is less reliable than a standard groin flap, and its size, when based on the DCIA, is quite variable, ranging from 7 by 10 to 15 by 30 cm.[137] Enhanced skin survival may result from "supercharging" its blood supply using both SCIA and DCIA vessels. An osteomuscular flap may also be raised, including a portion of the adjacent internal oblique muscle or transversalis muscle based on the ascending branch of the DCIA.

The DCIA arises from the external iliac artery 1 cm proximal to the inguinal ligament. Several branches supply the internal oblique and iliacus muscles, as well as the lateral femoral circumflex vessels. The DCIA courses obliquely cephalad and laterally between extraperitoneal fat and the transversus muscle, until it reaches the anterior superior iliac spine. At this level, it pierces the transversus muscle to run between it and the internal oblique muscle along the inner lip of the iliac crest adjacent to the iliacus muscle. At its origin, the artery has a mean diameter of 2.78 mm, and the vena comitans, 3.6 mm.[57]

Although the entire crest may be harvested, the practical limit of length is 10 cm as a vascularized graft because of its curved shape. It is relatively less well suited for diaphyseal reconstruction than the fibula because remodeling for tolerance of weight bearing is prolonged. Further, osteosynthesis is difficult and weak.

Technique

The patient is positioned supine. The patient is draped to the midline anteriorly, costal margin proximally, and as far posteriorly as possible. The leg is draped free to facilitate hip flexion for wound closure. The skin flap is marked, its axis along the inner margin of the iliac crest, centered at a point 4 to 8 cm posterior to the anterior superior iliac spine (ASIS).[137] The pubic tubercle, ASIS, femoral pulse, and iliac crest are marked. The skin flap is incised along its medial margin, extending it medially along the inguinal ligament and obliquely inferiorly along the femoral pulse. Just proximal to the inguinal ligament, the external oblique is incised, exposing the inguinal canal contents. These are secured and retracted medially with an elastic cord. The floor of the canal (internal oblique and transversalis fascia) is incised to visualize the DCIA and accompanying veins. After identifying their origin, they are traced laterally toward the ASIS, and ligation of multiple small branches, as well as the large ascending branch, is performed. The lateral femoral cutaneous nerve is identified and spared if it lies below the vessels. It will occasionally pass superficially and must then be divided for later repair. The external and internal oblique and transversus muscles are sectioned 2 cm medial to the iliac crest insertion to preserve the skin blood supply. At this point, the vessels are not visualized. Finally, the lateral skin incision is made and the tensor fascia femoris and gluteal vessels are dissected extraperiosteally from the outer table of the ilium. The ilium is osteotomized and the pedicle divided to complete the harvest. Closure is important to prevent herniation, first approximating the transversalis to the iliacus fascia, and then the internal and external oblique to the gluteus and tensor fascia femoris. It may be necessary to attach the abdominal wall muscles to the bone via suture holes or bone anchors. Skin closure is facilitated by hip flexion.

Iliac Crest Complications

Complications related to the iliac crest include incisional hernias and partial loss of the cutaneous portion of the composite flaps. The surgical approach to the vascular pedicle is through the inguinal canal; this approach raises the risk of an abdominal hernia.

Results: Large Segmental Bone Loss

Fibula Donor Results

The authors' review of 478 vascularized fibular grafts performed for all indications demonstrated the rate of primary union healing (without secondary bone grafting) to be 68%, with ultimate healing after supplemental bone grafting to occur in 82% of cases.* Healing, as well as hypertrophy, depends on a number of variables, including patient age, weight-bearing location, type of graft used, method of fixation, and vascular status of the graft. Hypertrophy, when it occurs, is seen by an average of 13.5 months postoperatively.[24] It occurs primarily in young individuals (age < 20 years) and is more common in the lower extremity when stresses of weight bearing are not shielded by rigid fixation spanning the fibular graft (Figure 46.7, *A* to *C*). Fibulas are more likely to hypertrophy than other grafts. Improving the biomechanics of the reconstruction will improve results. Options include simultaneous use of a size-matched cryopreserved structural allograft with either an onlay or an intramedullary fibula[34,103,112] or internal fixation spanning the entire reconstruction (plate or intramedullary rod).

Iliac Crest Donor Results

Vascularized iliac crest grafting is subject to higher rates of complications with lower overall success when compared with the fibula.[42,115,118,119,127,150] A summary of 97 flaps in the six reports cited reveals an average time to union of 7 months, with prolonged protected weight bearing (mean, 18 months). The overall frank failure rate was somewhat higher than with fibular grafts, with eventual union in 67% (38% requiring secondary bone grafting). Most authors are dissatisfied with the skin flap, noting a frequent tendency for necrosis of a part or all of the soft tissue.[5] Suggested solutions include use of an osteomuscular flap without skin, with inclusion of the internal oblique muscle, or improving skin perfusion with a double pedicle of both the DCIA and SCIA.[115] Revision of the anastomosis is more commonly required than for fibular grafts.

Fibular and Iliac Crest Grafts in the Upper Extremity

A review of fibula and iliac crest grafts for large upper extremity defects in 21 cases included graft placement in the humerus in 11 patients, radius in 5 patients, ulna in 3 patients, and clavicle in 2 patients.[148] Overall, primary bone union occurred in 15 patients (71.4%), and eventual union was achieved in 17 patients (81%). The most favorable results were achieved in cases of forearm bone reconstruction (100% union). Clavicle nonunions and shoulder fusions with vascularized bone carry a worse prognosis. Failure to correct deformed clavicular nonunions may result in brachial plexus compression as well as shoulder girdle weakness and pain. The use of the medial femoral condylar corticoperiosteal graft, combined with conventional graft and internal fixation, provides superior results for difficult clavicle nonunions (see Figure 46.11, *D*).[36] Results for shoulder fusion can be improved with improved stability using allograft proximal humerus/fibula composite grafts with rigid internal fixation (Figure 46.8),[112] although satisfactory results with the fibula alone have also been reported. Segmental loss of the humerus requires careful technique and planning to avoid prolonged healing and stress fracture. Use of a bridging plate and/or frozen allograft structural segment in addition to the fibula is to be recommended (Figure 46.9). In the forearm, radius reconstruction for sarcoma or aggressive benign tumors has provided acceptable healing and function. The average time

Figure 46.9 Vascularized fibula as intercalary graft following tumor resection in humeral diaphysis. A spanning plate minimizes risks of nonunion and fibular stress fracture.

to union for all locations is approximately 6 months, without significant difference based on anatomic location.[48]

Results by Diagnosis

The results of reconstruction of large defects with vascularized bone grafting differ significantly by diagnosis. A history of infection had the least favorable results overall. In a large series of 160 vascularized grafts, defects with infection had a primary union rate of 49% and an overall union rate of 77%. Reconstructions when no infection was present had a primary union rate of 69%, with 84% ultimate success after a secondary graft.[48]

Grafting for Defects Caused by Tumor Excision. Vascularized grafts are useful in limb salvage surgery of aggressive upper extremity tumors, including benign lesions such as giant cell tumor and aneurysmal bone cyst as well as primary bone malignant tumors (Figure 46.10, *A* to *C*). Many patients will receive preoperative and postoperative chemotherapy and/or radiotherapy, with their associated morbidities. Postoperative chemotherapy or radiotherapy increases the incidence of stress fracture and delays healing in experimental models, although most clinical cases eventually heal, often without surgery. Han reported successful union in 81% of 69 tumor patients in 1992,[48] and even more favorable results are seen in more recent studies.[19]

There is also a proven role for fibular grafts in correcting nonunion at the host-allograft junction following tumor reconstruction with conventional frozen allograft diaphyseal segments. A review of 33 patients treated with fibular onlay graft

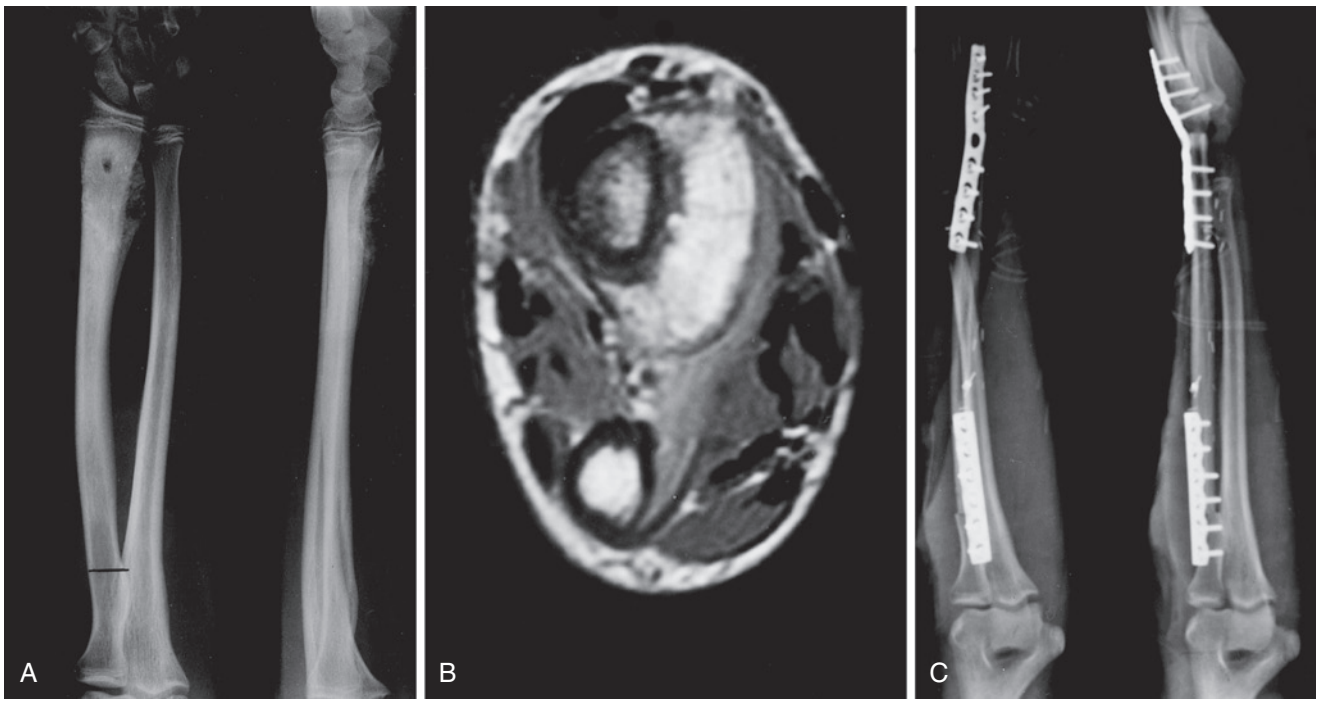

Figure 46.10 Osteogenic sarcoma of the distal radius, with diaphyseal medullary extension in a 14-year-old boy. **A,** Preoperative radiographs. **B,** Preoperative magnetic resonance imaging demonstrating a large soft tissue extension on the palmar surface of the radius. **C,** Immediate postoperative radiographs. Most of the radius has been excised and reconstructed with a vascularized free fibular graft, including a wrist arthrodesis distally.

salvage of allograft reconstruction failures resulted in successful salvage in 23, with 7 failures resulting in 5 amputations.[35] Pathologic fracture due to tumor invasion is also effectively treated by fibular flaps.[35]

Radiation necrosis of bone is a not-infrequent complication of radiotherapy for soft tissue and bone malignant tumors. This is a progressive fibrotic problem, which requires efforts to improve local blood flow. Fractures occur years later (mean, 111 months in one study[31]). Spanning the area of necrosis and fracture with vascularized onlay bone grafts provided healing in 16 of 18 cases in this series.

Grafting in Cases of Infection. The results are less satisfactory for patients who had had the reconstruction for bone loss due to osteomyelitis.[48] Experience with infected pseudarthrosis with segmental osseous defect, treated by débridement and microvascular bone transfer, has demonstrated an increased potential for a number of complications. These include recurrent infection, occasionally leading to amputation,[5] and nonunion. It is critical that vascularized bone transfer be delayed until sepsis is inactive. Criteria used for determining inactive sepsis include absence of sinus tracts, negative bacterial cultures, negative C-reactive protein levels, and a sedimentation rate of less than 15 mm/hour, maintained for at least 1 month following the last clinical evidence of infection.[96] Recurrent infection was seen after vascularized bone grafting in 16% of osteomyelitis patients in the large Mayo Clinic series.[48]

In the forearm, infected nonunions may not respond to conventional treatment. Dell reported success with the use of vascularized fibular grafts and conversion to a one-bone forearm after failure of as many as six procedures.[26] The fibula was fixed to the ulna proximally and the radius distally with internal fixation, and this was supplemented with an external fixator in three of the four patients. All wounds healed and all bone junctures healed, with one requiring supplemental cancellous grafting.

Grafting Following Trauma. The prognosis is better for traumatic nonunion without infection. Union rates are typically greater than 90% when patients requiring supplemental grafting are included.[48] Although some have reported poorer union rates for trauma than for tumor indications, trauma cases had the highest union rate overall in Han's series (primary union, 76%; overall, 92%).[48] Residual limb shortening and other problems are common, occurring more frequently in patients with scarred and relatively avascular soft tissues surrounding the long bone defects.

Grafting for Congenital Pseudarthrosis of the Forearm. The use of vascularized grafts for congenital tibial pseudarthrosis has been shown to be demonstrably superior to conventional methods, including bone graft, electrical stimulation, corticoperiosteal graft, or osteotomy of the involved bone.[98,108,142,144] Vascularized grafts have been used successfully in pseudarthrosis of the forearm as well. In the forearm, creation of a one-bone forearm may be reasonable, especially if conventional bone grafting has failed. Wide resection of associated neurofibromatosis is required. With this initial resection and a vascularized graft, good results may be anticipated.

Grafting for Epiphyseal Transfer and Growth. The superiority of vascularized growth plate transfer over nonvascularized transfer for physeal replacement has been well documented in experimental models.[7,10,154] Clinically, nearly normal longitudinal growth following digit replantation or toe transfer in children has been well documented.[73] The application of epiphyseal transfers to problems such as radial club hand and physeal arrest of long bones is currently showing substantial promise. Long-term longitudinal growth has been seen in 12 children with proximal humerus or distal radius epiphyseal reconstruction using the fibula, averaging more than 1 cm/year.

VASCULARIZED GRAFTS: SMALL BONE AND PERIOSTEAL FLAPS

Indications for Grafting in the Carpus

Grafting for Fracture of the Scaphoid

The scaphoid is the most frequently fractured carpal bone. With prompt appropriate diagnosis and treatment, over 90% will unite. Unfortunately, failure to diagnose acute injury or to surgically treat displaced scaphoid fractures increases the risk of nonunion substantially. The development of scaphoid foreshortening and associated carpal instability with elapsed time contributes to the risk of nonunion. In addition, the fracture may disrupt the proximal pole blood supply, particularly in proximal third fractures, resulting in avascular necrosis of the proximal fragment.

Many scaphoid fractures that fail to heal with inlay or wedge conventional grafts have impaired vascularity as a contributing factor, as demonstrated by sclerosis of the proximal pole on x-ray and MRI studies and absence of punctate bleeding at the time of surgery.[45] The risk is further increased in smokers. The use of conventional grafts, such as the Matti-Russe volar inlay graft, may be contraindicated in the presence of an avascular fragment.[45]

Vascularized bone grafts have been proposed as appropriate methods to increase the rate and frequency of healing in fractures with a poor prognosis. As early as 1965, Roy-Camille used the palmar tubercle of the scaphoid based on an abductor pollicis brevis muscle pedicle for this problem.[113] In recent years, palmar distal radius grafts,[77,87] dorsal radius grafts,[123,157] second metacarpal base grafts,[120] free medial femoral condylar grafts,[29,66] and free iliac grafts[106] have demonstrated improved results as compared with conventional grafts in difficult circumstances. These include displaced acute fractures with small proximal fragments or bone deficiency requiring grafting, failed conventional grafts, and nonunions associated with avascular necrosis.[124,131] Alternatively, inlay or wedge bone grafting coupled with vascular bundle implantation may be considered.[33,66] Vascularized grafts are also indicated in avascular necrosis of the entire scaphoid, prior to bone collapse and fragmentation.[102]

Grafting for Kienböck Disease

Treatment of Kienböck's disease remains controversial, with a large number of treatment options available. These include mechanical unloading and revascularization procedures. Examples of the former include joint leveling, angular radius osteotomy, capitate shortening and intercarpal fusions. Arteriovenous pedicles,[56,151] and vascularized bone grafts[6,101] are examples of the latter. In addition, salvage procedures for advanced changes with arthrosis may be necessary, including proximal row carpectomy or complete wrist arthrodesis.

Experimental studies have demonstrated the ability of vascularized bone grafts to revascularize ischemic bone.[139,140] The main function of the procedure appears to be the provision of vessels into avascular bone. The use of vascularized bone to both revascularize necrotic lunate cancellous bone and, if necessary, restore its dimensions once collapse begins is an attractive alternative to joint leveling and other load-altering options.

Medial Femoral Condyle Grafts

The medial femoral condyle flap was described originally as a corticoperiosteal flap for local use.[52] Its potential as a free corticoperiosteal flap was soon demonstrated and applied to upper limb defects.[30,36] Periosteal flaps in general have been demonstrated experimentally to produce predictable new bone formation, and a variety of other donor sites have been identified, including the clavicle, fibula, ilium, humerus, and tibia. In the upper extremity, thin corticoperiosteal grafts and small periosteal bone grafts harvested from the supracondylar region of the femur have proven to be of great use, based on either the descending genicular or medial superior genicular vessels (Figure 46.11, *A*). This graft is elastic and readily conforms to small tubular bones. Originally described as a pedicle flap, it has been successfully used as a free tissue transfer for clavicular, humeral, and forearm applications, including pathologic fractures from radiation necrosis and other recalcitrant nonunions.[30,36]

This versatile graft may also be harvested as a vascularized bone graft[28,29,66] and as an osteoarticular flap with bone and patellar facet cartilage for resurfacing of small damaged joints.[11,55] The ability to include substantial skin further enhances its versatility. At present, its value has been well demonstrated as a periosteal flap to induce healing in ununited fractures in the clavicle, humerus, and forearm without large gaps, and has been used similarly at allograft junction nonunions.[30,36,71] As a bone-only flap, it has been most widely used in scaphoid nonunion, but it has been applied to treat talus avascular necrosis and small defects in the metacarpals.[116,147] It is certain that the indications for this versatile flap will broaden in the near future.

ANATOMY OF THE MEDIAL FEMORAL CONDYLE

Corticoperiosteal, bone, and osteocartilaginous flaps with or without an accompanying skin island may be obtained from the medial femoral condylar and supracondylar region in a rather straightforward manner.[30] In most knees, a dual blood supply is demonstrable, including the descending genicular vessels and the medial superior genicular vessels. A segment of vascularized distal femoral metaphyseal bone 6 to 8 cm in length may be harvested from the medial femoral condyle for use in smaller

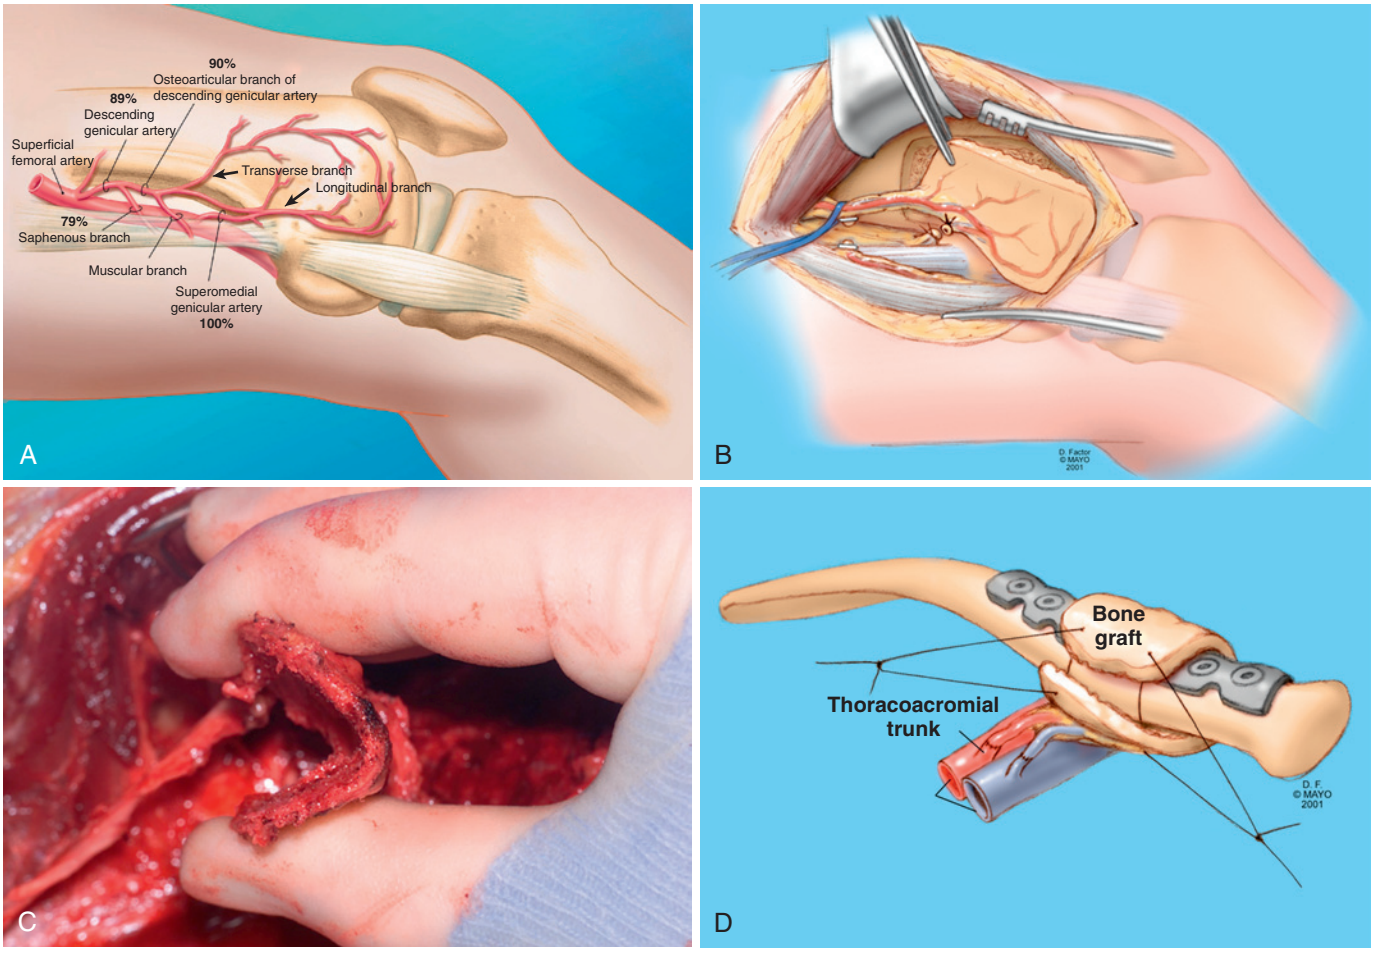

Figure 46.11 Corticoperiosteal flap (medial femoral condyle). **A,** The blood supply of the medial femoral condyle is provided by both the descending and superior medial genicular vessels. **B,** The corticoperiosteal flap elevated from medial femoral condyle. **C,** The flap is sufficiently flexible to wrap around small tubular bones. **D,** Flap wrapped around clavicle with vascular connections to thoracoacromial trunk.

defects, as well as corticoperiosteal flaps generally measuring 5 by 7 cm (see Figure 46.11, *C*).

As originally described,[52] the vascular supply to the surface of the distal medial femoral metaphysis is provided by two vessels in most individuals. Since the anatomy of the region was originally described, further details have been added. The two arteries supplying the medial distal femur are the descending genicular vessel, present in 89% of 20 adult knee specimens in a recent study,[152] and the superomedial genicular vessel, which is constantly present (see Figure 46.11, *A*).[81] The descending genicular vessel arises from the superficial femoral artery and vein proximal to the adductor hiatus at a mean distance of 13.7 mm proximal to the joint line (see Figure 46.11, *B*). The artery has a mean diameter of 1.5 mm and is the dominant vessel in 89% of the specimens studied by Yamamoto and colleagues.[152] When absent or small in size, the medial superior genicular vessel is invariably of sufficient size and length to serve as the vascular supply for an MFC flap.

The descending genicular vessels separate into osteoarticular and saphenous branches at an average distance of 11 cm proximal to the femorotibial joint. The osteoarticular branch supplies several small branches to the posterior border of the vastus medialis, which lies immediately anterior to it in the distal thigh. It is joined by the medial superior genicular vessel just proximal to the posterior aspect of the medial femoral condyle to supply the periosteum and bone of the medial distal femoral metaphysis. Together they form a nearly circular pattern of vessels lying on the bone just proximal to the knee joint capsule and medial collateral ligament origin. They form a nearly circular pattern on the surface of the medial femoral metaphysis. These osteoarticular vessels supplied an average of 30 perforators into the bone, with the largest number located in the distal posterior quadrant of the condylar surface (Figure 46.12, *A*).[152] They penetrated the cancellous bone to an average depth of 13 mm, supporting the use of the MFC as an ideal periosteal and bone flap. The branching pattern of the conjoined medial and descending genicular vessels was further described by Hugon and associates.[58] It separates into two main branches: an upper transverse branch and a central longitudinal artery. The former runs anteriorly to the patellar facet, and the latter toward the tibial joint line. The vessels are connected by an arcuate anastomotic vessel forming the previously described circular appearance easily seen on first inspection of the bone surface. The longitudinal vessel is used for harvest of vascularized bone, and the upper transverse vessel is required if an osteoarticular graft including patellar facet cartilage is to be used.

The safe dimensions of bone that may be harvested depend primarily on the location of the metaphyseal/diaphyseal junction. It is imperative that the bone graft not extend beyond the thin metaphyseal bone if weakening of the femur and potential disastrous femoral fracture is to be avoided. This complication is rare but has occurred when an overzealous graft is taken. This is due to the open-section effect that markedly weakens tubular diaphyseal bone when resected at this level. Thus, even though some proximal perforators may be identified as much as 13 cm proximal to the joint line,[62] no attempt should be made to harvest bone at this level. It is unlikely that grafts longer than 6 to 7 cm may be safely taken, based on the authors' experience, but the length most importantly should be based on preoperative or fluoroscopic findings at surgery, so as to not violate the

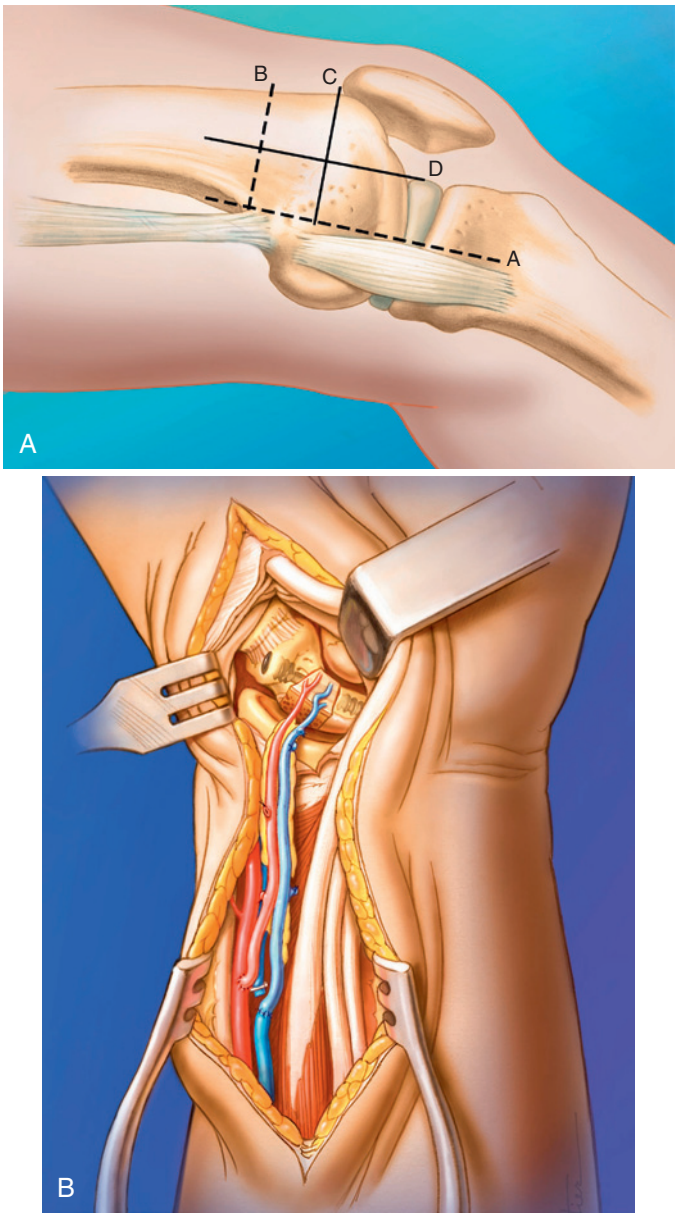

Figure 46.12 Use of a free vascularized wedge graft from the medial femoral condyle to treat a scaphoid nonunion. **A,** Borders of the medial femoral graft. The site is defined posteriorly by the hamstring and medial collateral ligament insertions *(A),* proximally by the insertion of the hamstring *(B),* distally by the proximal pole of the patella *(C),* and anteriorly by the anterior horn of the medial meniscus *(D).* The preferred site for graft harvest is from the distal posterior quadrant. **B,** The graft is placed from a Russe approach as a wedge graft to restore scaphoid length and is fixed with a scaphoid screw. Vascular connections are an end-to-side anastomosis to the radial artery in the forearm and an end-to-end venous anastomosis to a vena comitans or cephalic vein.

robust proximal diaphyseal cortex. No complications were seen in 10 patients who had undergone medial femoral condyle free flap procedures and were followed more than a year postoperatively with CT scans.[110] The average bone harvested per procedure was 16.1 cm^3 (range, 2 to 34 cm^3), representing an average condylar volume of 9% (range, 1% to 18%). The depth of the graft ranged from 4 to 6 mm in this study, and the longest graft harvested measured 7 cm in length. We have routinely used grafts as deep as 15 mm without problems when the other dimensions are similar or smaller. Because only minimal bone

regeneration was seen in Rao's study, one cannot expect the defect to fill in spontaneously. We routinely fill the MFC bone flap harvest site with bone substitute to facilitate remodeling for this reason.[110]

Inclusion of a skin island is advocated by some for monitoring flap viability and can also be used for soft tissue cover if needed. Use of the saphenous branch will require a long proximal pedicle if it is to be included with the descending genicular vessel because it arises approximately 2 cm distal to the descending genicular artery origin.[152] An additional distinct, reliable, further distal, descending genicular cutaneous branch can be found at condyle level, capable of supporting skin, as well.[63] This vessel provides an average perfusion area of 70 cm^2 centered over the medial knee. The saphenous artery branch was reported to support an average perfusion area of 361 cm^2 along the medial aspect of the distal thigh and proximal leg. Perforators may be identified by direct visualization at the time of flap exposure.

Inclusion of patellar facet cartilage is desirable when reconstructing damaged or missing joint surfaces, most commonly in fragmented small proximal scaphoid pole fractures and the proximal (radial) articular surface of the lunate in Kienböck disease. The bone is harvested from the medial trochlea, ideally slightly distal to the most proximal cartilage border.[58] This area has little or no patellar contact, but serves as a pulley for the medial aspect of the quadriceps tendon during knee flexion. Harvest of bone no larger than 7 to 8 mm in lateral/medial width and 10 to 12 mm in proximal/distal length has been recommended, based on limited data.[58]

Surgical Technique

Flap Exposure and Pedicle Dissection. The patient is positioned supine on the operating table. A sandbag taped to the table distal to the foot allows the knee to rest in 90 degrees of flexion. The limb is elevated but not exsanguinated prior to tourniquet elevation to more easily visualize the periosteal vessels. Once the tourniquet is elevated, the surgical approach for any of the medial femoral condyle flap variants (bone, corticoperiosteal, or osteochondral) is made along the posterior border of the vastus medialis muscle. The skin incision may be longitudinal for bone-only flaps, but may best curve in a convex-posterior direction for osteochondral flap harvest or to more safely identify skin perforators if a buoy flap is to be included. This incision is thus directed from posterior/proximal at the Hunter canal toward the medial border of the patella and again posteriorly to the joint line. The proximal border of the skin incision will overlie the adductor magnus and sartorius in the distal medial thigh.[66,81] By retracting the vastus medialis anteriorly and the sartorius muscle posteriorly, the descending genicular vessels and superomedial genicular vessels are visualized in the floor of the vastus compartment and behind the proximal medial condyle, respectively. They are generally closely applied to the vastus muscle to several muscular perforators that must be ligated and divided. As the vessels approach the femoral metaphysis, they follow its contour to lie more superficially, requiring attention of the surgeon in this area. At this level, they are joined by the medial superior genicular vessels, which follow the posterior surface of the femur toward their popliteal origin. They must be visualized and assessed for their diameter relative to the descending genicular pedicle. In 10% of cases, they will be larger and likely a superior pedicle. They are best found just anterior to the adductor longus tendon, by incising the thin fascial layer at its anterior surface to expose the posterior surface of the distal femur. A distal-first approach is often to be preferred, initially exposing the medial femoral metaphysis and the superficial and prominent periosteal vessels. This is easily done by following and mobilizing the posterior border of the quadriceps musculotendinous junction. Once the quadriceps tendon and distal vastus medialis muscle are mobilized and retracted anteriorly, the face of the medial femoral condyle is immediately exposed and the periosteal vessels identified, forming a robust, arching arcade on the surface of the medial femoral condyle (see Figure 46.11, *A*). A natural plane of dissection lies immediately superficial to the vessels, allowing their rapid more proximal exposure. As described previously, both the medial superior and descending genicular branches must be identified at the proximal condyle and a decision made regarding selection of the best vessels for microvascular anastomoses. Cutaneous branches are sought if a buoy flap is to be used, and muscular branches of the descending genicular ligated. It may be followed proximally to its superficial femoral origin some 13 cm above the joint line to maximize vessel diameter or to include a saphenous branch–based skin island. Shorter pedicles may be used with pedicle vessels of a smaller diameter. Similarly, the medial superior vessels may be followed toward the popliteal vessels with somewhat greater difficulty. Multiple bone and muscular branches will be encountered and require ligation. During this exposure process, the vessels are bathed with papaverine or other vasodilators. Care is taken to maintain the patient's core temperature to help minimize intraoperative vasospasm.

Medial Femoral Condyle Corticoperiosteal Flap Harvest. With the pedicles mobilized and the medial femoral condyle exposed, a corticoperiosteal graft is outlined to include the large arcuate vessels that follow the margins of the condyle. Distally and posteriorly, care must be taken to avoid injury of the medial collateral ligament. The superior margin is the reflection of the knee joint capsule at the medial patellar facet. Proximally, the change in cortical thickness at the diaphyseal-metaphyseal margin limits elevation. The periosteum, together with fragments of the underlying outer cortex, is elevated with the accompanying vessels, with a dimension of generally no more than 5 by 7 cm (see Figure 46.11, *C*). This is done by incising the margins and using a small osteotome to alternately cut, then pry, the periosteum from the underlying femur. Note that one should include fragments of the underlying thin cortex. Once elevated, the corticoperiosteal graft should be pliable (see Figure 46.11, *D*), enabling it to be wrapped around the small-diameter diaphysis of the clavicle, radius, or ulna, or to conform to the shape of a larger bone. Once elevated, the pedicle previously dissected as described above is ligated and divided.

At the recipient site, the corticoperiosteal flap may be wrapped around the nonunion site of the clavicle, radius, or ulna and secured with heavy nonabsorbable suture (see Figure 46.11, *D*). When applied as a patch over larger bones, suture anchors are a typical alternative. Microvascular anastomoses are performed to adjacent vessels. An end-to-end anastomosis of both vessels to the thoracoacromial trunk vessels is preferred for the clavicle, and end-to-side arterial anastomoses to the radial or ulnar artery in the forearm. Vessel patency and a bleeding flap surface confirm a successful transfer. A skin buoy flap

can be transferred for continuous monitoring if desired as described previously.

Medial Femoral Condyle Vascularized Bone Graft Harvest. Harvest of the MFC graft should be from the same side as the upper limb recipient, unless there is a compelling reason not to do so. This is potentially important because any donor site discomfort requiring support with a cane or crutch requires use of the opposite hand. Although significant temporary pain is uncommon, it is impossible to predict whether it will occur prior to surgery. With the pedicles mobilized and the medial femoral condyle exposed, the bone graft site is determined by visual inspection of the condyle. For scaphoid nonunions with a humpback deformity, the graft dimensions are generally 10 to 12 mm in proximal and distal length, and 10 mm in anterior and posterior width and depth. As described previously, the optimal location for the graft is the distal posterior quadrant of the condyle (see Figure 46.12, *A*). The graft is outlined in this area centered over the longitudinal branch of the conjoined medial genicular vessels. It is necessary to free the longitudinal branch proximal to the flap from the underlying periosteum. We prefer to do this using a microbipolar cautery and a small scalpel blade, elevating the pedicle by dissection 1 to 2 mm to either side of the vessels and gently dissecting beneath them with the aid of a small-diameter vessel loop. Multiple small periosteal vessels can be seen and dealt with in this fashion with the microbipolar cautery at a distance far enough from the pedicle so as not to endanger it. Once the pedicle is entirely freed to the desired position of the bone graft, the graft is outlined to the desired depth with a microsagittal saw along all four borders. Next, a small wedge of bone is removed to one side of the flap (Figure 46.13). This allows access to the deep surface of the graft with a small osteotome. It is used with a prying motion to complete the elevation of the graft from below. Attempts to free the graft in any other way risk fracture and separation of the cortex from the underlying cancellous bone. The excavated cavity may be filled with a bone substitute if desired prior to layered wound closure. Note that the graft must not extend into the thick cortex at the diaphyseal/metaphyseal junction. Such extension risks the possibility of a femoral fracture. Generally, the maximal length obtainable is no more than 6 to 7 cm. The graft is placed into the scaphoid as an interposition graft through a volar (Russe) incision in the floor of the flexor carpi radialis tendon sheath and is fixed with a cannulated scaphoid screw. Vascular repairs are end to side to the radial artery and end to end to a vena comitans (see Figure 46.12, *B*).

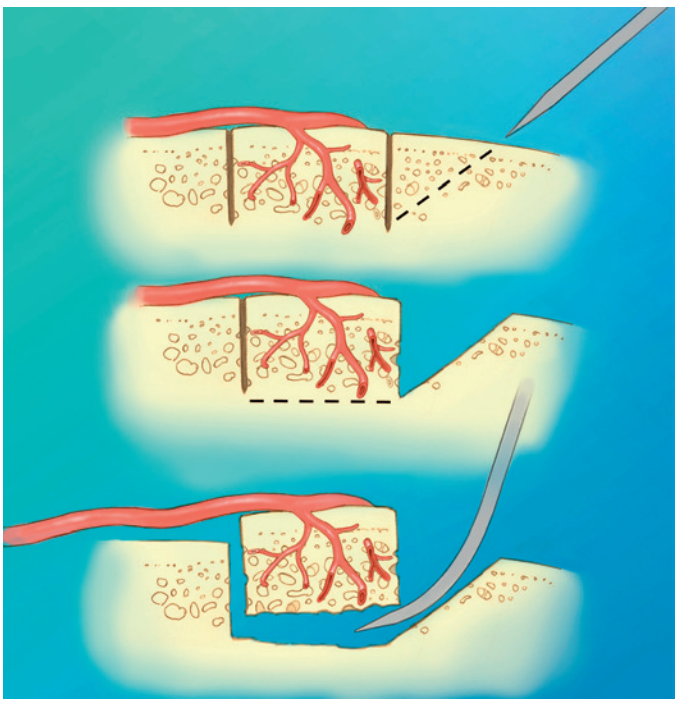

Figure 46.13 Technique of medial femoral condyle bone graft elevation. Removal of a small wedge of bone adjacent to the bone flap permits its elevation without risk of fracture or separation of the cortical from the cancellous bone. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Medial Femoral Condyle Osteochondral Graft Harvest. As stated previously, the common genicular artery and venae comitantes divide into two major periosteal vascular branches at the level of the condylar flare. The transverse branch courses 90 degrees anteriorly from the main pedicle and its longitudinal branch continuation. The transverse branch is directed toward the medial trochlea. It is followed to the proximal knee capsule, which is opened to visualize the trochlea and clearly see the multiple nutrient branches supplying bone and cartilage in this region. Their position marks the target area for harvest. A margin of bone and periosteum bordering the articular cartilage that includes these nutrient branches must be included with the flap. Before the graft is elevated, however, the transverse branch vessels proximal to the graft are mobilized to the proximal condyle as described for MFC bone graft harvest, completing the pedicle exposure. The pedicle vessels are bathed in papaverine or another vasodilator thereafter. In elevating the graft, it is important to minimize its dimensions because of potential donor site morbidity. Some form of preoperative or intraoperative modeling is helpful in this regard. One method described by Burger is the intraoperative molding of methyl methacrylate to the donor site defect.[11] A maximal suggested size is 8 by 12 mm.[58] Either small, sharp osteotomes or a microsagittal saw is used to elevate the bone.

Medial Femoral Condyle Graft Aftercare

All patients will experience discomfort at the donor site postoperatively. In the case of bone and corticoperiosteal flaps, the discomfort is caused primarily by motion of the soft tissues over the extraarticular area of the bone graft harvest. Weight bearing is not painful, but knee flexion and extension may be uncomfortable for up to 6 weeks. Patients begin immediate weight bearing without restrictions on the same day as surgery, although a knee immobilizer is provided for intermittent use at the patient's discretion. The patient is instructed in knee flexion and extension exercises and advised to increase activity as discomfort permits, without specific restrictions.

Donor Site Complications

All clinical reports in the literature to date describe donor site complications to be few and transient. All patients will have medial distal thigh discomfort as described previously. Suture intolerance, seroma, and numbness in the saphenous territory are occasionally seen and have been reported to be transient.[111] The saphenous nerve is vulnerable to injury and must be protected. Only a handful of osteochondral grafts have been

reported in the literature. Although there is certainly potential for patellofemoral problems, care regarding size and location of the graft should make this an uncommon problem. No published reports of femoral fracture have been published, and CT analysis of donor site morphologic characteristics postoperatively has failed to demonstrate any bony concerns.[110] Unpublished cases of femoral fracture have occurred, however, and remain a significant risk if graft harvest extends into the metaphyseal/diaphyseal junction. Safe dimensions of metaphyseal-only bone harvest are as yet not firmly established. Prudence is recommended. Rao found a graft volume of 16.1 cm^3 (range, 2 to 34 cm^3), representing an average condylar volume of 9% (range, 1% to 18%), to be safe.[110]

Radius Pedicle Grafts

Pedicled bone grafts from both the palmar and dorsal radius are widely used for treatment of carpal avascular necrosis and nonunion. These grafts are relatively easily harvested through the same operative field used for carpal exposure, based on arteriovenous pedicles whose position relative to anatomic landmarks (extensor retinaculum and dorsal compartments dorsally, and pronator quadratus palmarly) is constant.

Dorsal Radius Grafts

The blood supply to the distal dorsal radius is robust and constant, provided by a series of longitudinal vessels originating from the radial artery or anterior interosseous vessels that demonstrate consistent spatial relationships to surrounding anatomic landmarks and distal anastomotic vascular connections. The anatomy of the extraosseous and interosseous vascular supply of the distal radius has been described in some detail, including the design of several reverse-flow pedicle grafts applicable to the carpus.[123] Their location allows vascularized bone grafting for Kienböck disease or scaphoid nonunion with minimal if any additional morbidity. Blood flow is provided by a reverse-flow mechanism in both the artery and the venae comitantes (analogous to the radial forearm flap), with demonstrable preservation of flow possible by inclusion of cutaneous islands whether based on the radial artery or posterior division of the anterior interosseous artery. Experimental studies in the canine distal radius have demonstrated that similar reverse-flow pedicle bone grafts have measurable flow immediately after elevation, and marked hyperemia when reevaluated 2 weeks later.[139,140]

DORSAL RADIUS ANATOMY

Four extraosseous vessels contribute nutrient vessels to the distal radius and ulna. They demonstrate consistent spatial relationships to surrounding anatomic landmarks, and supply bone with predictable groups of nutrient arteries (Figure 46.14, *A*). The anterior interosseous artery divides into anterior and posterior divisions proximal to the distal radioulnar joint. The posterior divisions, together with the radial artery, are the primary sources of orthograde blood flow to the dorsal distal radius. The vessels also supply nutrition to soft tissues, making possible fabrication of composite pedicle flaps that include the posterior interosseous nerve, skin, and muscle.[157]

The four vessels supplying nutrient arteries to the dorsal radius are best described by their relationships to the extensor compartments of the wrist and the extensor retinaculum. Two of the vessels are superficial in location, lying on the dorsal surface of the extensor retinaculum between the first and second, and second and third dorsal compartments. At these locations, the retinaculum is adherent to an underlying bony tubercle separating the respective compartments, allowing nutrient vessels to penetrate bone. Because of the location of these arteries, they have been named the 1,2 and 2,3 intercompartmental supraretinacular arteries (1,2 and 2,3 ICSRAs) (see Figure 46.14, *A*).[123]

Two deep vessels also provide nutrient vessels to the dorsal distal radius. They lie on the surface of the radius within the fourth and fifth dorsal compartments. They are consequently named the fourth and fifth extensor compartment arteries (see Figure 46.14).[123]

1,2 Intercompartmental Supraretinacular Artery. The 1,2 ICSRA originates from the radial artery approximately 5 cm proximal to the radiocarpal joint, passing beneath the brachioradialis muscle and tendon to lie on the dorsal surface of the extensor retinaculum (see Figure 14.14, *A*). Distally, the artery enters the anatomic snuffbox to anastomose with the radial artery and/or the radiocarpal arch. Like the other vessels described below, it runs with two venae comitantes and has a distal anastomotic connection, in this case to the radial artery in the anatomic snuffbox. It provides nutrient vessels to the radius through the small tubercle to which the retinaculum attaches between the first and second dorsal compartments. Thus, elevation of the vessel with the underlying bone and ligation of the proximal origin result in creation of a retrograde-flow pedicled vascularized bone flap. The distal anastomotic connection or termination of the 1,2 ICSRA is the "ascending irrigating branch" described by Zaidenberg, used for scaphoid nonunion.[157] Its position superficial to the retinaculum and directly on the bony tubercle between the first and second extensor compartments makes its dissection and use as a vascularized pedicled graft to the scaphoid fairly straightforward. However, its arc of rotation is short, and its nutrient artery branches are small in number and caliber.

2,3 Intercompartmental Supraretinacular Artery. The 2,3 ICSRA originates from the posterior division of the anterior interosseous artery and runs superficial to the extensor retinaculum directly on the dorsal radial tubercle (Lister tubercle) between the second and third dorsal compartments, with a distal anastomotic connection most usually with the dorsal intercarpal arch (see Figure 46.14, *A*). As it passes over the dorsal radial tubercle of the radius, it reliably provides several nutrient branches, allowing it to be used as a retrograde pedicled flap, as well (see Figure 46.14, A). As the pedicle overlies the wrist joint capsule, however, it and the bone graft must be mobilized prior to inspection of the carpus. The more marginally located 1,2 ICSRA and fifth extensor compartment artery (ECA) pedicles are more attractive because they do not have this same issue. We do not routinely use this graft source for this reason.

Fourth Extensor Compartment Artery. The fourth ECA lies directly adjacent to the posterior interosseous nerve on the surface of the radius. It is found within the radial aspect of the floor of the fourth extensor compartment below the extensor digitorum communis tendons (see Figure 46.14, *A*). In some instances, it may lie within the 3,4 intercompartmental septum. It originates from the posterior division of the anterior

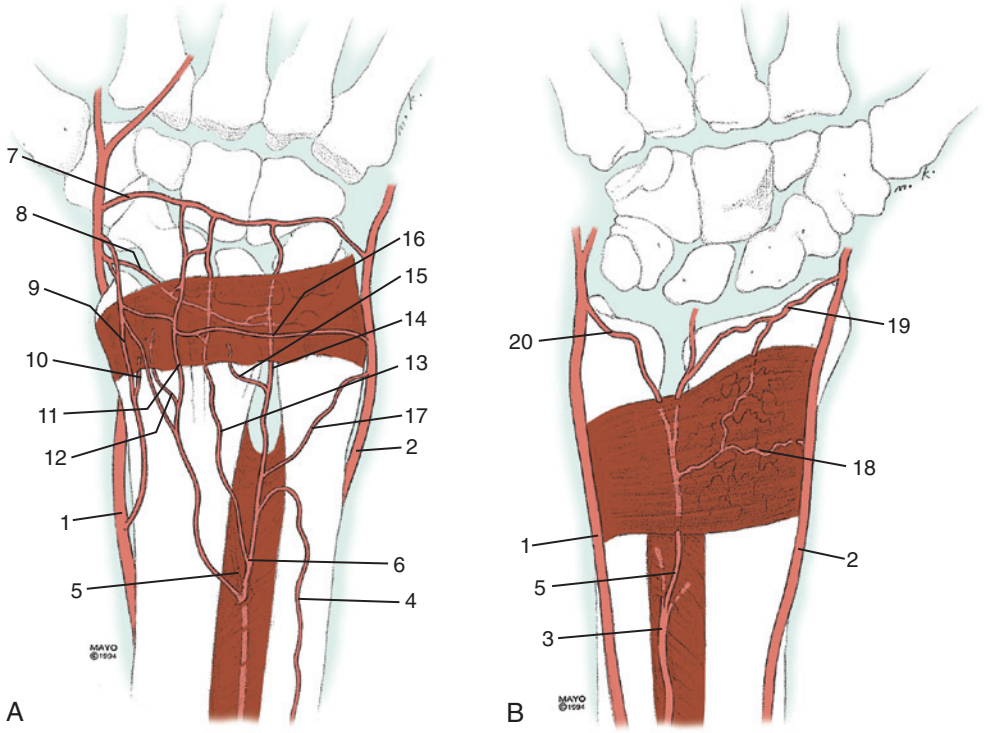

Figure 46.14 Vascular anatomy of the distal radius. **A,** Dorsal radius blood supply. Two superficial vessels lie on the surface of the extensor retinaculum (the 1,2 intercompartmental supraretinacular artery [ICSRA; 9] and the 2,3 ICSRA [11]). Two deep vessels lie directly on the radius beneath the tendons of the fourth extensor compartment (13) and the fifth extensor compartment (14). **B,** The palmar blood supply is provided by two arches connecting the anterior interosseous vessels and the radial artery (palmar carpal arch [19] and palmar metaphyseal arch [18]). 1, radial artery; 2, ulnar artery; 3, anterior interosseous artery; 4, posterior interosseous artery; 5, anterior division of anterior interosseous artery; 6, posterior division of anterior interosseous artery; 7, dorsal intercarpal arch; 8, dorsal radiocarpal arch; 9, 1,2 ICSRA; 10, second compartment branch of 1,2 ICSRA; 11, 2,3 ICSRA; 12, second compartment branch of 2,3 ICSRA; 13, fourth extensor compartment artery (ECA); 14, fifth ECA; 15, fourth compartment branch of fifth ECA; 16, dorsal supraretinacular arch; 17, oblique dorsal artery of the distal ulna; 18, palmar metaphyseal arch; 19, radial portion of palmar radiocarpal arch; 20, ulnar portion of palmar radiocarpal arch. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

interosseous artery, with a distal anastomotic connection to the dorsal intercarpal arch. It is the source of numerous nutrient vessels to the floor of the fourth compartment.

Fifth Extensor Compartment Artery. The fifth ECA is generally the largest of all the dorsal vessels and is located in the radial floor of the fifth extensor compartment, or at times partially in the intercompartmental septum between the fourth and fifth compartments (see Figure 46.14, *A*).[123] Its origin and distal anastomotic connections are the same as those of the fourth ECA. It generally overlies the distal radioulnar joint and most frequently has no nutrient branches to the radius. It is quite useful, however, as a large conduit of retrograde flow from the intercarpal arch. Ligation of the posterior division of the anterior interosseous artery proximally allows this blood flow to turn and flow in an antegrade direction through the fourth ECA, creating a vascularized bone graft with a long pedicle and a wide arc of coverage that can reach anywhere in the carpus.

Specific Dorsal Radius Pedicle Grafts. Although reverse-flow pedicle grafts may be taken based on any of the four dorsal vessels described above, the two grafts that are most practical in clinical application are the 1,2 ICSRA graft used for scaphoid nonunions and the 5 plus 4 ECA graft, which may be placed within a necrotic lunate in Kienböck disease.[18,101,123] The 5 plus 4 ECA graft may reach anywhere in the carpus and has been used for a number of purposes, including avascular necrosis (AVN) of the capitate.[50]

1,2 Intercompartmental Supraretinacular Artery Graft. Grafts based on a retrograde 1,2 ICSRA pedicle were originally described by Zaidenberg for scaphoid nonunion.[157] Because the vessel lies superficial to the extensor retinaculum, it is easily visible after retraction of the skin and subcutaneous tissue. It is useful only for scaphoid nonunions because it cannot reach other carpal bones because of its limited arc of rotation.[123]

Harvest technique. The extremity is elevated for exsanguination, and a tourniquet is inflated. Use of an Esmarch bandage before tourniquet elevation will make vessel visualization more difficult. The bone graft donor site and scaphoid are exposed through a gently curvilinear dorsoradial incision paralleling the course of the extensor pollicis longus tendon (Figure 46.15, *A*). Branches of the superficial radial nerve are identified and protected. Once the subcutaneous tissues are gently raised from the retinaculum, the 1,2 ICSRA and venae comitantes are visualized on the surface of the extensor retinaculum. They are dissected carefully toward their distal anastomosis with the radial artery and venae comitantes in the floor of the anatomic snuffbox. A vessel loop is placed around the distally based pedicle to protect it during later dissection. Next, the first and second dorsal compartments are opened at the graft elevation site to create a cuff

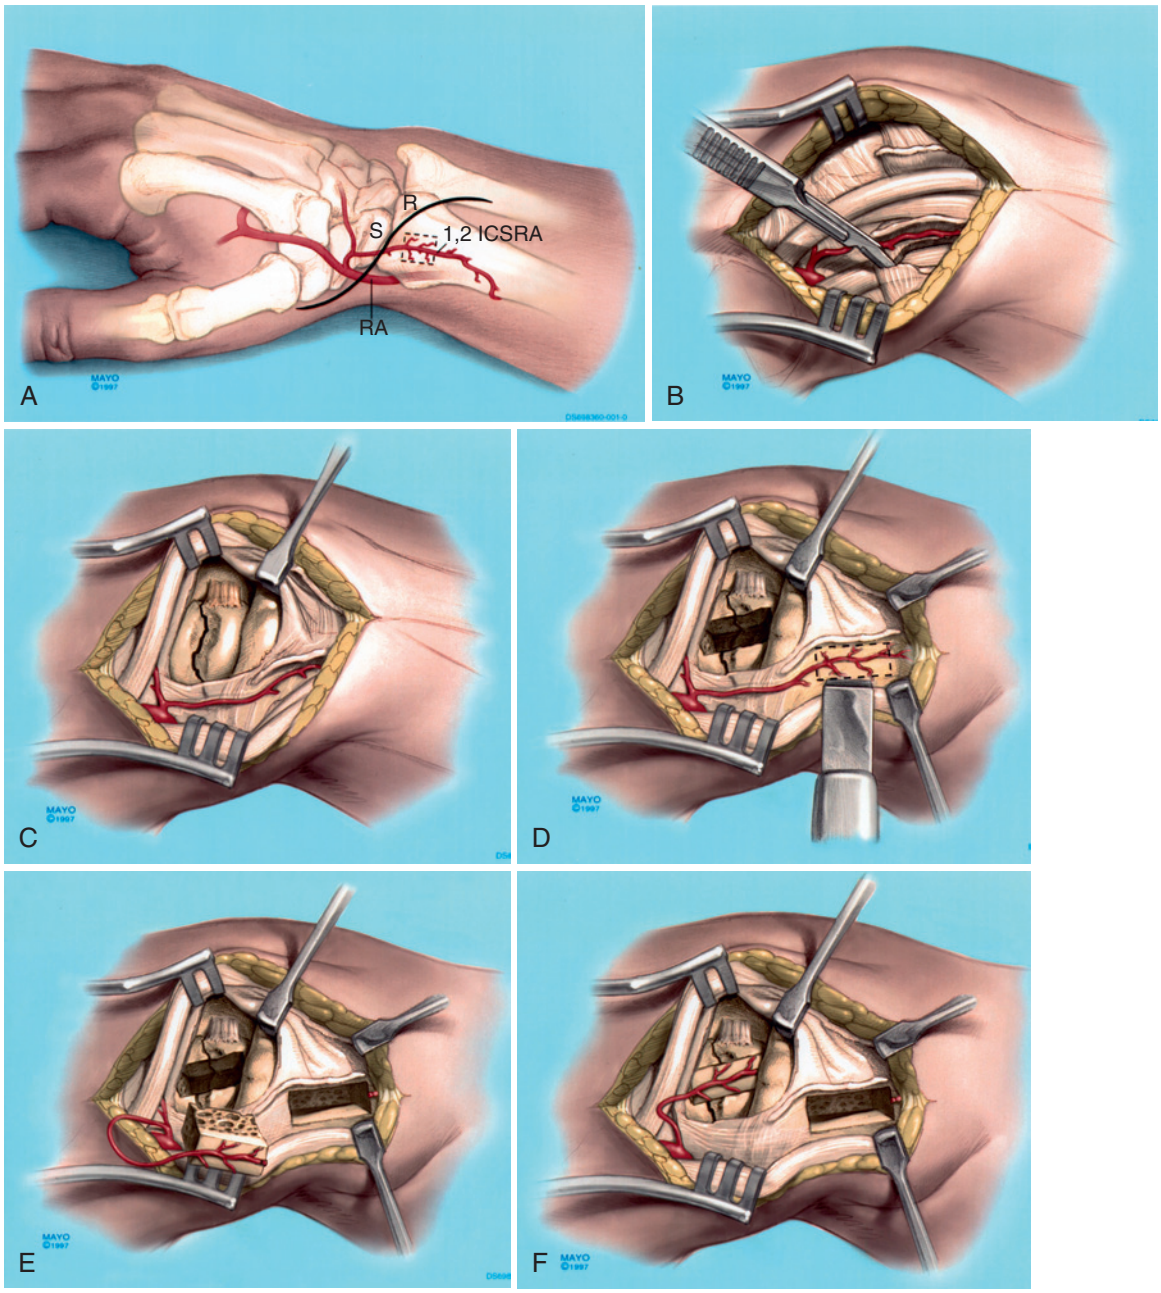

Figure 46.15 Treatment of scaphoid nonunion with a 1,2 intercompartmental supraretinacular artery (ICSRA) pedicle bone graft. **A,** A curvilinear dorsal radial incision is used for exposure of the scaphoid and the 1,2 ICSRA. **B,** The 1,2 ICSRA is identified on the surface of the extensor retinaculum. The first and second dorsal compartments are opened on either side of the vessels. **C,** The scaphoid nonunion is visualized after the vessel is identified and protected. **D,** A trough for a dorsal inlay graft has been prepared, spanning the nonunion. A distal radius graft including the 1,2 ICSRA is outlined. **E,** The graft is raised and transposed to the nonunion site. **F,** The graft is placed as a dorsal inlay. *R*, Radius; *RA*, radial artery; *S*, scaphoid. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

of retinaculum containing the vessels and their nutrient branches (see Figure 46.15, *B*). The center of the graft should be 1.5 cm proximal to the radiocarpal joint to include the nutrient vessels.

Scaphoid preparation. Before the graft is elevated, a transverse dorsoradial capsulotomy is made to expose the nonunion site (see Fig 46.15, *C*). In most cases, this will be a proximal pole fracture in which a dorsal inlay graft is most appropriate. If this is the case, a 2- to 3-mm bur or small, sharp osteotomes are used to prepare a slot to receive the bone graft, curetting any fibrous tissue from the nonunion site (see Figure 46.15, *D*). The slot will span the nonunion, unless the proximal pole fragment is very small, in which case the graft is shaped to lie within the concavity of the proximal pole fragment and slot into the distal fragment. Alternatively, a wedge graft may be used to expand the scaphoid length through the radial approach. In some cases, a limited radial styloidectomy may improve exposure, but it is not generally necessary. For either method, the size and orientation of the bone graft are carefully determined prior to graft elevation.

Placement of the dorsal inlay graft. Most of the cases in which vascularized grafts have been used have been proximal pole nonunions. In these cases, the use of a dorsal inlay graft is generally appropriate, allowing the graft to bridge the nonunion, facilitating stability and early union.

Preparation of the nonunion site should be performed following pedicle dissection but prior to graft elevation, as described previously. Careful inspection of the midcarpal and radiocarpal joint surfaces of the scaphoid is mandatory to prevent articular surface injury during creation of the trough. If the proximal pole fragment is very small, the bone graft is placed within it rather than fitted into a dorsal slot. The graft is removed from the radius, outlining the desired shape using small, sharp osteotomes and protecting the distally based pedicle. The proximal origin of the 1,2 ICSRA may be ligated or cauterized with a bipolar forceps. The graft is pried from the metaphyseal bone using an osteotome placed in the proximal cut at the desired depth (≈1 cm) (see Figure 46.15, *E*). Prior to placement of the graft, the scaphoid is stabilized with a cannulated scaphoid screw placed antegrade from the proximal pole. The graft is placed and carefully reshaped as needed so that it can be placed snugly in the slot with sufficient press-fit interference to maintain stability (see Figure 46.15, *F*).

Once the scaphoid is prepared, a graft of appropriate dimension, including the vessels and cuff of retinaculum between the first and second compartments, is raised. The location of harvest is positioned to include the nutrient vessels, centered a mean 15 mm from the radiocarpal joint margin.[123] The 1,2 ICSRA pedicle is ligated proximal to the graft. Next, the vessels are meticulously dissected subperiosteally distal to the graft to separate them from the radial styloid and joint capsule. To improve the arc of rotation, the pedicle may be dissected to its distal radial artery anastomosis. With the vessels mobilized, the graft is carefully separated from the radius with sharp osteotomes. The cancellous bone is fragile, requiring attention to detail to prevent its fracture as the graft is levered out from the radius. The graft is transposed beneath the radial wrist extensor tendons to reach the nonunion site, where it is gently impacted into position. When used as a dorsal inlay graft, the vessels and cortical bone are positioned on the dorsal surface of the scaphoid. For use as a wedge graft, the cortical bone is positioned palmarly.

5 plus 4 Extensor Compartment Artery Graft. A fourth compartment artery graft based on retrograde flow from the intercarpal arch may also be useful in Kienböck disease.[101] Its arc of rotation consistently reaches the lunate, and the nutrient arteries are numerous and large. The fourth ECA vessel is quite small distal to the radiocarpal joint in many patients. As a result, in most cases we now prefer to use the fifth ECA as the source of retrograde blood flow, with antegrade flow to the fourth compartment vessel nutrient branches via their common origin (Figure 46.16). The large diameter of the fifth ECA provides optimal blood flow to the bone graft, and straightening of the "Y"-bifurcation creates a very long pedicle twice the length of each vessel. This allows it to reach anywhere in the carpus, while easily protecting it from injury during wrist capsulotomy and carpal bone exposure due to its ulnar location. In nearly every wrist studied by Sheetz, the fifth ECA had no nutrient branches to bone.[123]

Harvest technique for the 5 plus 4 extensor compartment artery graft. Bone graft harvest requires identification of the fifth ECA by opening the fifth dorsal compartment (see Figure 46.16, *A* to *F*). A dorsal wrist incision is made to expose the extensor retinaculum. A single retinacular flap is created for wrist capsule exposure, radially based, with its initial opening directly overlying the fifth compartment (see Figure 46.16, *A*). The fifth ECA and accompanying veins are easily visualized on the radial aspect of the compartment with retraction of the extensor digiti minimi tendon, lying adjacent to the septum separating the fourth and fifth compartments and occasionally lying within the septum. Its distal anastomotic connections must be meticulously protected. The artery is traced proximally from the intercarpal arch to its origin from the anterior interosseous artery. During this mobilization, the oblique dorsal artery to the distal ulna and the communicating branch with the posterior interosseous artery must be ligated and divided. Proximal to the distal radioulnar joint, the origin of the fourth ECA should be identified for inclusion with the distally based fifth ECA pedicle (see Figure 46.16, *B*). At this point, the vascular pedicle overlying the joint capsule is protected with a vessel loop and an arthrotomy made to expose the carpal pathologic condition. Once the need for a graft is verified, a bone graft is elevated overlying the fourth ECA, including its nutrient artery branches, which enter the cortex a mean 11 mm proximal to the joint (see Figure 46.16, *C*). This creates a lengthy pedicle with retrograde flow from the fifth ECA, continuing in an orthograde fashion into the fourth ECA. The bone graft is then raised.

Graft Insetting for the Lunate. Once the graft is elevated and retracted distal to the lunate on its pedicle, a capsulotomy is performed to expose the joint using Berger's dorsal ligament-sparing approach[4] (see Figure 46.16, *C*). The lunate is inspected. If it is not fragmented, vascularized bone grafting is feasible. Necrotic bone is removed with the aid of direct inspection and an image intensifier, leaving a shell of intact cartilage and subchondral bone through a dorsal opening. This opening is placed to avoid injury to the dorsal scapholunate or lunotriquetral ligaments. The lunate may be expanded gently to normal dimensions if it has collapsed using a small elevator (see Figure 46.16, *D*). The bone graft is placed into the lunate, orienting the pedicle vertically and the cortical surface on which it lies arranged to serve as a proximodistally oriented strut to maintain lunate height during revascularization (see Figure 46.16, *E* and *F*). No internal fixation is necessary provided the lunate is not fractured and the graft is carefully shaped and impacted into the bone.

Palmar Radius Pedicle Grafts

ANATOMY

Palmar radius grafts have been described based on a pronator quadratus pedicle (palmar metaphyseal arch) or palmar radiocarpal arch.[9,87] We have found the pronator flap to have essentially no significant nutrient blood supply to the radius and cannot recommend this flap. The palmar radiocarpal arch, however, has anastomotic connections to the ulnar artery, radial artery, and anterior division of the anterior interosseous artery (see Figure 46.14, *B*).

Harvest of Palmar Radius Bone Grafts to Reach Either the Scaphoid or the Lunate. If inflow is based on the anterior interosseous

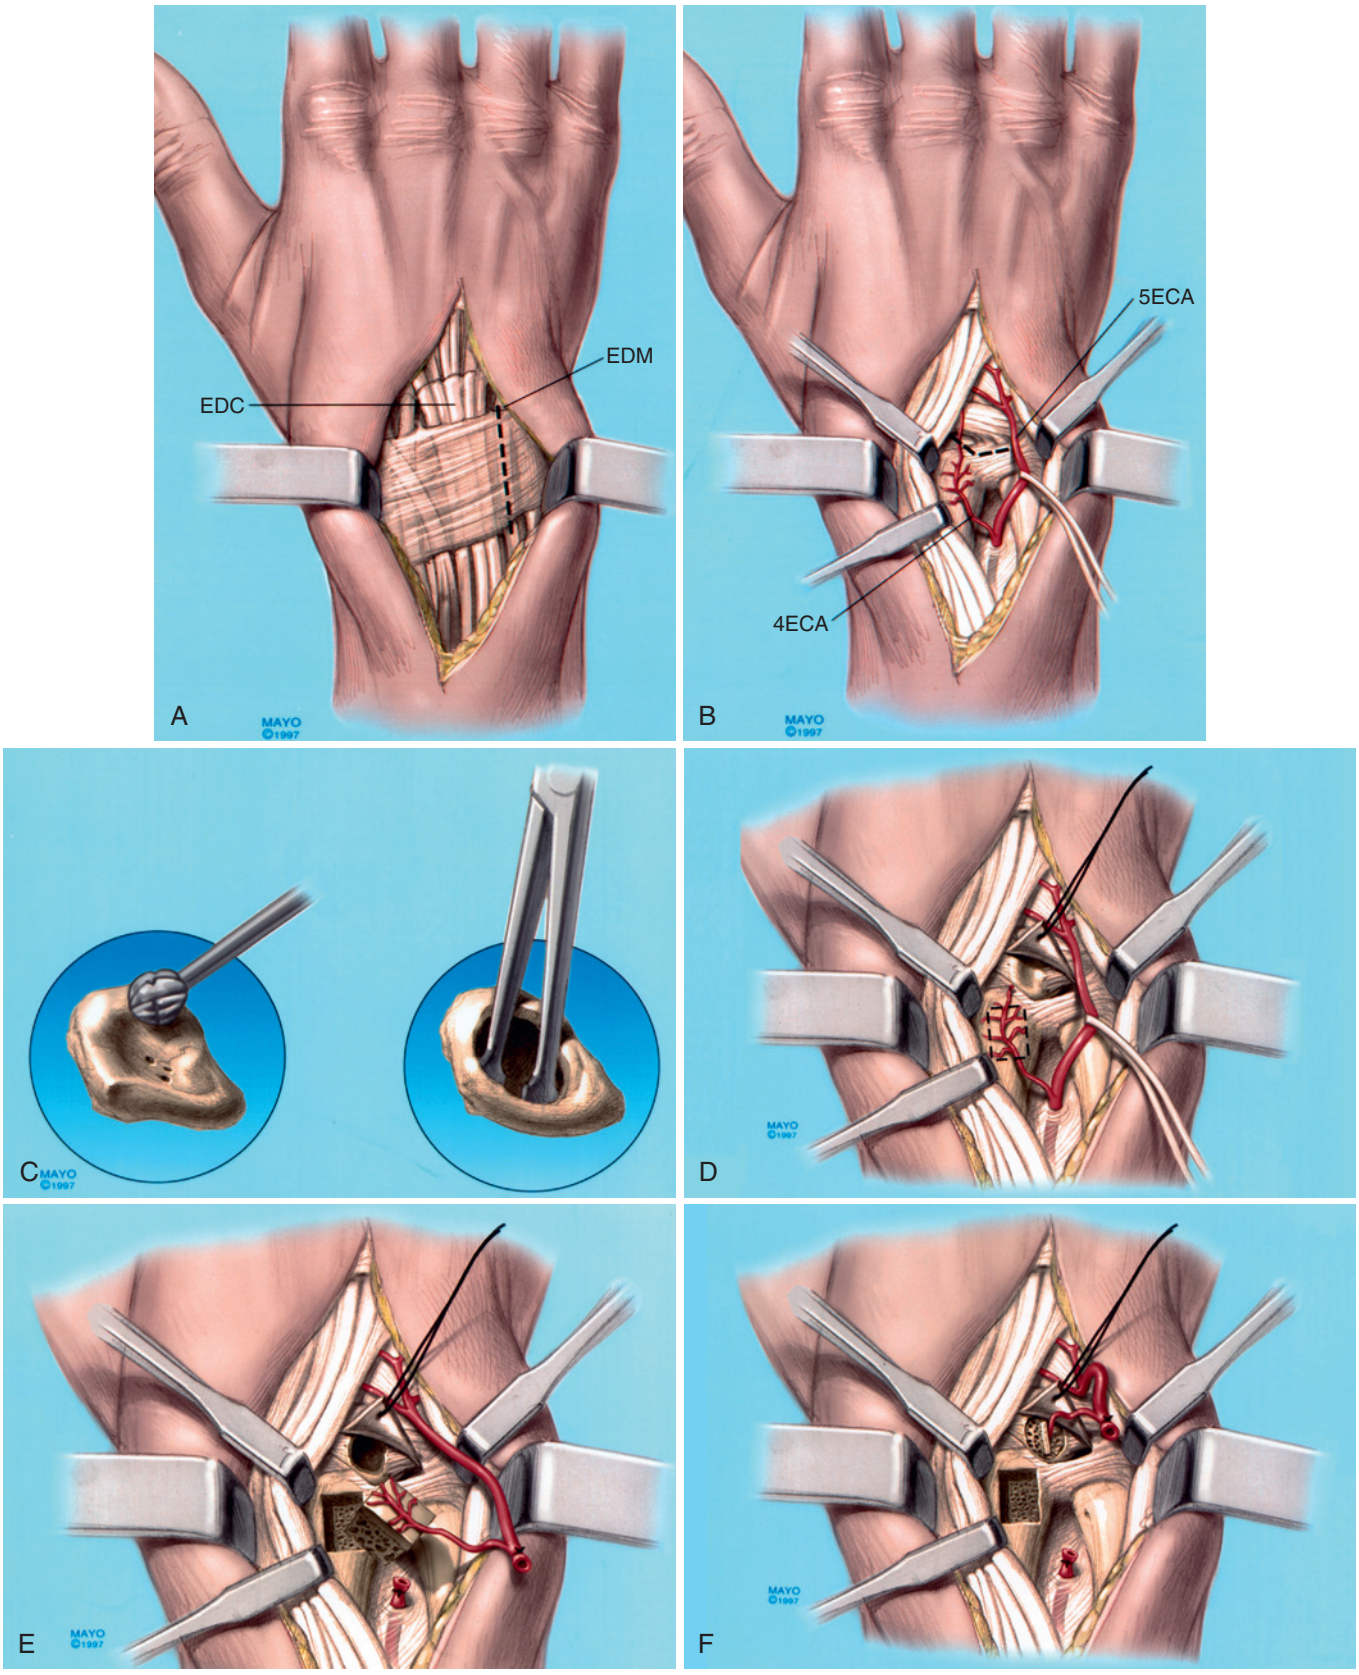

Figure 46.16 Vascularized graft for Kienbock disease using the 5 plus 4 extensor compartment artery (ECA) pedicle graft. **A,** The fifth ECA is exposed by opening the fifth extensor compartment. **B,** The fifth ECA is traced proximally to its origin from the posterior division of the anterior interosseous artery. A radial based retinacular flap exposes the fourth compartment tendons, which are retracted radially to expose the fourth ECA. A ligament sparing capsulotomy is performed, protecting the fifth ECA and exposing the lunate. **C,** The lunate necrotic bone is removed with a burr and expanded. **D,** The site of the bone graft including the fourth ECA. **E,** The graft is elevated, providing retrograde blood flow through the fifth ECA into the fourth ECA with attached radius bone. **F,** The graft is inserted vertically into the lunate. *EDC,* Extensor digitorum communis; *EDM,* extensor digiti minimi. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

artery, the graft must be harvested from the radialmost aspect of the palmar radius to provide an adequate pedicle to reach the lunate. When a radial-based pedicle supplied by the palmar radiocarpal branch of the radial artery is used, the bone is harvested from the ulnarmost aspect of the palmar distal radius for placement in the scaphoid.[123]

Although the location of the graft places the palmar radiocarpal ligaments and articular surfaces at risk, there is a robust supply of nutrient vessels to the radius from the palmar radiocarpal arch.[123] Graft placement also requires a palmar carpal exposure, of necessity through important radiocarpal ligaments. This limits exposure and may risk radiocarpal instability postoperatively. The pedicle is short, requiring careful dissection and accurate placement of the graft harvest if the carpal nonunion or AVN site is to be reached and reconstructed. Nevertheless, excellent clinical results have been reported with this flap.[22,44,89]

Technique. An extensile exposure is recommended to the palmar distal radius in the interval between the radial artery and flexor carpi radialis.[87] For scaphoid placement, the scaphoid is first exposed and prepared through a standard Russe approach. The graft is raised by incising the distal 1 cm of the pronator quadratus and elevating a 1 cm–wide cuff of tissue from the ulnar aspect of the radius, to include a bone graft directly adjacent to the sigmoid notch and lunate facet of the distal radius. At the ulnar border of the graft, contributions to the radiocarpal arch from the anterior interosseous and ulnar arteries are ligated and divided. The pedicle is progressively raised from the radius, and the graft rotated into the prepared scaphoid. For lunate placement, the graft is placed radially and distally, with the base of the pedicle at the ulnar border of the radius to provide inflow from the anterior interosseous and ulnar arteries.

Results. The proximity of the graft to articular surfaces and radiocarpal ligaments requires great care in graft elevation and harvest. Despite these difficulties, Mathoulin has reported excellent results for both scaphoid nonunion and Kienböck disease with palmar radius pedicle graft. He reported union in 96% of 112 scaphoid nonunion cases and healing in 17 of 22 patients with Kienböck disease.[86] Another recent report found a healing rate of only 73%[65]; only two of the cases were proximal pole fractures with avascular necrosis, and neither united. Complications were many, including two articular radius fractures occurring during graft harvest. Five patients had subsequent surgeries, including four proximal row carpectomies and one conventional bone graft.[65]

OTHER VASCULARIZED GRAFTS

Rib

The rib, although used in early reports,[91] has not been widely used for upper extremity reconstruction because of its membranous, weak structure and curved shape. When based on its anterior internal mammary or supracostal arterial blood supply, only periosteal vessels are supplied.[51] The posterior rib graft, which includes its nutrient artery, requires ligation of the dorsal branch of the posterior intercostal artery. Another alternative, however, is the use of an osteomuscular composite graft including one or more lower slips of the serratus anterior, which provide a periosteal supply to the ribs. Provided nonadjacent ribs are selected, a double-rib graft may be used for long bone reconstruction. This prevents chest wall instability and allows stable reconstruction and soft tissue coverage in cases of segmental bone loss as an alternative to the fibula. Because the entire thoracodorsal system may be included, composite flaps including the latissimus dorsi, scapular, and parascapular skin are also possible on a single vascular pedicle (Figure 46.17, *A* to *D*).[83] It may also be used as a pedicle graft for clavicular reconstruction.

Scapula

Scapular free flaps may be based on the lateral border (lateral scapular osteocutaneous flap) or on the medial ridge of the scapula. The lateral scapular flap is based on the circumflex scapular circulation and is usually taken as a composite flap. The dissection requires division of the teres major and minor, resulting in some shoulder impairment. The medial flap, based on the same pedicle, depends on the periosteal blood supply for bone nutrition. No donor site morbidity has been reported, although scapular winging from division of the serratus anterior is a likely potential problem. The utility of the flaps as composite flaps in the hand and forearm has been well demonstrated.

Humerus

Portions of the humeral diaphysis can be taken at the lateral intermuscular septum as part of an osteocutaneous lateral arm flap.[72] Periosteal flaps may also be raised from the humerus.[128]

Pisiform

The pisiform receives its blood supply from the ulnar artery via its deep volar and dorsal carpal branches.[94] The dorsal carpal branch is the major vessel, with at least two descending branches entering the proximal tip of the bone. This allows elevation of a pedicled pisiform graft, which may be used to replace the lunate,[32] or, when placed as a decorticated graft with the lunate, to revascularize it.[6] A recent series of 21 Kienböck disease patients treated with lunate excision and pisiform replacement reported preservation of preoperative ranges of motion and high patient satisfaction with wrist function. Over the longer term, however, carpal collapse and resultant osteoarthritis were seen in 50% of the patients.[21]

Second Metacarpal

A small amount of bone may be raised as a vascularized graft from the first or second metacarpal, based on the first dorsal metacarpal artery. The second metacarpal may be harvested entirely for skeletal thumb reconstruction associated with destruction of the index finger, or partially as an elective procedure for carpal pathologic conditions. The arc of rotation allows transposition within the radial side of the hand, for applications in the thumb and carpus.[109] Dorsal proximal metaphyseal grafts have been used successfully for scaphoid nonunions and Kienböck disease.[120,156]

Manufactured Bone Grafts

Another future possibility is the creation of pedicled vascularized bone grafts in desired shapes. This has been demonstrated in the laboratory by implantation of vascular bundles into bone fragments or demineralized bone matrix.[99,151] When

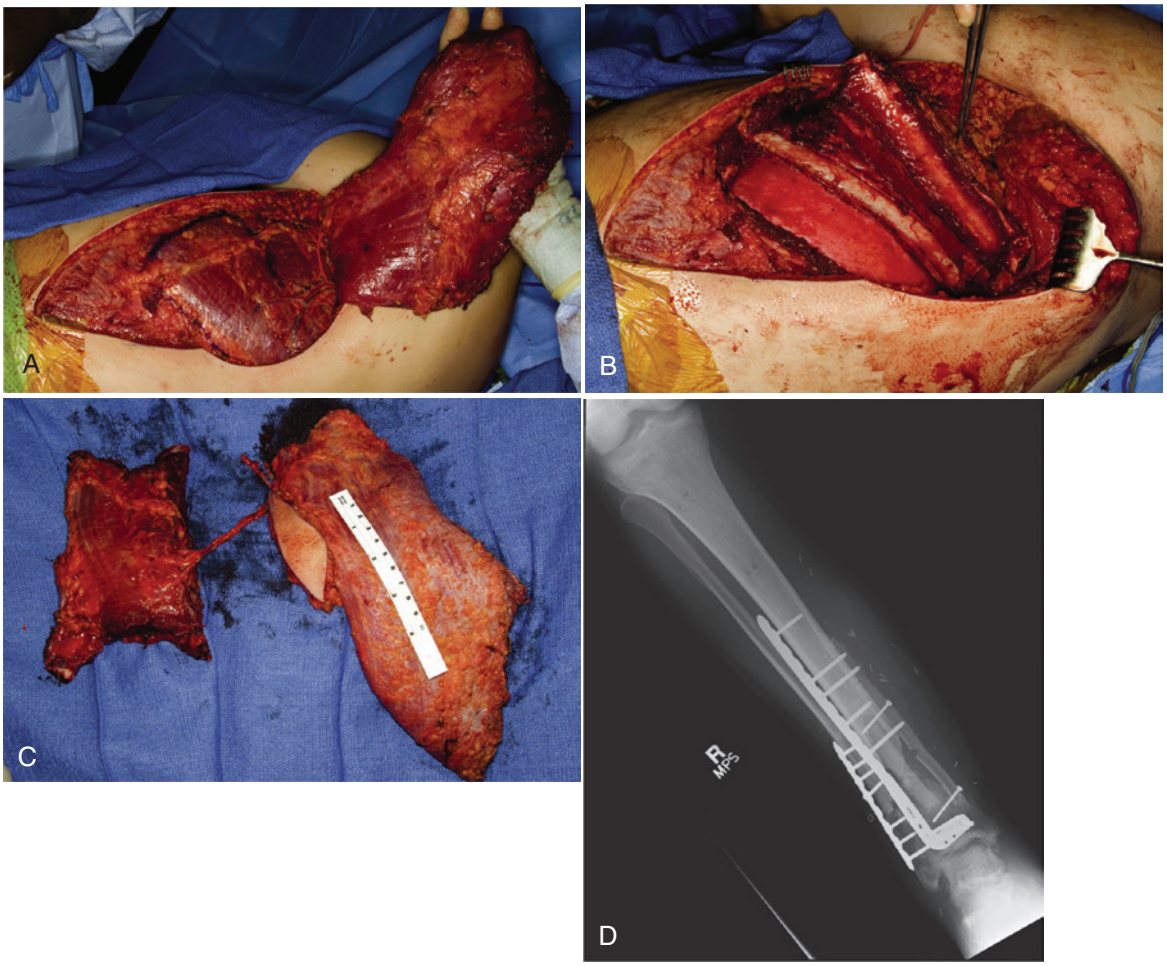

Figure 46.17 A composite rib–serratus anterior–latissimus dorsi osteomuscular flap. **A,** The latissimus dorsi has been elevated, and the inferior portion of the serratus identified for elevation, to include two nonadjacent ribs. **B,** Inferior surface of rib/serratus flap, with one intact rib spanning the donor site. **C,** The composite rib/serratus and latissimus dorsi flap based on a common thoracodorsal artery and vein pedicle. **D,** Flap transferred to reconstruct a combined bone and soft tissue defect with ankle arthrodesis. Similar methods are useful in the upper extremity.

arteriovenous pedicles are enclosed in titanium or hydroxyapatite or polyethylene chambers, or wrapped with vascularized periosteum in vivo, bone formation and remodeling occur in the shape of the chamber, along with microangiographic evidence of a sprouting vascular network that may occur only 4 weeks later.[99] Similarly, Khouri has demonstrated the ability to transform muscle into bone of any desired shape using silicone rubber molds containing the recently purified osteoinductive factor osteogenin, when coated with demineralized bone matrix.[75] These findings support the concept of creating a preformed vascularized bone graft to reconstruct segmental bone defects.[99] Demonstration of clinical applicability remains to be performed.

Allogeneic Bone Grafts

The ability to safely restore viability of cryopreserved structural allografts or maintain long-term viability of allogeneic transplanted bone would be an important advance in reconstructive surgery that might in the future obviate other means of long bone reconstruction. Expendable autogenous sources for large vascularized bone segments are limited, primarily to the fibula and iliac crest. Both are generally poor structural replacements for missing metaphyseal or diaphyseal bone, particularly in the humerus, femur, and tibia, due to gross size mismatch. In these locations, load sharing by rigid internal fixation, external fixators, or allograft plus autograft composites, or a protracted period of no weight bearing and/or bracing, is necessary if the risk of stress fracture is to be minimized.[48] An ideal replacement for such large-segment bone and joint defects would be a living bone and/or joint allogeneic transplant, or a "revitalized" cryopreserved allograft revascularized and repopulated with living bone. Not only would such allogeneic bone match the dimensions and structural property of the missing tissue, but it would also have the same enhanced healing and remodeling potential as a vascularized autogenous bone graft. Survival of musculoskeletal allotransplants at present requires long-term immunosuppression, with a significant risk of opportunistic infections, malignant disease, and organ toxicity that is difficult to justify in transplantations not critical to preserve life. It is not surprising, therefore, that living musculoskeletal allografts have been seldom used clinically, and that late failure due to rejection or infection has been the rule.[27]

Characterization of the immune response to vascularized bone allografts may subsequently allow more specific modification of the host response and/or graft tissue. The use of surgical angiogenesis to revitalize cryopreserved allograft bone[90,146] or replace allogeneic circulation of living allotransplanted bone with recipient-derived autogenous vessels[40,79,80,107,112,145] is an alternative to conventional immune modulation that may provide a new source for living bone in future clinical practice.

Recipient Site

Clavicle

Although most clavicular fracture nonunions are successfully treated with conventional grafting and plate fixation, at times, bone loss, infection, or irradiation-induced pathologic fracture makes union challenging.[36] Partial excision of the clavicle, often advocated in this situation, may result in persisting pain, weakness, sensation of instability, and brachial plexopathy. Because of the thin soft tissue envelope covering the clavicle, bulky bone and/or soft tissue reconstruction is preferentially avoided. Several methods of surgical reconstruction have been described. In cases involving failed prior plating or infection, conventional nonvascularized iliac tricortical bone grafting may not be successful, especially if a significant defect remains in the clavicle. Microvascular fibular transfer combined with autografting has been reported as an appropriate treatment option for difficult nonunions associated with previously irradiated long bones[31]; a high failure rate for the clavicular site has been shown, however. Other biologic options include the vascularized transfer of a rib as a composite flap, including the serratus anterior and/or latissimus dorsi, or the use of free corticoperiosteal grafts to envelop and revitalize the nonunion site.[36]

Because of their osteogenic capability, vascularized periosteal grafts have considerable potential for the reconstruction of bone defects. The transfer of free vascularized corticoperiosteal bone flaps seems to be ideally suited for radiation-induced fractures or chronic nonunions of the clavicle without substantial bone loss but with a poor chance of healing on their own. Successful use of periosteal flaps from the medial femoral condyle has been reported, with much higher success rates than other methods.[36] The flap is thin and can be shaped according to the reconstructive requirements without compromising its blood supply. It can be wrapped around the clavicle without visible bulk, thereby avoiding further stress on the previously irradiated overlying skin. Rapid subperiosteal new bone and improved local blood flow both serve to correct many of the changes attributed to radiation necrosis of bone. Although microvascular expertise is necessary, flap exposure and elevation are straightforward. The dual blood supply from the medial superior and descending genicular vessels enables identification of vessels of sufficient diameter and pedicle length for reliable microsurgical anastomoses. Improved healing over other methods has been demonstrated.[36]

Vascular connections are most easily accomplished by direct end-to-end anastomoses to the thoracoacromial trunk artery and cephalic vein. A corticoperiosteal flap raised from the medial femoral condyle will envelop at least three quarters of the bone circumference and span the nonunion site, leaving sufficient room for plate-and-screw stabilization on the remaining exposed bone surface. Additional cancellous bone graft may be used beneath the periosteal flap.

Shoulder and Humerus

Proximal humerus resections are reconstructive challenges, particularly when tumor resection results in loss of the rotator cuff and/or deltoid tissue. Preservation of glenohumeral joint function may be possible with fibular free flaps, including the femoral head with its suspension from the scapula and the reattachment of these muscles. A vascularized fibular flap including the fibular head and physis has the potential to provide longitudinal growth as well as partial joint function, an important consideration in children. Deficient soft tissue in adults favors a glenohumeral arthrodesis, providing the patient with very satisfactory upper limb function.[143] Arthrodesis after segmental resection of the proximal humerus is best accomplished with an allograft/fibula construct, in the authors' experience[112] (see Figure 46.8), placing the fibula obliquely from interior glenoid to humerus. Fixation with lag screws proximally and distally requires a shoulder spica cast for stabilization, which is unnecessary with plate-and-screw fixation.

When a fibular segment is used for humeral shaft reconstruction, stability is also an important issue. Bone fixation of a fibular graft is best performed with plate-and-screw fixation, with a long compression plate spanning the humeral defect. The graft may be placed as an interposition graft in the defect, doweled into the proximal and distal humerus when possible (see Figure 46.9).[112] Alternatively, reconstruction with an allograft interposition graft and an onlay fibula spanning the reconstructed segment provides enhanced stability. Vascular anastomoses are straightforward because the brachial vessels lie adjacent to the bone. End-to-side anastomosis to the brachial artery and end-to-end repair to the cephalic vein or a brachial vena comitans is preferred in most cases.

Forearm

Bone stabilization with rigid internal fixation is relatively easily obtained. In cases of massive bone loss of both forearm bones, creating a one-bone forearm may be the best solution, placing the fibula between the proximal ulna and distal radius. Alternatively, both bones may be reconstructed with a double-barrel graft or dual fibular grafts. Positioning of the fibula may be either orthograde or retrograde, depending on the optimal location for vessel approximation. Fixation with dual plating at either end is reasonable. Vascular anastomoses to radial or ulnar vessels are easily performed, usually as end-to-side arterial anastomoses. The venae comitantes or superficial (cephalic or basilic) veins are satisfactory for end-to-end anastomosis. A long-arm cast is maintained until radiographic signs of union occur.

Reconstruction of the radius alone, commonly for giant cell tumor, is also successfully accomplished with fibular grafts. If the distal radius must be resected, one has the alternative of performing a wrist arthrodesis or attempting to spare some carpal motion. In the latter case, in which the incorporation of the proximal fibular head and its articular cartilage is needed, use of the anterior tibial artery pedicle rather than a peroneal artery pedicle is required to maintain circulation to the head and neck of the fibula.[61] The procedure is technically more difficult, and results in carpal subluxation and arthritic changes in a substantial number of cases (5 of 12 patients in a recent series).[20] Alternatively, it is the authors' preference to use a fibular diaphyseal segment (the peroneal pedicle). Either a

complete wrist arthrodesis with a standard arthrodesis plate is performed or a procedure is done with fusion to the scaphoid and lunate only, permitting some midcarpal mobility.[64] Most commonly in these cases, the ulna is intact, and a bridging plate is not necessary. Two shorter proximal and distal plates are used instead.

Recalcitrant forearm nonunions with minimal bone loss are successfully treated with corticoperiosteal flap envelopment, as described above for the clavicle.[25]

Wrist and Hand

Vascularized bone grafts have demonstrated their utility in the treatment of carpal pathologic conditions. These include difficult scaphoid nonunions of the proximal pole or associated with avascular necrosis and bone loss producing a humpback deformity. The grafts have also been effective in the treatment of Kienböck disease. Pedicled grafts from the adjacent dorsal or palmar radius, pisiform, ulna, or metacarpals have been described and used for this purpose. Pedicled grafts allow harvest of the vascularized bone graft and preparation of the recipient site through a single incision. Increasingly, free microvascular bone flaps, most commonly from the medial femoral condyle, are demonstrating their usefulness, as well.[66] Because the exposure must not damage the vascular pedicle or its anastomotic connections, pedicle preparation precedes preparation of the recipient site. Free bone flap vascular anastomoses may be made to the radial artery from end to side. Graft placement and stabilization are carefully planned in advance. Recent evidence suggests that local pedicle flaps are appropriate in scaphoid nonunion with or without avascular necrosis, so long as the scaphoid dimensions and carpal alignment remain normal.[18] A humpback deformity with carpal collapse requires a substantial interposition graft. Although it may indeed be possible to use a larger distal radius graft to correct the deformity and resultant carpal instability,[44] the authors favor a stronger, larger graft from the medial femoral condyle. An injury with small proximal pole fragments, particularly when fragmented or shell-like, or an irreparable lunate articular cartilage injury has been treated with a salvage procedure. New developments using osteoarticular flaps from the distal femur appear promising. They enable partial replacement of the proximal aspect of either bone, including the articular cartilage and strong subchondral bone, with a radius of curvature closely matched to that of the normal contours.[58]

Results

Scaphoid

Vascularized bone grafting has been applied to the scaphoid in an effort to improve the results of treatment of nonunion. Roy-Camille used the palmar tubercle of the scaphoid on an abductor pollicis brevis pedicle in 1965.[113] Grafts from the palmar distal radius based on a pronator quadratus pedicle resulted in successful treatment of 13 nonunions in two series,[9,74] and palmar grafts based on the palmar radiocarpal arch have been similarly effective in cases with AVN.[88] Zaidenberg reported successful results with a dorsal reverse-flow pedicle graft from the distal radius in 11 cases,[157] using the vessel subsequently described as the 1,2 ICSRA.[123] Our initial experience was similar, with successful healing in 15 patients with established scaphoid nonunions.[87] The time to union averaged 11.1 weeks (range, 5.5–16 weeks), judged by bridging trabeculae on CT scans. The experience with vascularized bone grafting of the scaphoid has not been uniformly successful, however. Although many authors report rates of healing of over 90%, others have demonstrated healing rates of 27 to 80%.[8,18,39,129] Variations in type and length of internal fixation, numbers of individuals with documented AVN, and other variables certainly may affect the results. A metaanalysis of scaphoid nonunions has demonstrated that vascularized bone grafts provide better union rates overall in scaphoids with avascular necrosis, and a trend to better results than conventional grafts in patients who have failed previous surgery.[93]

Role of Internal Fixation. Supplemental internal fixation is necessary for scaphoid nonunions, even with the use of vascularized grafts. In most cases, a scaphoid screw may be safely placed without jeopardy to the pedicle. Kirschner wires are required at times when insufficient bone is available to allow screw purchase. A recent metaanalysis of scaphoid nonunion literature has demonstrated that Kirschner wire fixation results in higher rates of pseudarthrosis than does the use of screws.[93] This has also been our experience.[18] The authors' preferred method (discussed previously) is placement of the screw in an antegrade direction prior to graft placement. A recent review of 50 such cases demonstrated the method to be inappropriate in cases where the proximal pole was fragmented.[18]

1,2 Intercompartmental Supraretinacular Artery Inlay Graft. Chances of successful union using a 1,2 ICSRA pedicled graft placed as a dorsal inlay graft were only 50% when associated with carpal collapse and a humpback deformity combined with an avascular proximal pole. We now reserve the use of this graft for proximal pole nonunions without significant scaphoid deformity and shortening because the graft is generally too small and perhaps too weak to provide the large interposition wedge generally required to restore scaphoid length.[18,84] With this more limited set of indications, we continue to find the 1,2 ICSRA graft useful and appropriate.

Medial Femoral Condyle Bone Flap. Wedge grafts that enhance vascularity are important for successful healing when AVN is combined with humpback deformity and carpal collapse. These may be conventional iliac crest grafts combined with an arteriovenous pedicle,[33,84] or large vascularized grafts placed to lengthen the scaphoid (Figure 46.18, *A* to *H*).[66,81] Both methods result in reliable scaphoid healing, although the healing time for conventional wedge graft with avascular bundle implantation is twice as long.[66] We now favor the use of large vascularized interposition grafts from the medial femoral condyle when both humpback deformity and avascular necrosis are present. An additional indication for the use of the MFC flap is a foreshortened scaphoid with a failed prior bone grafting procedure.

Medial Femoral Condyle Osteochondral Flap. When the authors analyzed the reasons behind the failure of vascularized grafting for scaphoid nonunion, we found fragmentation of the proximal pole or a very small, shell-like proximal fragment to be less likely to heal than scaphoids with more proximal bone stock. Prior use of large-diameter scaphoid screws played a role in this process, leaving little bone for fixation.[67] In these instances, it may be preferable to consider the use of a free osteochondral graft to replace the proximal scaphoid, as recently described by Burger.[11] Because the scapholunate ligament is generally not reconstructed, Burger's technique of sparing the distal

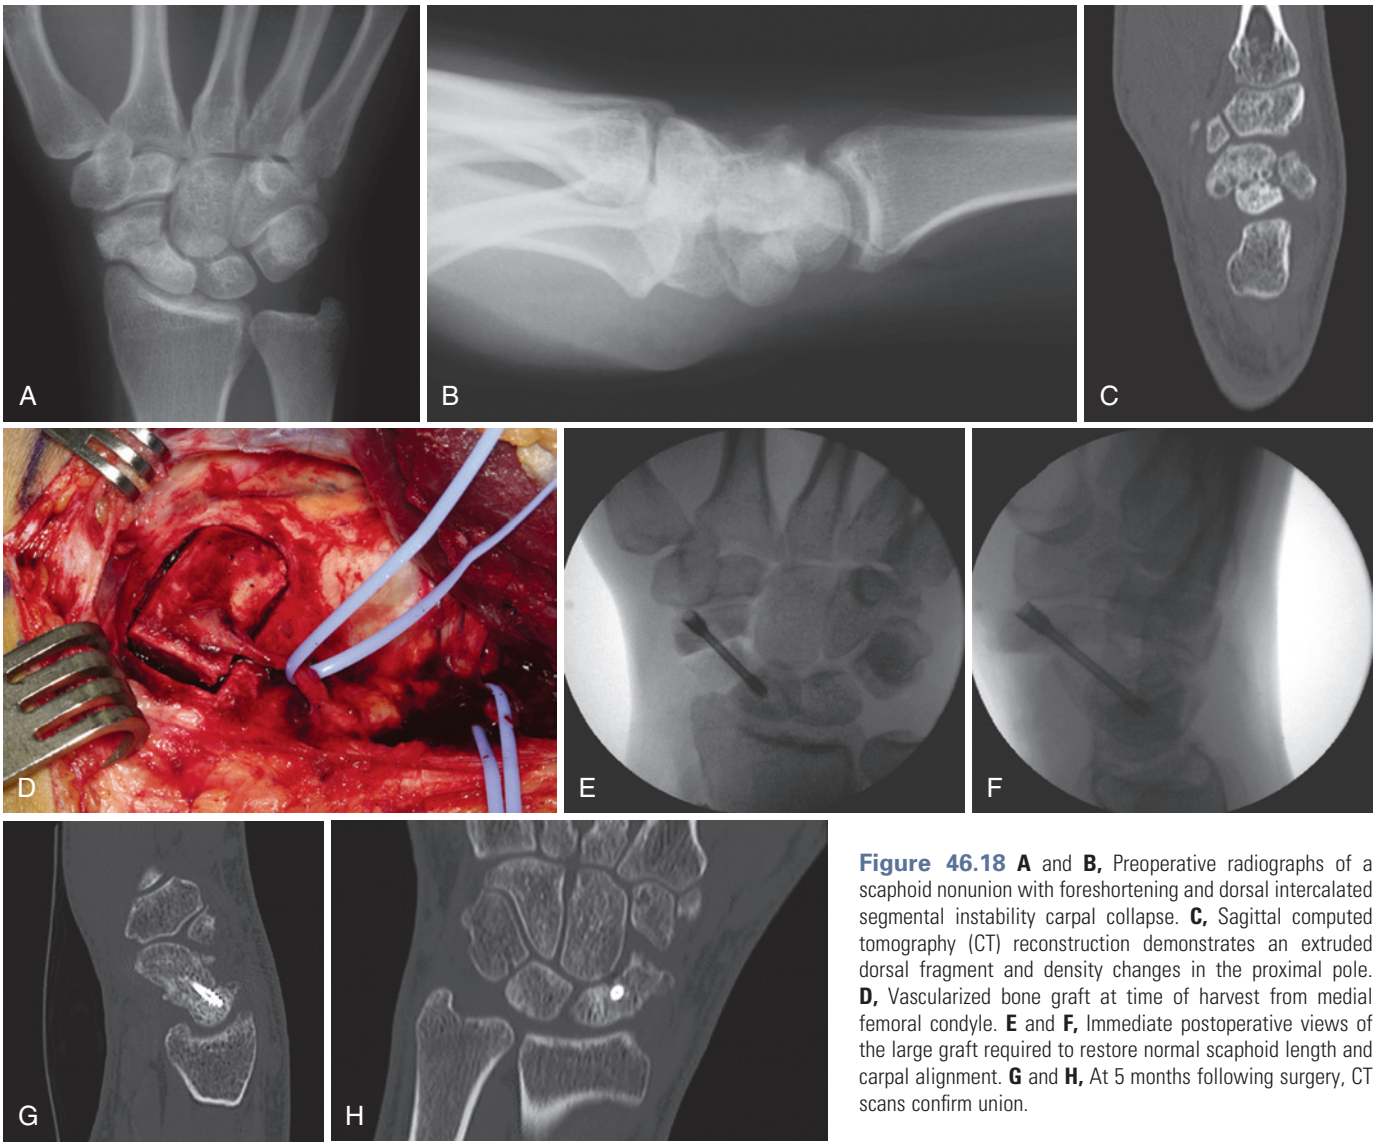

Figure 46.18 **A** and **B,** Preoperative radiographs of a scaphoid nonunion with foreshortening and dorsal intercalated segmental instability carpal collapse. **C,** Sagittal computed tomography (CT) reconstruction demonstrates an extruded dorsal fragment and density changes in the proximal pole. **D,** Vascularized bone graft at time of harvest from medial femoral condyle. **E** and **F,** Immediate postoperative views of the large graft required to restore normal scaphoid length and carpal alignment. **G** and **H,** At 5 months following surgery, CT scans confirm union.

(capitate) articular surface and thus some of the dorsal and palmar scapholunate ligament may be important for long-term success of such a procedure. Alternatively, it may be that a large "overstuffed" osteochondral graft may provide stability that is adequate to prevent carpal collapse (Figure 46.19, *A* and *B*).[13]

Lunate Graft in Kienböck Disease

Vascularized grafts in general have demonstrated satisfactory clinical results in Kienböck disease, with excellent pain relief and improvement in range of motion and strength. Radiograph progression of lunate and carpal height collapse occurred in 0 to 15% of patients in three recent studies[6,101,134] and radiographic or MRI evidence of revascularization may be minimal for an extended period of time.[101] Vascularized grafts may be especially useful in cases of ulnar-positive or neutral Kienböck disease, when joint leveling is contraindicated to avoid ulnar impaction syndrome. The lunate may be expanded with the graft, resulting in improvement of the lunate index and carpal height ratio postoperatively in stage IIIA disease. Use of the graft is questionable with displaced coronal fractures of the lunate, due to the unreliable healing of such fractures; in cases with marked carpal collapse; which may progress radiographically with osteoarthritic changes or fragmentation of the lunate[134]; and when the articular surfaces are damaged. Protection during early healing is necessary to prevent lunate collapse with revascularization.

Twenty-six Kienböck patients treated with a 5 plus 4 extensor compartment artery dorsal radius pedicle graft were followed for a mean of 31 months in one study; grip strength improved (from 50 to 89% of the opposite side), as did motion.[101] Fully 92% of patients reported improvement in pain, with 85% having satisfactory results overall. MRI data demonstrated some progressive signs of revascularization with time, but months to years were often required. Wrists with evidence of lunate revascularization generally fared better than those without MRI findings of improvement.

Advanced changes resulting in destruction of the articular surfaces of the lunate have generally been an indication for a salvage procedure. Recently, the osteochondral flap has been used for replacement of the majority of the lunate, including

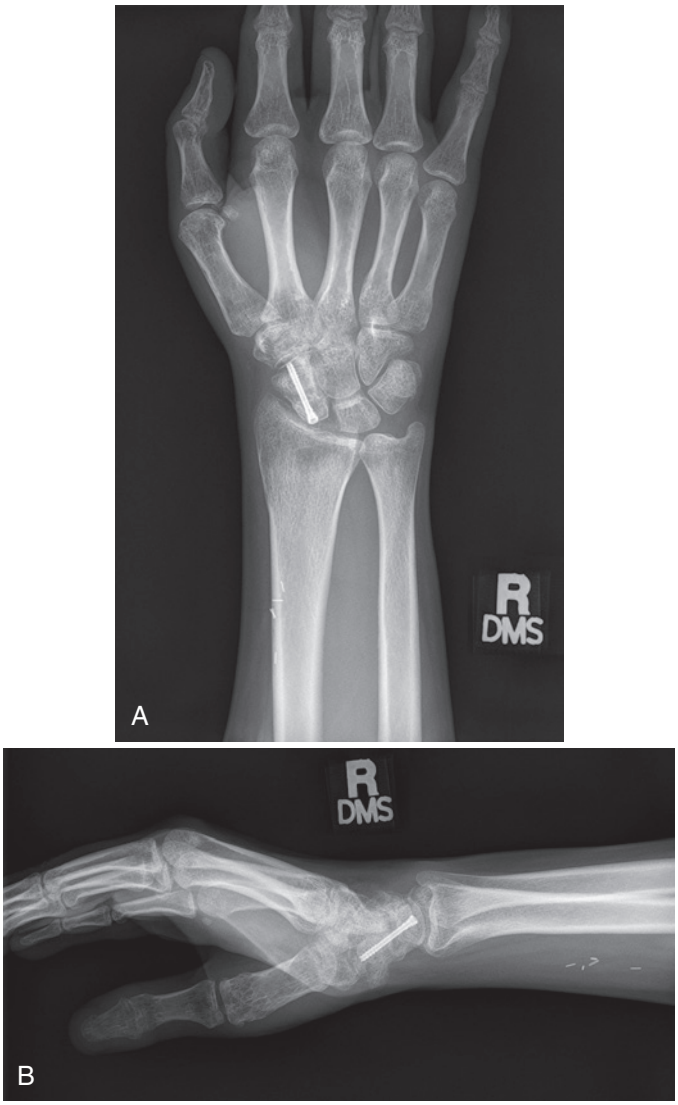

Figure 46.19 Replacement of the proximal scaphoid with a free medial femoral condyle osteochondral flap 6 months following operation.

the proximal joint surface. Generally, only the distal (capitate) surface of the lunate is preserved for function. All but 1 patient had had a good clinical result, and the radiographic changes demonstrated either no further collapse or improvement in lunate and carpal height over time (in 14 of 16 patients). Thus, the use of small osteochondral grafts in the near future may be expected to become more generally used, with the potential to provide improved clinical outcomes for this challenging clinical problem.

SUMMARY

Vascularized bone grafting is indicated in the upper extremity following segmental bone loss of greater than 6 cm as a result of trauma, infection, or tumor resection. Grafting is also indicated in smaller long bone defects in the presence of radionecrosis, failed prior graft, scarred beds, or the need for composite tissue reconstruction. Currently, restoration of growth by inclusion of the epiphysis is possible, as well. Primary sources of vascularized bone for long bone reconstruction include the fibula and iliac crest. In cases with minimal bone loss but with recalcitrant nonunion due to scarring, prior infection, or irradiation-induced damage, free corticoperiosteal flaps that envelop the bone permit revascularization and healing.

In the wrist, vascularized grafts have proven value in scaphoid fracture and nonunion, as well as in carpal avascular necrosis (Preiser disease, Kienböck disease, capitate AVN). For carpal indications, the primary options currently considered are reverse-flow pedicle grafts from the dorsal distal radius, and both bone-only and osteoarticular flaps from the medial femoral condyle. We now reserve 1,2 ICSRA pedicle grafts for scaphoid nonunions with minimal displacement, and 5 plus 4 ECA grafts for patients with Kienböck disease without collapse or injury to the articular surfaces. MFC grafting is now the procedure of choice for scaphoid nonunions when the unfavorable combination of humpback deformity and proximal pole AVN is present, or when a prior operation has failed with bone loss and/or avascular necrosis. Osteochondral flaps for fragmented and very small proximal pole scaphoid nonunions may prove to be a useful option for common salvage procedures, but data are limited at present. Similarly, lunates with extruded fragments, damaged articular surfaces, and extensive collapse that currently cannot be healed may prove to be best treated with osteochondral flap replacement.

Toe-to-Hand Transplantation

Fu-Chan Wei and Nidal F. AlDeek

The first report on a toe-to-hand transfer ever done to a human goes back in time to the 19th century when Nicoladoni described staged, pedicled toe-to-hand transfer over a four-week period. Davis was the first to combine staged transfer with microsurgical anastomosis of the dorsalis pedis artery; however, the credit for the first, one-stage toe transplantation to the thumb actually goes to Yang who transplanted the second toe in 1966.[1] Cobbett, on the other hand, transferred the great toe to the thumb for the first time in 1968.[14] After that, many clinical reports using various forms of toe transfer ensued during the 1970s and 1980s reflecting the intimate relationship between toe transfer and advances in microsurgery.[19,22,24,29,30,35,39,65,82–85,93,95,101,104,113,114] Nowadays, toe transplantation is the only safe and reliable procedure that replaces "like with like" in cases of missing or lost thumb and/or fingers.

For thumb reconstruction, either functional or aesthetic, toe transfer is a widely accepted option; in contrast, for finger reconstruction, toe transplantation has been somewhat controversial. It is getting more acceptance now because patients have become better informed and more demanding, and colleagues have accumulated additional experience.[19,48,69,88,93,95,101,104,114] Not surprisingly, digital and thumb amputations have a profound impact on quality of life, psychosocial functioning, and the ability of the patient to return to work.[64,88] Such an impact is expected to have a debilitating effect when mutilating injuries involve multiple digits. Therefore, "like-with-like" reconstruction using feet as donor sites is a good alternative to restore function and appearance after digital amputations.

In comparison to the results obtained with prostheses or some conventional techniques,[4] microsurgical toe transfer is the only procedure that provides functioning digits with sensitivity[39,91,102]; and in contrast to hand transplantation, toe transfer does not involve lifelong immunosuppressant administration. Plus, satisfactory hand function and patients' approval are still achievable.[32,47,49] Reports on the use of toe transplantation for finger replacement include multiple-digit reconstruction with bilateral toe transplantation,[82,104,105] combined transplantation of the second and third toes,[100] combined transplantation of the third and fourth toes,[82,106] single transplantation of the third toe,[101,108] and other toe combinations transplanted as one unit.[8]

Microsurgical restoration of distal digit function with partial toe transfer was first suggested in 1979 by Buncke and Rose,[3] who used pulp neurosensory free flaps for finger reconstruction. During the past 10 years more attention has been focused on this complex anatomic region, and various surgical procedures have been described and refined for distal digit reconstruction, including vascularized nail grafts,[39] toe hemipulp free flaps,[60] lesser toe wraparound procedures,[44,53,96] and partial transplantation of a lesser toe[21] or a great toe.[112] This brief review leaves no doubt that microsurgical toe transplantation has revolutionized hand reconstruction and that its role will continue to expand.

This chapter focuses on toe-to-finger reconstruction but also covers many aspects of thumb reconstruction and some topics about congenital hand reconstruction.

GENERAL CONSIDERATIONS

Although technically feasible, not every patient who experiences digit amputation is a candidate for microsurgical toe-to-hand transplantation. In selecting the right patients for this type of surgery, a multifactorial assessment, which has to be thorough and complete, should be conducted focusing on amputation level, number of digits involved, patient's age and parents' motivation (in the pediatric population), and patient's needs and motivations (in the adult population). For instance, a distal amputation of one digit might be psychologically more important and meaningful to one patient than a metacarpal hand deformity is to another, even though a higher functional deficit is present in the latter patient. Moreover, although it may seem counterintuitive, a single-finger amputation distal to the proximal interphalangeal (PIP) joint constitutes one of the best indications for toe transfer because of the excellent functional results that can be achieved; whereas, a single-finger amputation proximal to this joint is probably best addressed with ray amputation.[19] The patient's overall general health, medical problems, and associated injuries should be considered as well.

Age deserves special discussion; although advanced age is not an absolute contraindication to toe transplantation, functional requirements in the hand are lower in elderly patients. Furthermore, a higher risk of medical complications and less sensory recovery can be expected at an advanced age.[17] In contrast to elderly patients, infants appear to benefit significantly from toe transplantation, as remarkable gains in function, sensation, and ability to perform daily activities with high psychological satisfaction of the growing children and their parents are achievable[39,40]; however, performing toe-to-hand transplantation in children younger than two can be technically challenging.[39] Occupation, hand dominance, and activity levels are all important factors for adults. Surgical indications may also differ from country to country, based on the level of worker's compensation coverage, job opportunities, and cultural demands.[79]

The location and number of missing digits are important for establishing reconstructive priorities.[99] Radial pulp defects in the index and middle finger and the ulnar aspect of the thumb are more important for fine pinch and the handling of small objects.[35] With multiple-digit amputation, reconstruction should encompass at least two adjacent fingers to enhance stability and strength and to provide tripod pinch to ensure that the thumb is functional. The radial digits (index and middle) are more important for patients with occupations that require fine manipulation, whereas the ulnar digits (ring and middle) are more necessary for work that requires a powerful grasp.[97,102]

When toe-to-hand transplantation is being considered as a reconstructive option, donor site morbidity should be extensively discussed with the patient and relatives. Although foot function for most ambulatory activities is not restricted after the resection of one or two toes, it might be limited to some degree for specific activities (e.g., certain sports). Moreover, when both feet are used for transfer, the dominant foot, which generally is the right, should be given preference in terms of the least donor site morbidity. For instance, if a great toe and combined second and third toes are considered, the right foot is chosen to be the donor for combined second and third toes given the fact that donor site deficit will be less than that following the loss of the hallux. Foot cosmesis should not be overlooked and can be important in some cultures and in young patients. Finally, for surgeons involved in hand reconstruction, experience and familiarity with the various toe transplantation techniques are a must in order to avoid failures and complications and to offer their patients the optimal result.

Initial Care and Preoperative Evaluation

Digit replantation, including use of the distal parts, remains the best option for the management of acute traumatic amputations. This is a reliable procedure that should be attempted whenever indicated and possible.[6,28] Toe transplantation for digit reconstruction must be considered from the time of initial injury; however, and when practical, it should be discussed with the patient and relatives as an option for future reconstruction, even before replantation. This is particularly true for patients with multiple-digit amputations and when conditions for replantation are not ideal (e.g., severe crushing or avulsion injuries).[80] If replantation fails or is not feasible, toe transplantation for reconstruction should be planned during the initial care period. Bone, tendon, and neurovascular bundle length must be preserved after debridement of all nonviable tissue and provision of adequate soft tissue coverage (Figure 47.1).[66,90] The length of all anatomic structures retained in the stump is likely to determine the type of toe transplantation and its functional and aesthetic outcome. Moreover, preservation of stump length reduces the likelihood of requiring nerve or tendon grafts, and vein grafts for vascular anastomoses, during finger reconstruction, thus avoiding extensive dissection in the donor foot.

Bone and Joint

It is a common mistake to excessively shorten the digital skeleton to achieve direct or primary closure of the wound with local flaps. For skeletal fixation with toe-to-hand transplantation, bone stumps as short as 5 mm can be used for intraosseous wiring.[115] It is therefore recommended that bone length be

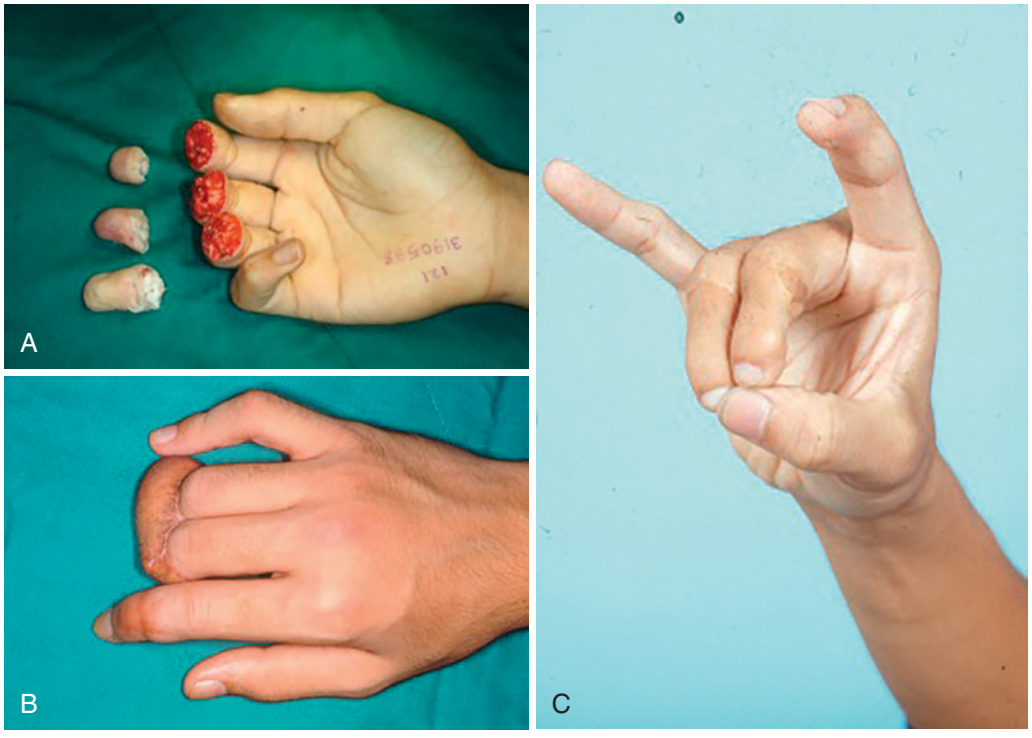

FIGURE 47.1 **A**, Distal amputation of the index, middle, and ring fingers. **B**, Only the index finger was successfully replanted, and the middle and ring finger stumps were covered with a pedicled groin flap after debridement and preservation of the fingers' skeleton, tendons, and neurovascular bundle length. **C**, Final result showing pinch function after reconstruction involving bilateral partial second-toe simultaneous transplantation.

preserved to the extent that complete soft tissue coverage is still possible. Every effort should be made to maintain functioning joints or the cartilage surface with the articular capsule. The transferred toe can be harvested through disarticulation, and the joint capsule can be directly repaired with the recipient finger to achieve good functional results, particularly in thumb reconstruction.[78] Metacarpal stumps can be augmented to the desired length with a nonvascularized bone block,[100] thus avoiding proximal transmetatarsal osteotomies during toe transfer and preserving metatarsal length, which minimizes donor foot morbidity.

Tendons

Preservation of the extensor mechanism in the finger is important for maintenance of balance between the intrinsic and extrinsic systems involved in extension. For distal amputations, the extensor apparatus should be left in situ on the digital stump, and the intrinsic insertions on the proximal phalanx should be preserved. For more proximal amputations at the metacarpophalangeal (MP) joint level, retention of the extensor hood is necessary for the same reason.[66,90] Conservative debridement of flexor tendon length is important in distal digit amputations because functional results are better when the insertion of the flexor digitorum superficialis (FDS) is present. For more proximal amputations, the finger flexors must be left in situ, although they might be shortened for future tendon repair in zone 3. By preserving the flexor tendons in place, it is possible to maintain the integrity of and space within the pulley system, which is vital for future function, especially the A2 and A4 pulleys.

Vessels

The digital arteries and veins are seldom intact after crushing or avulsion injuries. Every effort should be made to retain the arteries' length in nonreplantable digit amputations because these can be used as recipient vessels for toe transplantation in the future. The ulnar digital artery in particular is larger than its counterpart in the radial side of the fingers. The veins are less of a concern, given that a rich venous network on the dorsum of the hand is usually present.

Nerves

To prevent the development of neuromas in amputation stumps, proximal resection of the digital nerves has been advocated.[37] When toe-to-hand transplantation is considered for future reconstruction, however, the nerves' length must be preserved because recovery of sensation is faster when neurorrhaphies are performed closer to the transferred toe.

Skin

Instead of using local or regional flaps to cover the wound, soft tissue augmentation with a pedicle groin flap is a better alternative. The use of local flaps may increase morbidity, create additional deformity, and impede functional rehabilitation.[23] The redundant skin provided by a groin flap may later prove useful for covering the transferred toe (see Figure 47.1, *C*). It can also be used to protect the pedicle, create an adequate web space, and decrease scarring. Moreover, when there is enough skin available on the recipient finger (or hand), it is possible to minimize the amount of skin included during toe transfer, thus facilitating primary closure of the foot incision and enhancing donor site appearance.[21]

In some circumstances it may be possible to overcome hand skin deficiency in a single stage if additional tissue is taken from the foot along with the toe. Although readily available, the dorsalis pedis fasciocutaneous flap is not recommended because of donor site morbidity; however, a fasciosubcutaneous flap (excluding skin) based on the dorsalis pedis or metatarsal arteries, followed by a skin graft, has been reported to lead to good success.[20]

Primary Versus Secondary Toe-to-Hand Transplantation

Toe-to-hand transplantation can be performed either primarily or secondarily. Primary reconstruction refers to transfer in the setting of an open wound. Secondary reconstruction refers to transfer after definitive wound closure is achieved. Acute, subacute, and chronic are confusing terms and of no clinical relevance to toe-to-hand surgery. It is important, however, to emphasize that in primary transfer adequate debridement should be achieved and associated injuries should be managed before toe-to-hand transplantation is performed. Moreover, primary toe-to-hand transfer may not be suitable for nonreplantable finger amputations in children due to the potential risk of loss of the transferred toe; however, further studies are needed.[57] Nevertheless, parents should be made aware of such a possibility and stump closure should not compromise future toe-to-hand transfer.

From the standpoint of functional outcome, primary transfer maybe more beneficial compared to secondary transfer. A retrospective study of 31 primary and 144 secondary toe-to-hand procedures showed a survival rate of 96.9% in primary and 96.5% in secondary transplants. There was no statistical difference between the two groups in terms of intraoperative anastomotic revision, reexploration, complications, and secondary procedures.[116] Similar results were reported in a study by Woo and associates, who also noted a 30% reduction in convalescent time and a greater likelihood of patients returning to their original jobs after immediate reconstruction.[112] Early transfer may also result in better sensory recovery than delayed transfer.[11]

Primary toe-to-hand transplantation can be performed safely either for functional or aesthetic restoration whether a single or multiple toes are involved. Compared with secondary procedures, it reduces hospital stay, restores hand function, and the patient's body image in less time. In some cases, primary transfer may also be technically easier because dissection of the neurovascular bundles is not impeded by fibrosis or scar adhesion. It is recommended in highly motivated, well-informed patients in good physical condition and when wounds are clearly demarcated and clean (Figure 47.2).[72,112,116] It is also recommended in the setting of multiple-extremity injury when spare parts are available. Woo and associates found that patient satisfaction with the aesthetic appearance is less in primary versus secondary transfer.[112] Some surgeons therefore recommend delayed transfer in all cases to give the patient time to understand the extent of the hand deficit, appreciate the need for the procedure, and accept the reconstructive limitations and possible donor site morbidity.[19] In our opinion, however, the benefits of immediate transfer far outweigh these considerations.

FIGURE 47.2 **A**, Amputation of the index, middle, and ring fingers seven days after debridement in a patient who sustained a severe crushing injury. The finger stumps are prepared for primary reconstruction by toe transplantation. **B, C**, After using two second toes for index and middle finger reconstruction, full active extension and flexion are possible.

RECONSTRUCTIVE OPTIONS

Thumb Amputation

Although a thumb amputated at the interphalangeal (IP) joint level can still perform its basic functions, fine manipulation ability and hand appearance are compromised. Therefore, when replantation is not possible, toe transplantation should always be offered as a reconstructive option, even at a distal level. The thumb can be reconstructed with either the great toe or a lesser toe. Transfer of the great toe can include the entire toe or modified transfers such as the great-toe wraparound flap, trimmed great toe, twisted toe, and many others. The methods of thumb reconstruction should be individualized, taking into consideration the functional and cosmetic needs of the patient as well as donor site morbidity. In general, thumbs reconstructed with the great toe and its variants have a better functional and aesthetic result than those reconstructed with lesser toes.

In cases of thumb amputation between the IP joint and metacarpal head, the functional outcome is significantly affected by the level of amputation and thenar musculature status. Amputations proximal to the metacarpophalangeal joint inevitably result in destruction of the thenar musculature and secondary loss of opposition. Opposable tripod pinch is one of the essential goals in toe-to-thumb reconstruction, which is usually achieved by pronation osteosynthesis in the setting of loss of the muscles of opposition. However, Lin and associates recommended primary opponensplasty in toe transfers to provide active restoration of opposition and better restoration of tripod pinch.[57]

In cases of thumb amputation at the metacarpal level, the toe alone is inadequate to restore normal function. Although a larger flap from the foot, which includes the toe and metatarsal bone, is feasible, donor site morbidity can be quite high. Separate thumb ray reconstruction using osteoplastic techniques should be performed first, followed by second-stage toe transfer.[56]

Reconstruction of Single-Finger Amputation

Just as replantation of single-digit amputations has been a matter of debate for many years, single-digit reconstruction with toe transplantation remains controversial. Because the functional deficit in the hand is minimal when only one finger is missing, some authors believe that sacrificing a toe for finger reconstruction (other than the thumb) is not justified, especially in the nondominant hand.[34,36,79] However, when optimal reconstruction is desired, finger reconstruction with like-tissue transplantation from the foot usually offers satisfactory results, particularly in distal finger amputations.[98,103]

Reconstruction of Distal Digit Amputation

The distal end of a digit is most frequently injured. It is defined as the end portion of the digit distal to the insertion of the flexor pollicis longus in the thumb or the flexor digitorum superficialis (FDS) in the finger.[21,103] The highest density of innervation in the body surface is contained in the finger pulp; thus, it is considered the "end organ of touch." Specialized components of the distal digit include a sensate glabrous pulp and stable adherent nail. Glabrous skin characteristics allow resistance to wear and tear and provide a nonslippery surface for grasping. Attachment of the pulp skin to the underlying distal phalanx by a network of septa prevents excessive skin gliding and shearing, which is essential for strong pinching. The fatty tissue arrangement between the septa allows the pulp to conform to the shape of objects during pinch and grasp. The nail plays a major role in tactile sensibility of the pulp and in tip pinch, and it is an important aesthetic component, especially in women and in some cultures. None of these characteristics can be replicated by local or regional flaps, such as the cross-finger flap or

thenar flap, explaining their limitations and inferiority compared with tissue transferred from the toe.

The ideal reconstruction in this part of the finger maintains digit length with adequate soft tissue padding, provides near-normal sensation, and results in recovery of nail function. Reconstructive options using partial toe transplantation in distal defects include a combination of different portions of the nail, pulp, and distal phalanx from the great or lesser toes. Depending on the defect, vascularized nail grafts,[46,67] onychocutaneous flaps,[44,45] wraparound flaps,[53,96] pulp and hemipulp flaps,[16,60,71] and partial lesser toe transplantation[21,98,103] can be selected for reconstruction (Figure 47.3).

Amputations between the base of the distal phalanx and the middle of the middle phalanx require partial toe transfer with inclusion of the distal interphalangeal (DIP) joint and the flexor and long extensor tendons.[21] Modern jobs and hobbies often demand the presence of all digits (e.g., using a computer keyboard, playing a musical instrument). When indicated, this is the amputation level for which the most rewarding results are obtained with toe-to-finger transplantation (see Figure 47.1).

Reconstruction of Proximal Digit Amputation

Finger amputation between the FDS insertion and the web space (i.e., base of the proximal phalanx) presents a more controversial indication for reconstruction with lesser toes because a shorter finger might result. If the finger amputation has occurred distal to the middle of the proximal phalanx, the second or third total toe (with the PIP joint) may be long enough to achieve adequate function and aesthetic results in some patients (see Figure 47.2, *B*). Because of the resulting

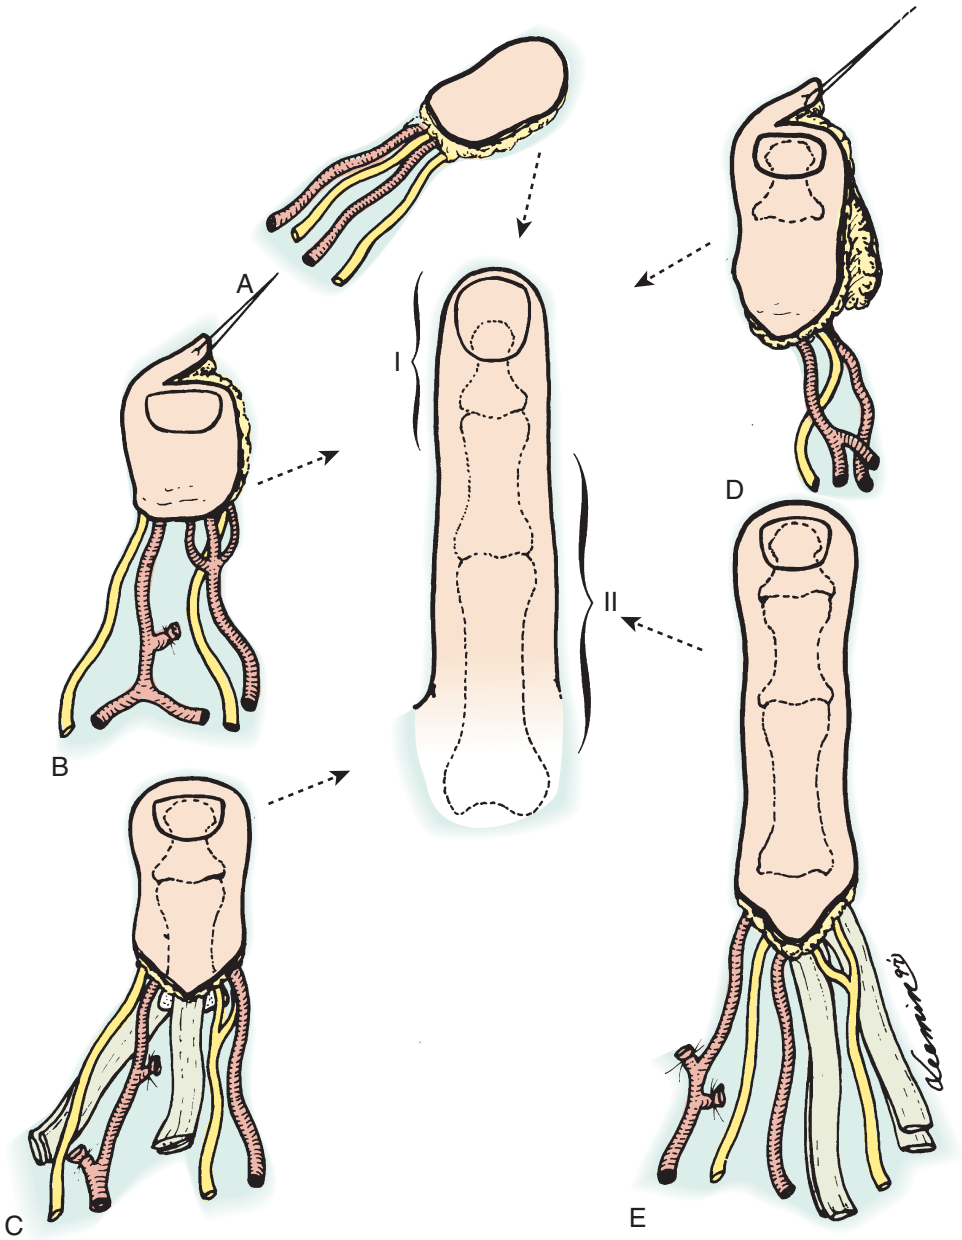

FIGURE 47.3 Single-finger amputation levels and reconstructive options with toe-to-finger transplantation. A pulp toe flap (**A**), vascularized nail graft (**B**), partial lesser toe flap (**C**), or wraparound lesser toe flap (**D**) can be used for distal finger amputation (*I*). Total lesser toe transplantation (**E**) is used for proximal finger amputation (*II*).

length discrepancy with the remaining fingers, more proximal amputations in a single finger might not be suitable for reconstruction with total toe transplantation, and ray amputation could yield more acceptable results.[19] Nevertheless, a functional finger with a suboptimal but acceptable appearance can be achieved with highly motivated patients.

Reconstruction of Multiple-Digit Amputation in the Nonmetacarpal Hand

Reconstruction of Multiple Digits in Distal Amputation

The same principles described for single-digit distal amputation apply to the reconstruction of two or more fingers with distal amputation. Priority should be given to reconstruction of the index and middle fingers because they play a more important role in global hand function, specifically in fine manipulation.[98]

Reconstruction of Multiple Digits in Proximal Amputation

For proximal amputation of two or more fingers, the main purpose of reconstruction is to provide improved prehension ability. It is therefore recommended that reconstruction of at least two fingers be considered.[97,99] The advantages of this approach are provision of a useful tripod pinch, stronger hook grip, lateral stability, and handling precision (Figure 47.4). Reconstructive options for adjacent finger amputations include two separate lesser-toe transplantations or a combined second- and third-toe (or third- and fourth-toe) transplantation on a single vascular pedicle. For two adjacent fingers amputation proximal to the web space, reconstruction with combined second- and third-toe transplantation is a better choice, not only because it reconstructs the web but also because it limits donor morbidity to a single foot and requires only one pair of anastomoses (Figure 47.5). In amputations distal to the web space, combined toe transplantation may create a syndactylous appearance, so two separate toes (e.g., bilateral second toes) may be preferable.[100,104,105]

Recently, Lin and colleagues described the use of split second- and third-toe transplantation in situations in which the web space was preserved but bilateral second-toe transplantation was undesirable owing to harvesting of the great toe.[54] For experienced surgeons, this approach may combine the best of both options in these special situations. An additional consideration, when considering tandem second- and third-toe transplantation for reconstruction of two adjacent digits, is the length of the remaining fingers. As a general rule, the remaining fingers have to be shorter than the tip of the normal little finger; otherwise, the transplanted unit cannot simulate the pinch point and grasp arch of full-length fingers.[83,100]

In cases with an intact articular surface on the metacarpal, the tandem toes can be disarticulated at the metatarsophalangeal joint, and the joint capsule and ligaments are circularly divided and used for reconstruction of the MP joint (i.e., composite joint reconstruction). If the metacarpal articular surface has been damaged or is absent, transmetatarsal toe transplantation is performed.

Reconstruction of Multiple Digits at Various Amputation Levels

It is not uncommon for a reconstructive surgeon to be confronted with the scenario of multiple-digit amputations. It becomes difficult to provide a treatment algorithm because these injuries have a wide array of combinations. The same principles apply here as in other digital reconstructions with toe

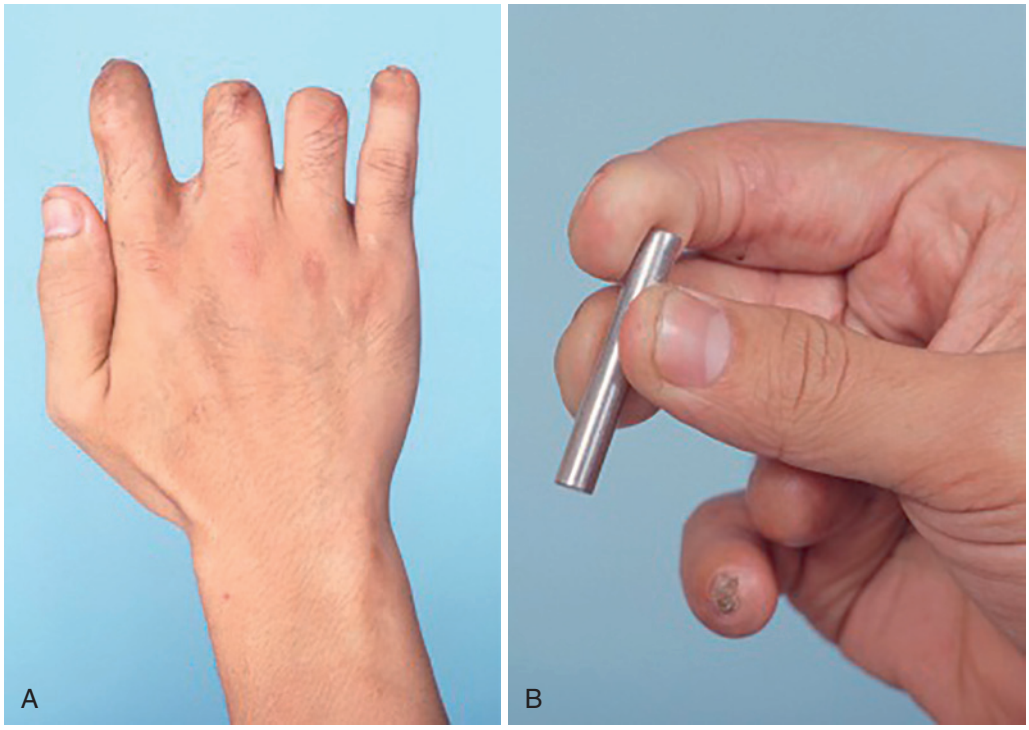

FIGURE 47.4 **A, B**, With multiple-digit amputation, it is best to aim at reconstructing at least two adjacent fingers to provide useful tripod pinch, stronger hook grip, lateral stability, and handling precision.

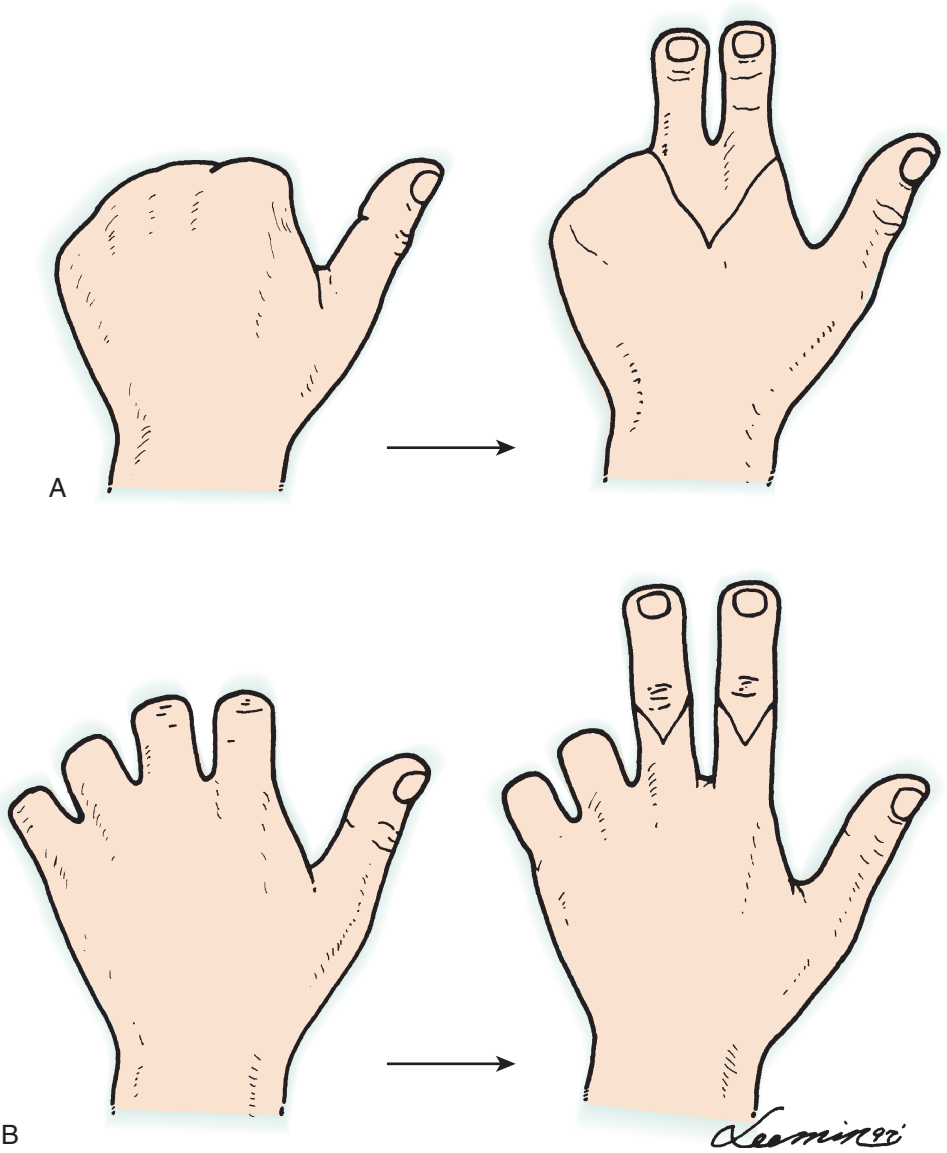

FIGURE 47.5 In digit amputation proximal to the web spaces, combined second- and third-toe transplantation is advocated (**A**), whereas in digit amputation distal to the web spaces, bilateral second-toe transplantation in one stage is preferable (**B**).

transfers. The proportional length of the fingers should not be disregarded as even minimal shortening of one finger draws attention to the others and gives a disfigured appearance. Therefore, the reconstructive surgeon should feel free to use whatever is available to achieve the aforementioned goals of digital reconstruction. A combination of toe transfer, ray amputation, and lengthening procedures may be necessary. To simplify management, the hand is converted into an acceptable one (Del Pinal classification) by means of toe transfer to the distally amputated finger and ray amputation to the proximally amputated finger with great effort to provide three functioning fingers whenever possible.[18,19]

Reconstruction of the Metacarpal Hand

A more severe functional deficit and deformity are present when mutilating hand injuries involve all digits at a proximal level, with or without thumb amputation—a condition referred to as metacarpal hand.[93] The senior author (F-C.W.) and his colleagues have proposed a practical classification of metacarpal hands and defined specific reconstructive options for toe transplantation (Tables 47.1 and 47.2).[61,63,102,104,105] This classification divides the metacarpal hand into two types for reconstructive purposes.

In type I, amputation has occurred in all fingers proximal to the middle of the proximal phalanx, and the thumb is either intact or amputated distal to the IP joint (considered the minimum functional length required for precise prehension). In type II, amputation of all fingers is proximal to the middle of the proximal phalanx, with thumb amputation proximal to the IP joint. For the type I metacarpal hand, it is recommended that at least two adjacent digits be replaced. Depending on the finger amputation level relative to the MP joint (subtypes IA, IB, and IC), bilateral lesser toes or combined second- and third-toe transplantation can be used for reconstruction. For the type II metacarpal hand, a systematic strategy must be followed for the selection of donor toes and reconstructive stages.

TABLE 47.1 Type I Metacarpal Hand

Subtype	Level of Thumb Amputation	Level of Finger Amputation	Recommendations
IA	Intact or distal to IP joint	Distal to MP joint	Bilateral second toes for amputations distal to web space Combined second and third toes for amputations proximal to web space (transproximal phalanx transfer)
IB	Intact or distal to IP joint	Through MP joint with intact metacarpal articular surface	Combined second and third toes (composite joint transfer)
IC	Intact or distal to IP joint	Through MP joint with damaged metacarpal articular surface or transmetacarpal amputation	Combined second and third toes (transmetatarsal transfer)

IP, Interphalangeal; *MP,* metacarpophalangeal.

TABLE 47.2 Type II Metacarpal Hand

Subtype	Level of Thumb Amputation	Level of Finger Amputation	Recommendations
IIA	Distal to metacarpal neck	Four fingers at any level proximal to middle of proximal phalanx	Whole or trimmed great-toe transfer (transproximal phalanx transfer)
IIB	Proximal to metacarpal neck with adequate thenar muscle function	Four fingers at any level proximal to middle of proximal phalanx	Preliminary distraction lengthening or interpositional bone graft, followed by whole or trimmed great-toe transfer *or* Transmetatarsal second-toe transfer
IIC	Any level with inadequate thenar musculature	Four fingers at any level proximal to middle of proximal phalanx	Thumb reconstruction in a second stage after finger reconstruction *and* Tendon transfer to restore opposition
IID	Any level with damaged carpometacarpal joint	Four fingers at any level proximal to middle of proximal phalanx	Same as for IIA and IIB, but aiming at reconstruction of an immobile thumb post

If thenar muscle function is adequate (subtypes IIA and IIB), simultaneous reconstruction of the thumb and two adjacent fingers in one stage is preferable (Figure 47.6). If thenar muscle function is inadequate (subtype IIC), a staged reconstruction is appropriate; the fingers are reconstructed first, and a prosthetic thumb post is used temporarily to assist in determining the length and position of the transferred toe for thumb reconstruction during the second stage (Figure 47.7). Even more complex are conditions in which both hands are involved because the selection of donor toes should take into account functional impairment and deformity of the feet.[102,105]

In the bilateral type II metacarpal hand, the dominant hand can be reconstructed with three toes to achieve tripod pinch, and the nondominant hand can be reconstructed with two toes to provide key or pulp-to-pulp pinch.[61,63,81] The five toes harvested can be the right second and third toes and the left great, third, and fourth toes, sparing the second toe for foot balance.[81] Our experience has revealed good functional recovery of the hands and no significant donor site morbidity with such an approach (Figure 47.8).

Congenital and Traumatic Loss of Digits in a Pediatric Hand

O'Brien and colleagues described the first toe-to-hand transfer for a congenital hand anomaly in 1978 and several series on different hand malformations, including but not limited to, thumb hypoplasia, adactylous hand, symbrachydactyly, and so on.[42,59,73,75,86,87]

For traumatic amputation of fingers in the pediatric population, management is similar to what has been described thus far. Replantation should always be attempted even in single-digit amputation. In nonreplantable digit(s), toe-to-hand transfer should be discussed with the parents extensively, and this complex procedure is clearly indicated even in the setting of a single-digit amputation. However, timing is affected by the child's age (two years old) and primary transfer is usually avoided in children younger than this.

For congenital absence of fingers, constriction ring syndrome is the ideal indication because the joints, muscles, and tendons proximal to the amputation site are typically present and normal. However, aplastic or hypoplastic conditions, including symbrachydactyly, have also been addressed successfully with toe transfers (Figure 47.9).[24,73] Thumb hypoplasia, in particular, remains controversial because many surgeons believe that results obtained by pollicization are better than toe transfers.[24] Reconstruction of the adactylous hand is usually a staged procedure; although reconstructing the thumb is suggested for the first stage followed by ulnar digit reconstruction in the second stage, it can be done in reverse order.[87]

Technical considerations in congenital reconstructions are similar to those outlined elsewhere in this chapter with a few notable exceptions. Although Lister described performing a successful transfer as early as 6 months to a year old, toe transfer should usually not be attempted until the patient is around two when the vessels are of adequate caliber for microvascular anastomosis. Another consideration regarding timing is the

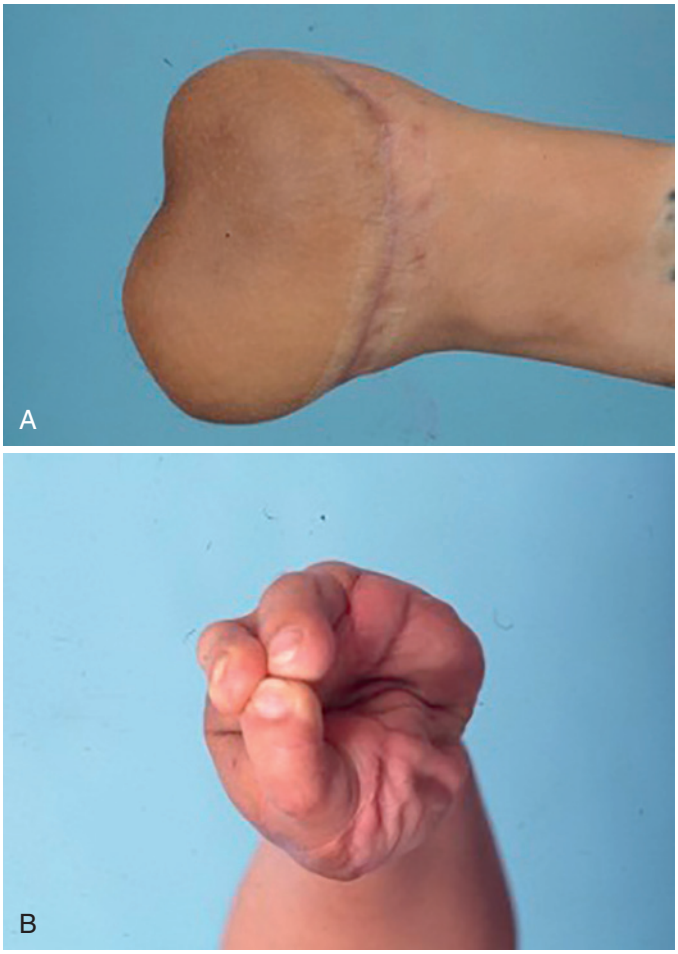

FIGURE 47.6 **A**, Metacarpal hand subtype IIB: amputation of the thumb and all fingers proximal to the metacarpophalangeal joint with good thenar muscle function. **B**, Tripod pinch after reconstruction of the thumb by trimmed great-toe transplantation and reconstruction of the two radial fingers by combined transplantation of the second and third toes from the contralateral foot.

unilateral type of the anomaly. It is best to treat children with unilateral malformations early before adaptive patterns are developed and the use of the abnormal hand is superseded by the normal hand. This situation does not occur in children with bilateral deficiencies.

In aplastic cases, the recipient vessels, nerves, and tendons must be identified before toe harvesting. The toes themselves also may be abnormal in patients with congenital hand abnormalities. As with adults, the first dorsal metatarsal artery (FDMA) is usually dominant and provides the pedicle for the flap. When multiple digits are required, flaps combining two or three toes can be transferred based on the plantar arch. Bony fixation must preserve the epiphyseal plates. Recipient tendons in the aplastic hand may be absent, and primary tendon transfers may be required.[39]

Success rates as high as 96% have been reported. Sensory recovery is usually quite good, with moving two-point discrimination of 5 mm in the series of studies of Foucher and coworkers.[24] However, the most commonly encountered problem is the unpredictable range of motion of the transplanted toe. Transferred toes usually have minimal active DIP motion, an extension deficit at the PIP joint, and a fixed-flexion deformity. Foucher and colleagues reported on 58 children with 65

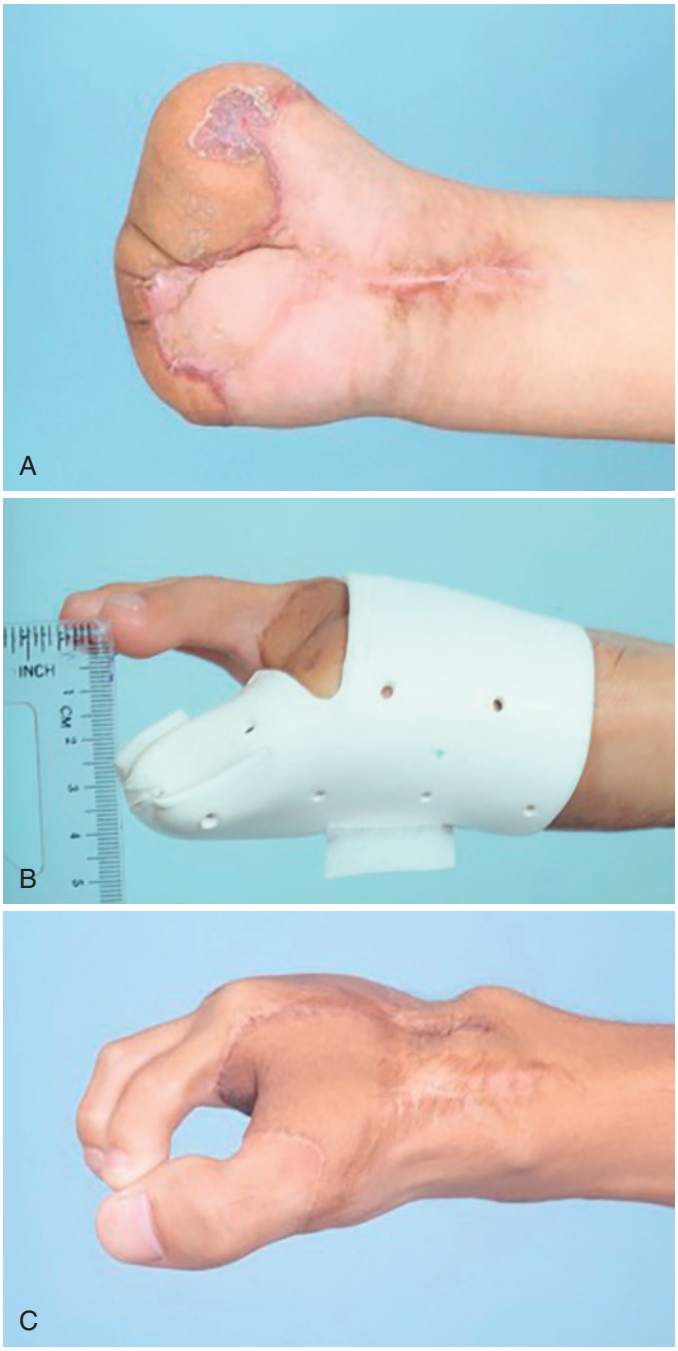

FIGURE 47.7 **A**, Metacarpal hand subtype IIC. **B**, After reconstruction of two adjacent fingers with combined second- and third-toe transplantation, a post is used to enhance pinch function of the transplanted unit and to determine the future position of the toe that will be used for thumb reconstruction. **C**, Eight months after thumb reconstruction by total great-toe transplantation, the patient has a stable pinch function.

toe-to-hand transfers with a mean active range of motion of 38 degrees and a mean extension lag of 25 degrees.[24] Nevertheless, children appear to incorporate the transferred toe into their hand function quite well. Growth of the transferred toe is 60 to 100% of the normal toe.[22,42]

Anatomy for Toe Dissection

Most surgical procedures involved in partial or total toe transplantation use the arterial pedicle to the great and second toe.

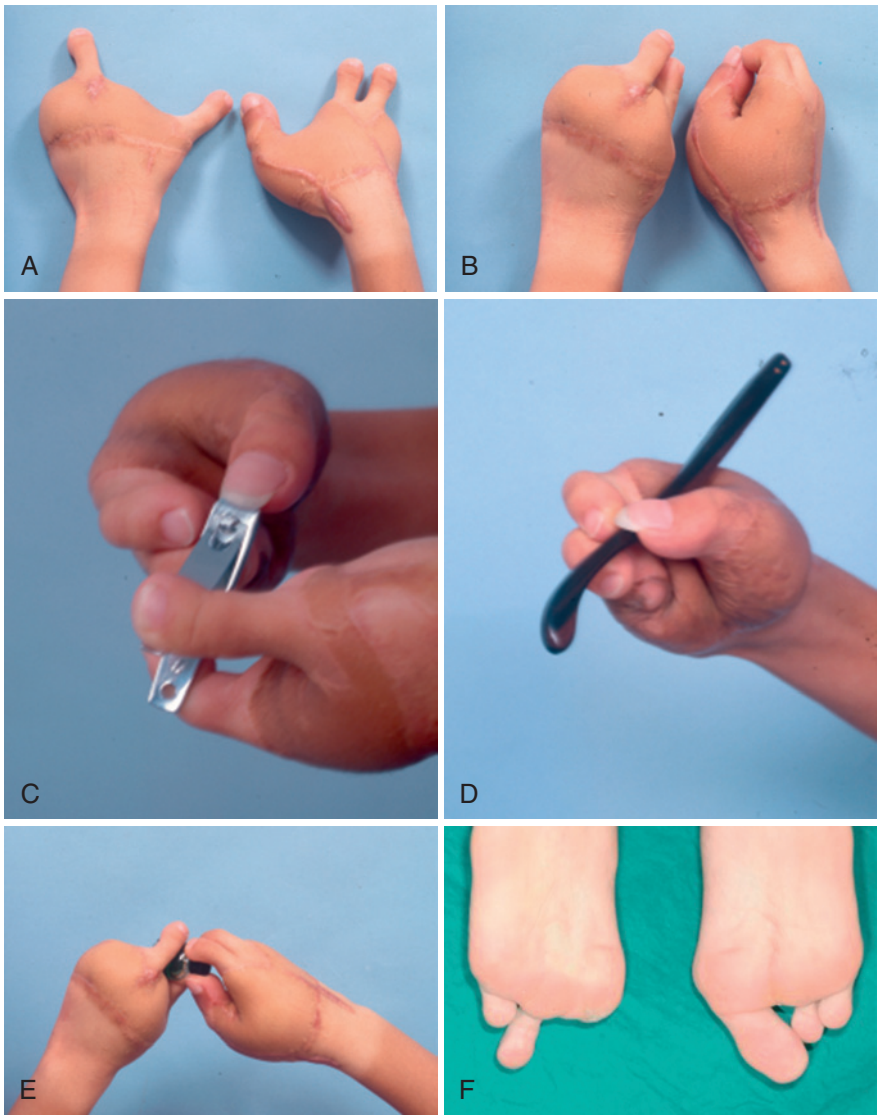

FIGURE 47.8 **A** through **E**, Bilateral metacarpal hand type IIB reconstructed with a total of five toe transplantations to provide tripod pinch for the dominant right hand and pulp-to-pulp pinch for the nondominant left hand. **F**, The donor feet have no callus formations, which is evidence of good maintenance of the original weight-bearing areas.

Several authors have proposed various classifications of the vascular anatomy in the first metatarsal space.[30] All of them describe anatomic variations in the origin of the FDMA; in the relationship between the FDMA and the interosseous muscle; and intermetatarsal ligament, FDMA diameter, and branching patterns. These descriptions have created an image of a complex and highly variable network of vessels in the first–second metatarsal interspace, making the vascular anatomy difficult to understand.

Classically, with most surgical techniques, vascular dissection begins proximally in the dorsum of the foot to identify and follow the course of the dorsalis pedis artery and its continuity as the FDMA. In the senior author's experience, the FDMA was the dominant artery in approximately 70% of cases, the first plantar metatarsal artery (FPMA) was dominant in 20% of cases, and both arteries had the same caliber in the remaining 10% (Figure 47.10). (Notably, the pattern of dominance is asymmetric between the two feet in approximately 20% of people.[77]) In the presence of a plantar-dominant arterial system, dissection of the dorsal aspect in the first metatarsal space needs to include only one superficial vein, and there is no need to deepen the dissection, which might damage the foot and is a waste of time.

It is easier to harvest the great or second toe (or any of the various flaps in this anatomic region) by identifying the dominant vascular pattern in the first web space at the beginning of the dissection and proceeding with dissection of the artery in a retrograde fashion.[107] Dissection always starts in the dorsal aspect of the first web space. The junction of the lateral digital artery of the great toe and the medial digital artery of the second toe, arising from the FDMA, is identified over the intermetatarsal ligament (Figure 47.11). Further dissection of the pedicle is then proximally carried out 2 to 3 cm from this junction. If a dorsal-dominant system is present, retrograde dissection of the FDMA is facilitated by early ligation of the smaller plantar vessel, and the FDMA is isolated proximally. In most cases the

FIGURE 47.9 **A**, Symbrachydactyly of the left hand in a 3-year-old boy. The patient has nearly complete absence of all digits of the hand with the exception of a rudimentary fifth finger. The thenar muscles are hypoplastic but maintain some function. **B**, The second toe was transferred from the right foot, which required concurrent release of syndactyly. (There was a congenital absence of toes on the left foot, necessitating use of the right foot as the donor.) **C**, The harvested toe based on the first dorsal metatarsal artery. The upper arrow indicates the vein, the middle arrow the artery, and the lower arrow the nerve. **D, E**, Ten years after the procedure the patient demonstrates good function. Although he cannot achieve pulp-to-pulp pinch owing to thenar hypoplasia and poor interphalangeal joint motion, he has excellent span and a useful grip.

artery is superficial to the muscle; however, it may also be localized within or deep in the interosseous muscle. If both vessels have a similar caliber, dissection of the FDMA is preferable because it is much easier and more straightforward.[107] If a plantar-dominant system is noted and the FDMA is either absent or very small, the dissection is continued later during the plantar dissection.

The FPMA is usually isolated up to the middle of the metatarsal shaft on the plantar surface. At this point, the union between the FPMA and the dorsalis pedis artery is located at the proximal communicating artery (or deep perforator). If a longer arterial pedicle is required, dissection of the communicating branch in continuity with the dorsalis pedis artery may be too tedious and destructive to the foot. Thus, it is advisable to divide the FPMA and use a vein graft for the vascular anastomosis.

Retrograde dissection is particularly helpful in partial toe transplantation for distal digit reconstruction when only a short pedicle is needed because proximal dissection of the vascular pedicle will not be necessary. In addition, retrograde dissection is helpful in pediatric toe dissection because donor vessel diameter is the most important factor after recipient vessel availability. Therefore, if the FDMA is found to have adequate diameter, dissection proceeds more proximally; otherwise, the

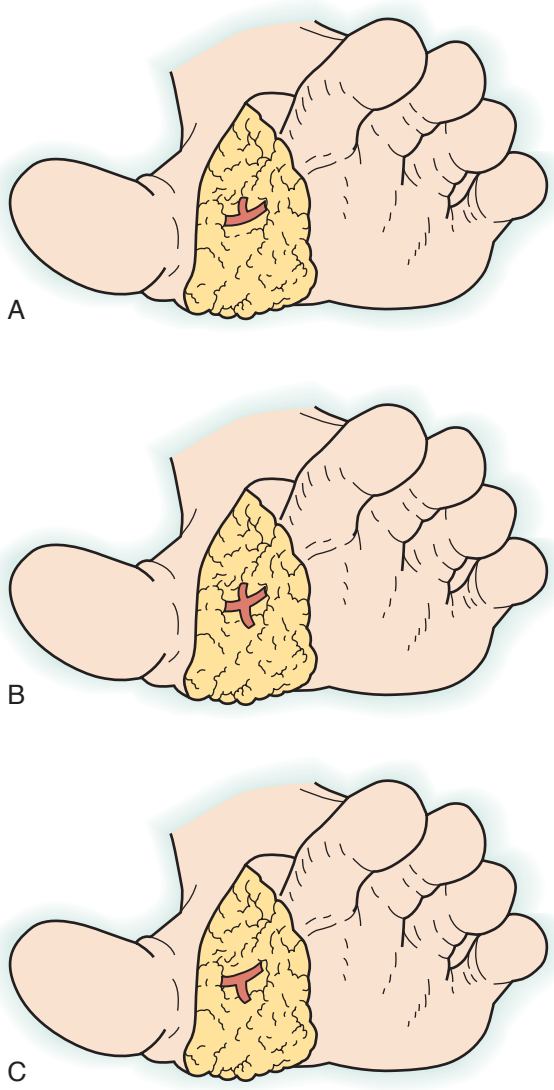

FIGURE 47.10 Retrograde dissection of the first web space in the foot. **A**, In approximately 70% of dissections, the first dorsal metatarsal artery (FDMA) is the larger (dominant) vessel and gives origin to the dorsal proper digital arteries to the great toe and the second toe. **B**, In 10% of cases, the FDMA and first plantar metatarsal artery (FPMA) have the same caliber. **C**, In 20% of cases, the FPMA is the dominant vessel.

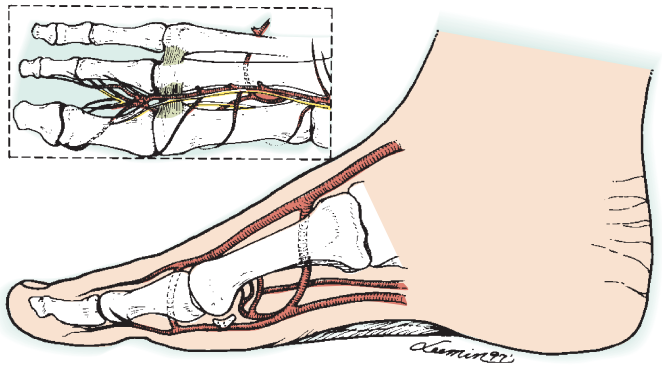

FIGURE 47.11 Anatomic relationship between the first dorsal metatarsal artery over the intermetatarsal ligament and the first plantar metatarsal artery. Communicating branches are present in the web space distally and in the base between the first and second metatarsal bones (also known as the deep perforator or proximal communicating artery).

FPMA is chosen and no time is wasted.[107] Moreover, routine preoperative angiography of the donor foot is not required when this approach is used to harvest any toe or flap based on the arterial system of the first metatarsal space.[107]

SURGICAL TECHNIQUES

Total or Trimmed Transplantation of the Great Toe

Indications

Total transfer of the great toe is selected for thumb reconstruction when the amputation level is at either the proximal phalanx or metacarpal level. It aims to provide a new thumb with a better range of motion and a broader pulp surface for a more powerful pinch. However, it is often too large to simulate the normal thumb on the opposite side. The great-toe wraparound technique was developed by Morrison using the great toenail, skin envelope, and conventional bone graft to circumvent the size problem.[68] Although it yields a nice looking thumb, it does not provide a mobile IP joint. Trimmed transplantation of the great toe combines the advantages of total transfer and the great-toe wraparound technique.[93,94] It is indicated when there is an unacceptable size difference between the thumb on the normal opposite side and the great toe to be harvested, especially when a mobile IP joint is desirable. It is worth mentioning that with the trimmed great-toe technique a reduction of 18 degrees in IP joint motion is expected, which does not seem to affect pulp-to-pulp pinch prehension.[95]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

The great toe usually looks portlier than the thumb, with wider transverse and anteroposterior diameters. The discrepancy involves bone as well as soft tissue elements (Figure 47.12, *A*). To assess the size discrepancy between the great toe and the normal thumb, the circumferences of the great toe and the normal thumb are measured at three points: the nail eponychium, the widest point (corresponding to the IP joint), and the middle of the proximal phalanx. The thumb measurements are transposed to their corresponding points on the great toe. An additional 2 to 3 mm is added to each measurement to allow direct closure without tension. The residual medial skin strip usually measures 0.5 to 0.8 cm wide, which represents the difference between the toe and thumb circumferences. This should be tapered to a point around the tip of the toe, leaving 2 mm of nail fold to facilitate skin closure. The proximal skin incision is determined by the level of thumb amputation and is usually marked in a circular or "V" shape (Figure 47.12, *B*). Although it is possible to trim the nail together with the underlying nail bed, this is not recommended because the nail fold may become deformed.

The procedure starts by identifying one sizable vein and the dominant arterial supply in the first web space. The vascular pedicle is dissected in a retrograde fashion to the desired length and diameter. Branches of the deep peroneal nerves are preserved. The extensor tendon is then dissected on the dorsal side, and the neurovascular bundle and flexor tendon are isolated on the plantar side. Care is taken to place the incision on the plantar aspect, lateral to the head of the first metatarsal, to prevent a scar over the weight-bearing area.

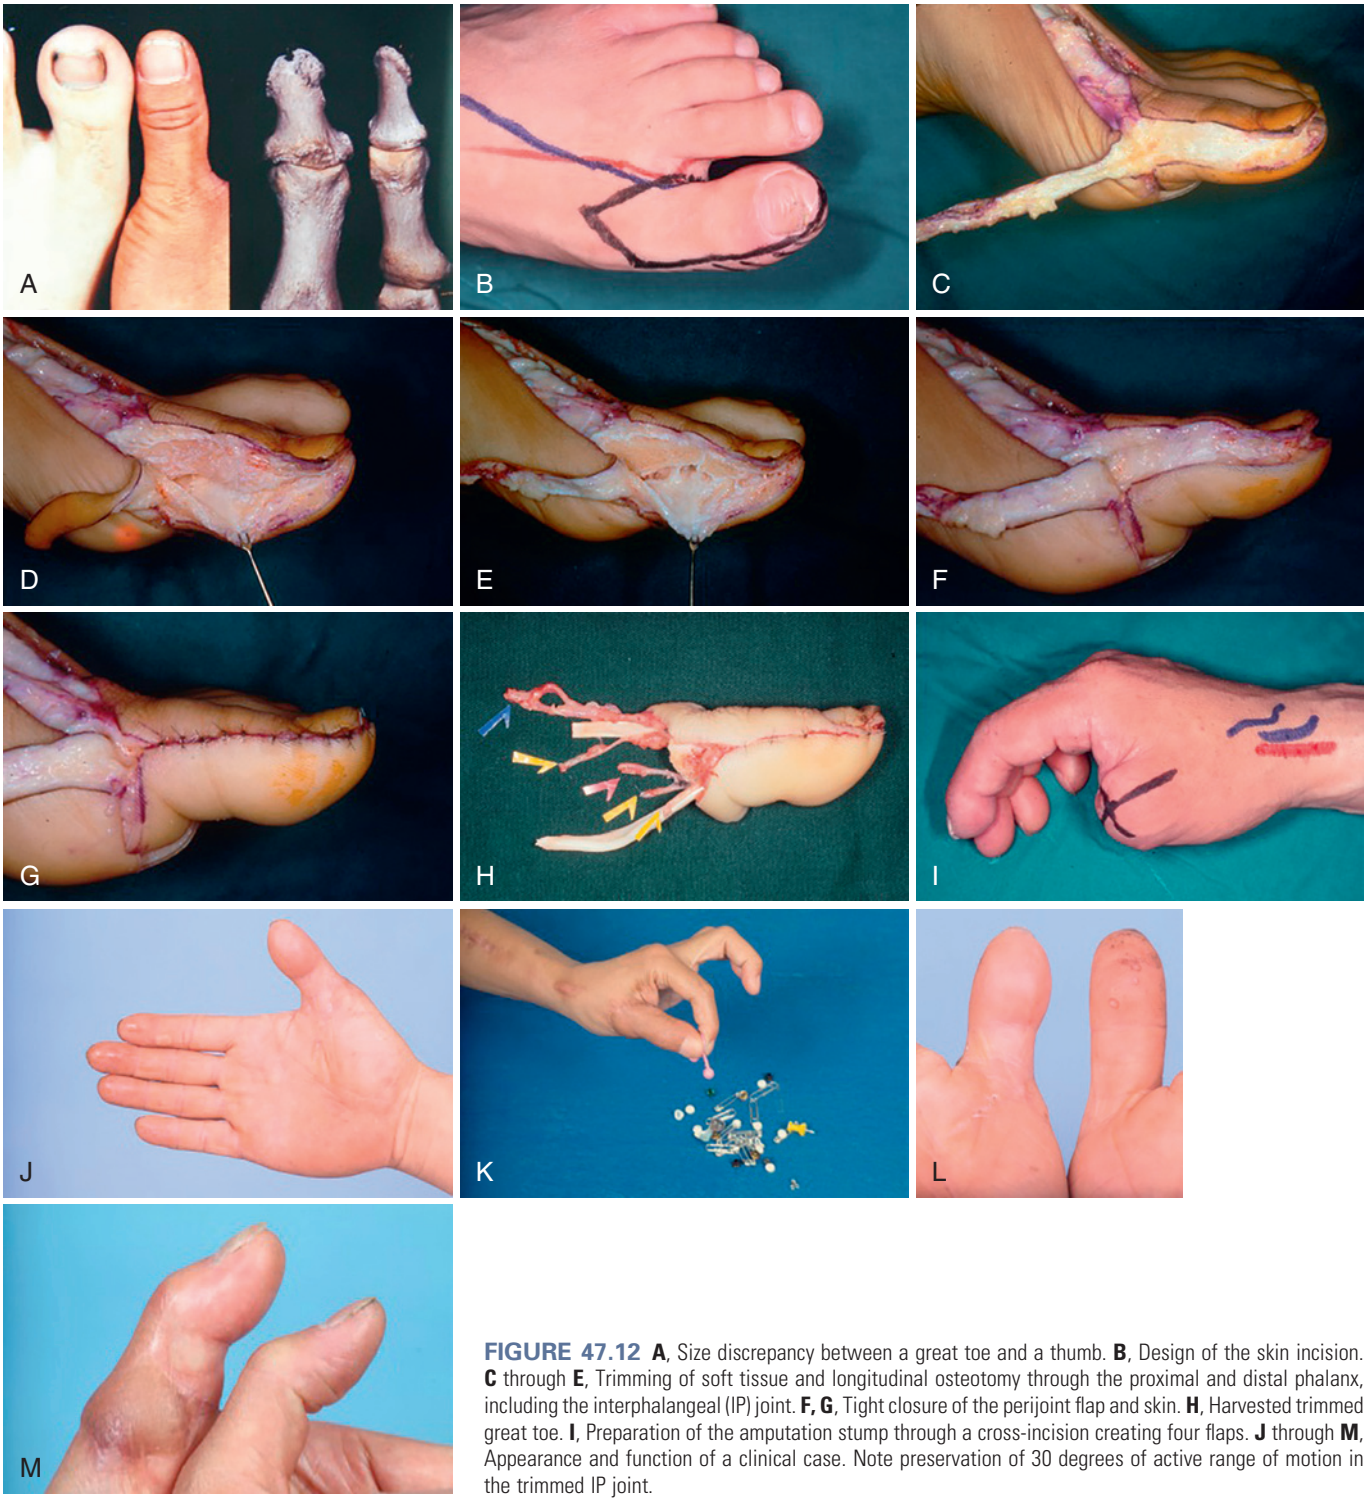

FIGURE 47.12 **A**, Size discrepancy between a great toe and a thumb. **B**, Design of the skin incision. **C** through **E**, Trimming of soft tissue and longitudinal osteotomy through the proximal and distal phalanx, including the interphalangeal (IP) joint. **F, G**, Tight closure of the perijoint flap and skin. **H**, Harvested trimmed great toe. **I**, Preparation of the amputation stump through a cross-incision creating four flaps. **J** through **M**, Appearance and function of a clinical case. Note preservation of 30 degrees of active range of motion in the trimmed IP joint.

Next, the medial skin strip is incised and elevated from distal to proximal. The incision is deepened to the periosteum at the tip of the distal phalanx (Figure 47.12, *C*) but remains superficial to the medial collateral ligament on the medial surface of the IP joint. The second incision is made all the way through the periosteum. The collateral ligament, joint capsule, and periosteum are elevated as a plantar-based single, thick, strong composite soft tissue envelope, which we have designated a "perijoint flap." This subperiosteal (perijoint flap) elevation is continued along the hemicircumference to the middle of the plantar surfaces of both the proximal and distal phalanges (Figure 47.12, *D*). A longitudinal osteotomy (Figure 47.12, *E*) is then performed with an oscillating saw while carefully protecting the neurovascular bundle. This removes a 4- to 6-mm width of the medial joint prominence, along with a 2- to 4-mm width of the phalangeal shafts.

A smooth contour of the osteotomy edges is obtained using a high-speed bur. The hemicircumferential composite perijoint

flap is redraped and the redundant portion is trimmed, followed by repair under proper tension with interrupted sutures using nonabsorbable material. The repair should be tight enough to maintain joint stability (Figure 47.12, *F*). The medial skin incision is also approximated with interrupted sutures (Figure 47.12, *G*). Care should be taken to prevent injury to the nail bed or matrix because this can result in a deformed nail. Finally, the proximal phalanx is osteotomized, preserving at least 1 cm of the base of the proximal phalanx and leaving the great toe attached only by its vascular pedicle. After removal of the tourniquet, the transplant is allowed to perfuse for at least 20 minutes before proceeding with transplantation (Figure 47.12, *H*). The donor site is closed primarily. The osteotomy edges are smoothed and the remaining proximal portion of the medial skin flap of the great toe can be used to assist tension-free closure, if required.

The amputated stump is prepared through a cross-incision creating four flaps (Figure 47.12, *I*). These flaps are mobilized to prepare the bone, extensor and flexor tendons, and digital nerves. They also allow smooth closure of the skin between the recipient site and transplanted toe for a better appearance of the reconstructed thumb. The recipient artery can be the common digital artery (our first choice), the princeps pollicis artery, or the radial artery in the anatomic snuffbox. The bone, extensor and flexor tendons, recipient artery, vein, and nerves are prepared at the recipient site in the usual manner.

Flap insetting and repair of tendons and neurovascular bundles are performed as described in other sections of this text. When closing the wound defect, preservation of skeletal length and good skin coverage are important. In transplantation of the great toe, it is advisable to preserve at least 1 cm of the proximal phalanx to maintain foot span for a better appearance and to preserve push-off function of the donor foot. Skin grafting of the donor site should be avoided. With adequate planning, rarely should there be a problem achieving tension-free closure of the wound in the foot. No drains are required at the donor site.

Partial or Total Transplantation of the Second Toe

Indications

In adults, although selection of the second toe for thumb reconstruction may be controversial,[53,92] use of the second toe for finger reconstruction is a well-accepted procedure. However, thumb amputation proximal to the carpometacarpal (CMC) joint may, in particular, benefit from a second-toe transfer that provides valuable length up to the proximal metatarsal bone compared to the proximal phalanx with great-toe transfer. For pediatric patients, second-toe transfer is usually preferred for both thumb and finger amputations.[41] Partial transplantation of the second toe is used for digit amputations distal to the insertion of the superficial flexor tendon (Figure 47.13),[21,98,103] whereas total transplantation is used for the reconstruction of more proximal finger amputations (Figure 47.14).[26,44]

Flap Design and Elevation

Most surgical techniques designed to harvest the second toe use a combined dorsal and plantar approach.[53] Foucher and Norris suggested harvesting the second toe alone from a dorsal approach to avoid incision and dissection of the fibrofatty tissue in the plantar surface and to allow faster recovery and early walking.[27] In addition, the blood supply to the second toe is theoretically improved because the first- and second-dorsal metatarsal arteries and the plantar arteries are included in a vascular network. Access to the plantar structures from the dorsal approach is facilitated by removing the second metatarsal bone.

For less experienced surgeons, this technique can be more difficult than a combined dorsal and plantar approach and may entail excessive manipulation of the vessels, which might increase the risk of pedicle injury and postoperative vascular complications. Furthermore, resection of the second metatarsal is not necessary in many cases, and the plantar skin flap usually included in the transferred toe is often needed to provide glabrous skin on the volar aspect and to cover the pedicle in the recipient's hand. For these reasons, we prefer the combined approach.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

The length of the second toe to be harvested is determined before surgery and depends on the level of finger amputation and radiographic findings. Two microsurgical teams work simultaneously to reduce surgical time. The exact lengths of the tendons, nerves, and vascular pedicle in the toe are assessed intraoperatively before dividing them. The dorsal and plantar skin flaps are designed in a "V" shape to ensure primary wound closure without tension. The vertex of the "V"-shaped skin incision is marked 5 to 10 mm proximal to the osteotomy site on the dorsal and plantar aspects of the toe, and the two divergent points of the "V" flap are marked at the midpoint of the first and second web space. The incision is extended proximally in a lazy "S" course for exposure of the vessels and nerves. On the plantar surface, this incision is always made in a vertical direction, and the weight-bearing surface is avoided.

The skin in the dorsal flap is incised and elevated superficially to protect the dorsal veins. Only one sizable vein, usually in the first metatarsal space, is selected and dissected proximally. The dissection continues in the first web space where the dominant arterial pattern is identified and dissected in a retrograde direction (see "Anatomy for Toe Dissection" section). All fatty tissue is carefully removed from the nerves and vessels and the transmetatarsal ligament is then divided. In a dorsal-dominant arterial system, the FDMA is dissected proximally until an adequate length is obtained. If a plantar-dominant system is present, dissection on the dorsal surface is necessary only for the vein; the FPMA is isolated afterward. All small veins and arteries in the second metatarsal space are divided. Branches of the superficial peroneal nerve in the first and second metatarsal space are dissected and used together with the proper digital nerves only when sensory recipient nerves are available; otherwise, just the digital nerves are used for sensory recovery of the transplanted toe. The extensor retinaculum is opened and the extensor digitorum longus and brevis tendons are isolated and followed distally.

The skin flap on the plantar aspect is raised to the base of the proximal phalanx with only 2 to 3 mm of subcutaneous tissue left attached to the dermis. All fibrofatty tissue between the plantar skin and neurovascular bundles is discarded to minimize anteroposterior bulkiness and maximize joint motion in the reconstructed finger. The proper digital nerves are

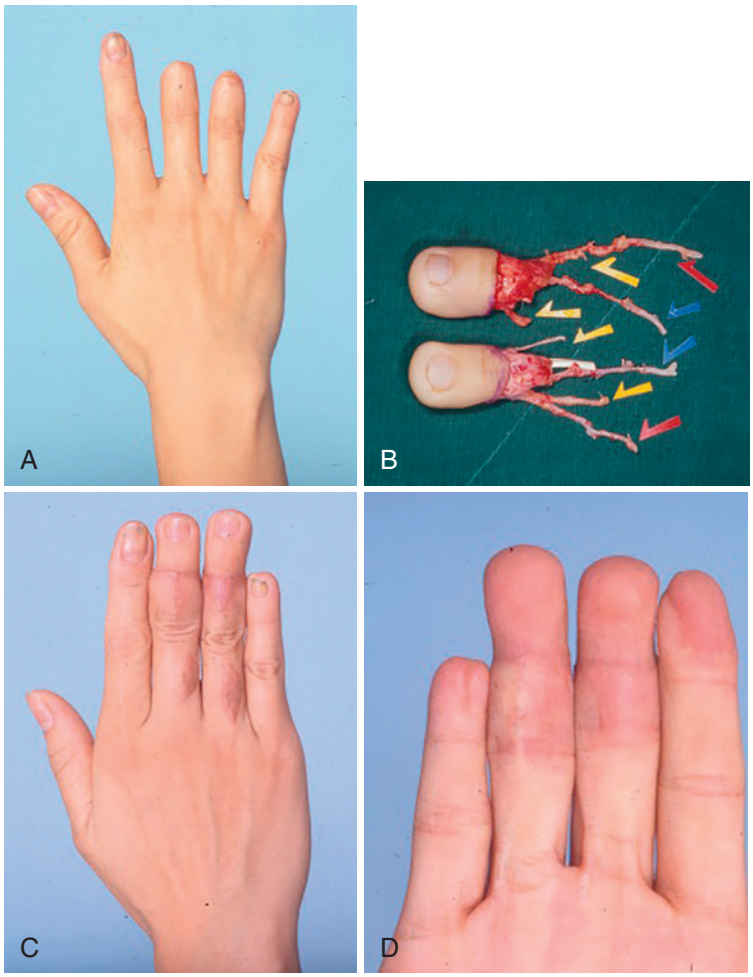

FIGURE 47.13 **A**, Amputation of the middle and ring fingers distal to the insertion of the superficialis flexor tendon. **B**, Bilateral second toes harvested with an osteotomy at the middle of the middle phalanx level. **C, D**, Results three months after reconstruction.

identified distally in the web space, close to the proper digital plantar arteries, on the medial and lateral aspects. Both plantar nerves are dissected proximally up to their union with the respective common digital nerves, which also contain the proper digital nerves to the great and third toes. When a long digital nerve is required, the common digital nerve can be internally neurolysed for several centimeters to extend the length of the proper digital nerve to be harvested. Next, the flexor tendon sheath is approached and opened vertically to expose the short- and long-flexor tendons.

To facilitate tailoring and insetting of the toe, it is advisable to extend the dissection for several millimeters distal to the osteotomy site. This allows skeletonization of the artery and nerves and removal of all fibrofatty tissue, especially what is between the skin and the flexor tendon in the plantar aspect.[94] These refinements are more meaningful in partial transplantation of the second toe, which is associated with a higher incidence of vasospasm. Often the vessels need to be tunneled under the skin proximally, and fixation of the partial toe transfer is critical for a good cosmetic and functional result.[21]

Once all the anatomic structures have been isolated and the required length has been determined, the nerves are divided and marked with 6-0 nylon. The flexor tendons are pulled out and cut. In total transplantation of the second toe, the proximal phalanx is cut at the proper level; alternatively, the metatarsophalangeal joint may be disarticulated and the proximal phalanx shortened to the length needed in the reconstructed finger (see Figure 47.13). In partial transplantation, the veins, nerves, and tendons are dissected distal to the PIP joint, and the middle phalanx is osteotomized in a dorsal-to-plantar direction; otherwise, the distal toe is disarticulated at the PIP joint (see Figure 47.14, *B*). The tourniquet is then released, and the toe is allowed to reperfuse for at least 20 minutes before dividing the main artery and vein.

The donor site in the foot should be closed primarily without tension. It is not necessary to repair the intermetatarsal ligament, and no drains are needed. In unusual cases in which primary closure is difficult, metatarsophalangeal joint disarticulation or transverse metatarsal amputation should be performed. Skin grafting of the donor site should be avoided to prevent foot morbidity and deformity.

Wraparound Flap of the Second Toe

Indications

Despite the fact that the great-toe wraparound flap was initially described for thumb reconstruction,[68] this flap also can be used for other injured fingers. Wraparound flaps can be elevated

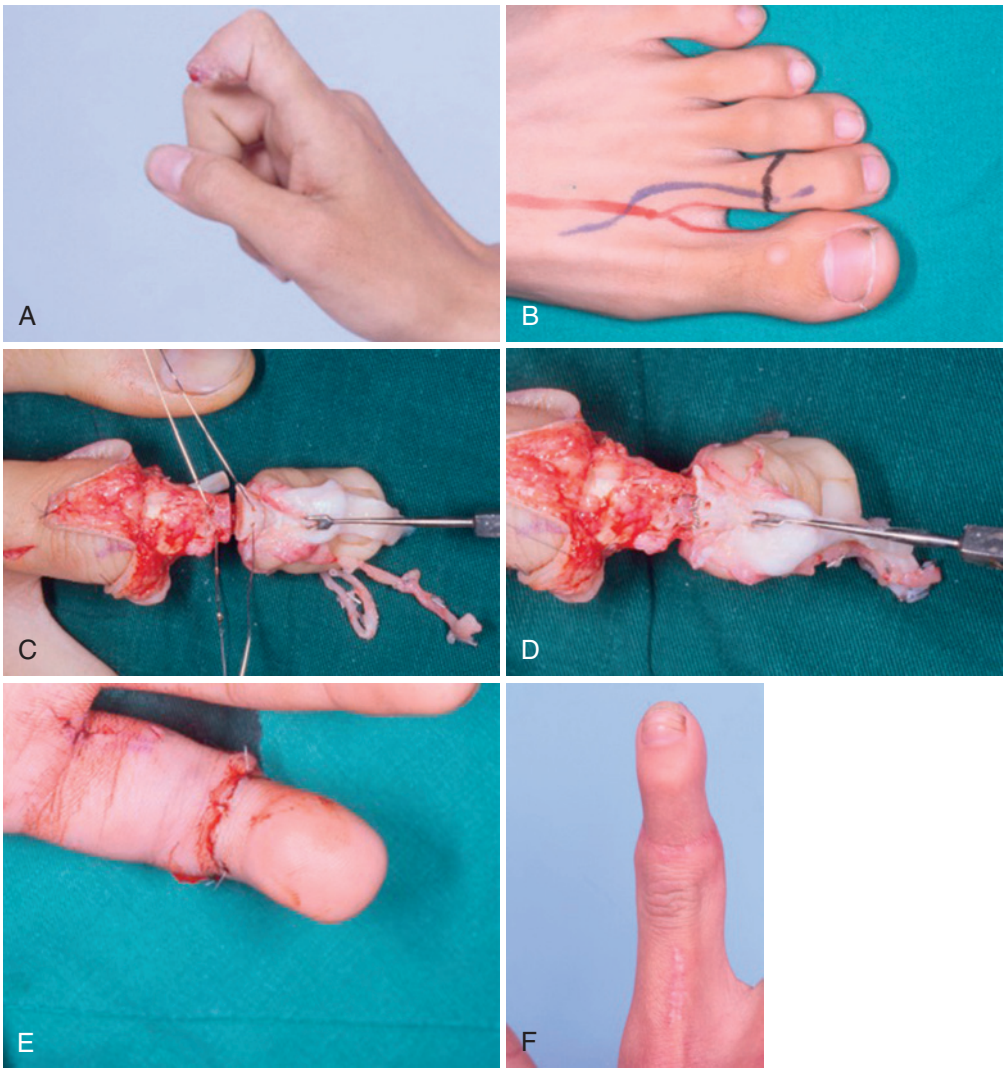

FIGURE 47.14 **A**, Distal amputation of the index finger. **B**, Planned disarticulation of the second toe at the proximal interphalangeal joint in preparation for partial second-toe transfer. **C**, **D**, Osteosynthesis of the partial 2nd toe after shortening the middle phalanx. **E, F**, Immediately after surgery and months later, respectively.

from a lesser toe as well. The senior author advocates the second-toe wraparound flap for finger reconstruction because the size usually matches the distal digit better, especially the toenail.[96] However, it can also be used for thumb reconstruction (although the nail size may be different), particularly for patients who will not accept or cannot tolerate partial loss of the great toe.

The second-toe wraparound flap is indicated for the reconstruction of a circumferential or dorsal hemicircumferential loss of skin and nail that is localized distal to the proximal portion of the middle phalanx with intact skeleton, tendons, and PIP joint (Figure 47.15).[96] No tendons are harvested with the second-toe wraparound flap, but the distal phalanx is always included to prevent swiveling, instability, and bone resorption of the reconstructed finger.

Flap Design

The second-toe wraparound flap can be adapted for either foot depending on the nail configuration, size of the defect, previous surgery or injury to the foot, and patient preference. The object of the incisions in the hand and foot is to avoid scars on the radial aspect of the index, middle, and ring fingers and on the ulnar aspect of the thumb and little fingers. Proximally, the dorsal and plantar skin incisions are usually outlined in a circular or "V" shape.

The same guidelines described for harvest of the second toe are used to dissect the wraparound flap but with an emphasis on skeletonization of the neurovascular bundle. The distal phalanx of the second toe is always included, and the tendons are cut close to their insertion. The remaining portion of the toe is disarticulated at the metatarsophalangeal joint to close the wound and provide an aesthetic appearance.

Pulp and Web Space Neurosensory Flaps

Indications

Pulp-free flaps from the great toe or second toe are appropriate for large finger pulp defects that cannot be covered with local

FIGURE 47.15 **A**, After an avulsion injury of the ring and little fingers, there is circumferential loss of skin and nails with an intact skeleton, tendons, and proximal interphalangeal joint. **B, C**, Results six months after reconstruction with bilateral second-toe wraparound flaps.

or regional flaps (Figure 47.16), or when the use of such flaps may create unacceptable donor site morbidity or restrict global function of an already compromised hand. Although local flaps have many indications for repairing pulp defects, under certain conditions they may be inconvenient because of limited mobility, size, position, and time of immobilization. In addition, the anatomic features of the pulp cannot be imitated by other tissue; specialized skin with rich sensory innervation is unique to the fingers and palm, and, ideally, any defect in these surfaces should be repaired with "like tissue."[2,16,25,41,44,60,68]

Pulp flaps are also a good choice when sensory recovery is essential for proper hand function and protection. Although pulp-free flaps are best to use for thumb reconstruction, they also are useful for other finger defects in patients with special jobs or hobbies that require critical sensation in all fingers (e.g., artist, musician).[55]

In cases where regenerating axons are too far from the injured surface or local sensory neurotization cannot reliably be expected, pulp flaps are an excellent alternative. In addition, they may be utilized to replace skin grafts or local flaps previously used for pulp reconstruction that resulted in an unstable or painful scar.[103]

The neurosensory first web space free flap is an alternative option. A good indication for this flap would be a soft tissue defect in one finger (Figure 47.17). It is also appropriate when thin, glabrous soft tissue is needed, as in the palm with minimal subcutaneous tissue.[3,23,33,41,51,65] A flap extending to the tip of the great and second toes can be as wide as 7.3 cm and as long as 14 cm (Figure 47.18). Adjacent fingers with contiguous defects in the pulp or in the proximal ventral aspect can be reconstructed with one first-web neurosensory flap and a temporary syndactyly, which is divided later.

The first web receives its blood supply from the distal communicating artery that connects the FDMA and FPMA. If the design of the flap includes an extension to the lateral aspect of the great toe or the medial aspect of the second toe, the respective digital arteries should be included in the pedicle dissection. Innervation of the dorsal aspect is provided mainly by the deep peroneal nerve and, to a lesser extent, the superficial peroneal nerves. However, when a wider flap with extension to the pulp of the great or second toe is desired, the respective common digital nerves in the plantar aspect also should be included.

Flap Design and Elevation

Pulp Flap. The great toe is selected more often than the second toe as a donor source of pulp flaps for the following reasons: the great toe has better superficial sensation than the second toe (two-point discrimination, 7-18 mm vs. 10-25 mm)[2]; more donor tissue can be obtained from the great toe; and it is possible to directly close the donor defect, speeding recovery and resulting in less morbidity.

The flap can be designed on the lateral aspect of the pulp in the great toe or the medial hemipulp in the second toe and extended to the first web space proximally, depending on the size of the defect in the recipient finger. The deep peroneal nerve supplies these surfaces, and its sensory innervation overlaps with that of the corresponding proper digital nerves; thus, two nerves always need to be included with a hemipulp flap from either of these two toes. The skin incisions are outlined according to a template of the recipient site defect or a drawing of the finger defect on the surgeon's corresponding finger to compare with the patient's toe. Outlining the incision for dissection of the pedicle follows the course of the proper digital artery to the great or second toe in continuity with the FDMA and FPMA in the first web space.

During elevation of the flap, special care should be taken to dissect all superficial veins on the lateral and dorsal surface of the great toe in continuity with one sizable vein. Next, the dominant artery to the great and second toes is localized in the first web space and dissected in a retrograde fashion. All small

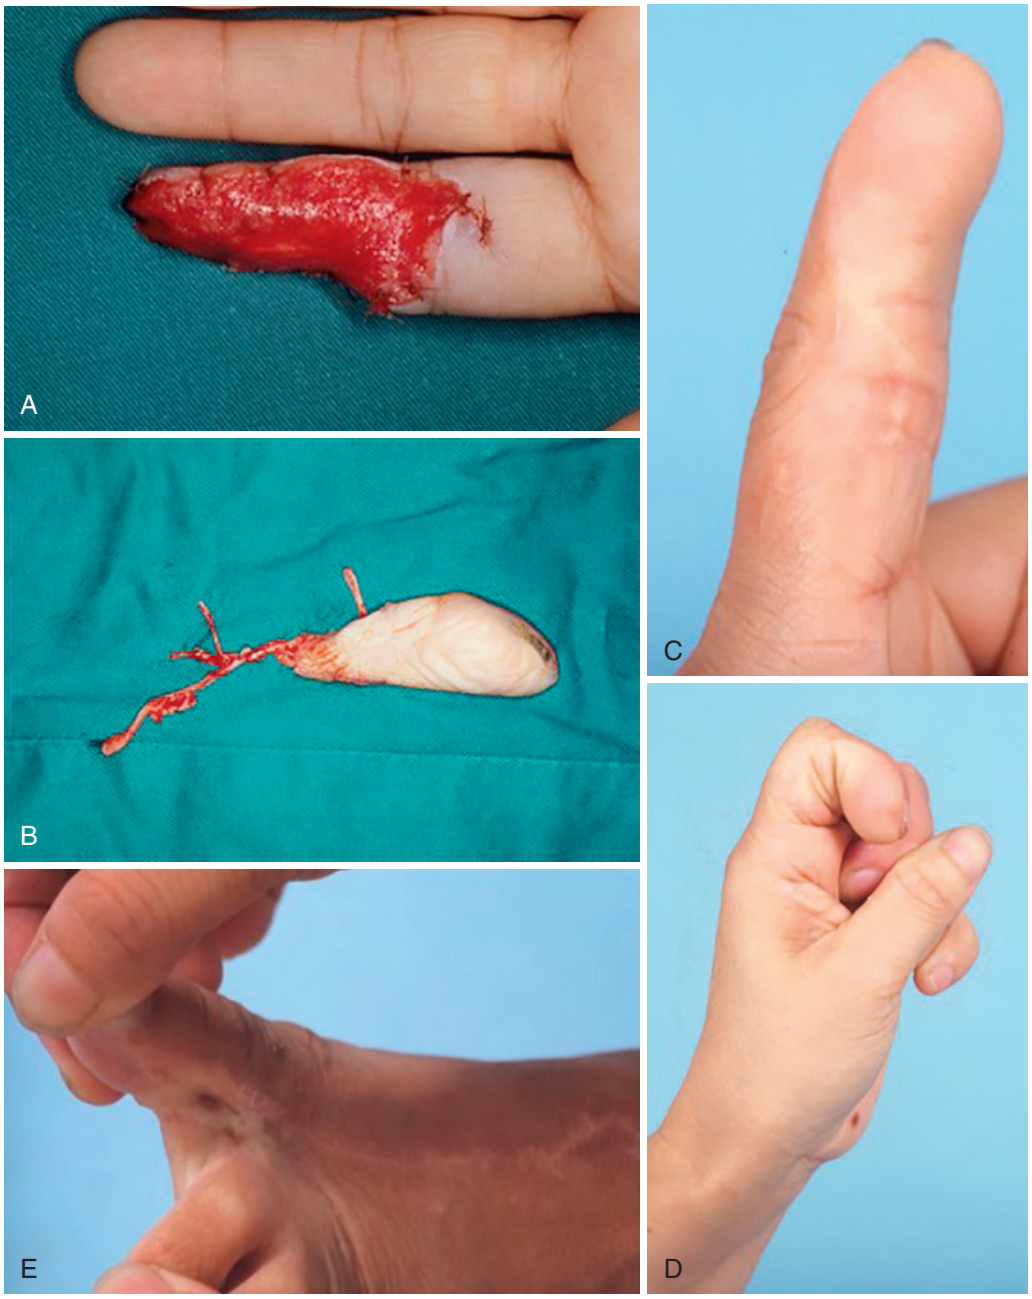

FIGURE 47.16 **A**, Avulsion injury of the index finger involving skin and subcutaneous tissue in the palmar aspect. **B**, Hemipulp free flap from the great toe. **C, D**, Final results showing full flexion and extension of the reconstructed finger. **E**, Donor site appearance after primary closure.

arterial branches must be skeletonized (see Figure 47.16, *B*) to facilitate passage of the vessels in the subcutaneous tissue during insetting of the flap.

When primary closure of the defect is not possible, a split-thickness skin graft (usually from the instep area) is required to close the donor site defect. Because delayed healing of the toe can prolong foot recovery and affect walking, skin grafting of the donor site should be performed with the utmost care.

First Web Space Neurocutaneous Flap. The flap is outlined according to the size of the defect in the hand. The posterior border of the flap is incised first, and the incision is extended in a lazy "S" fashion over the dorsal surface between the first and second metatarsals to the level of the metatarsal head. After isolating one sizable vein draining the flap, the artery is dissected distally over the intermetatarsal ligament. When the FDMA is dominant, retrograde dissection of this artery in continuity with the dorsalis pedis artery is straightforward. The deep peroneal nerve lies beside the artery along its course, under the extensor retinaculum proximally. The rest of the island flap is readily dissected. If the FDMA is very small or absent, elevation of the island flap starts on the plantar aspect of the web space where the FPMA is localized. From this point, the artery is dissected in a retrograde fashion until the desired length is

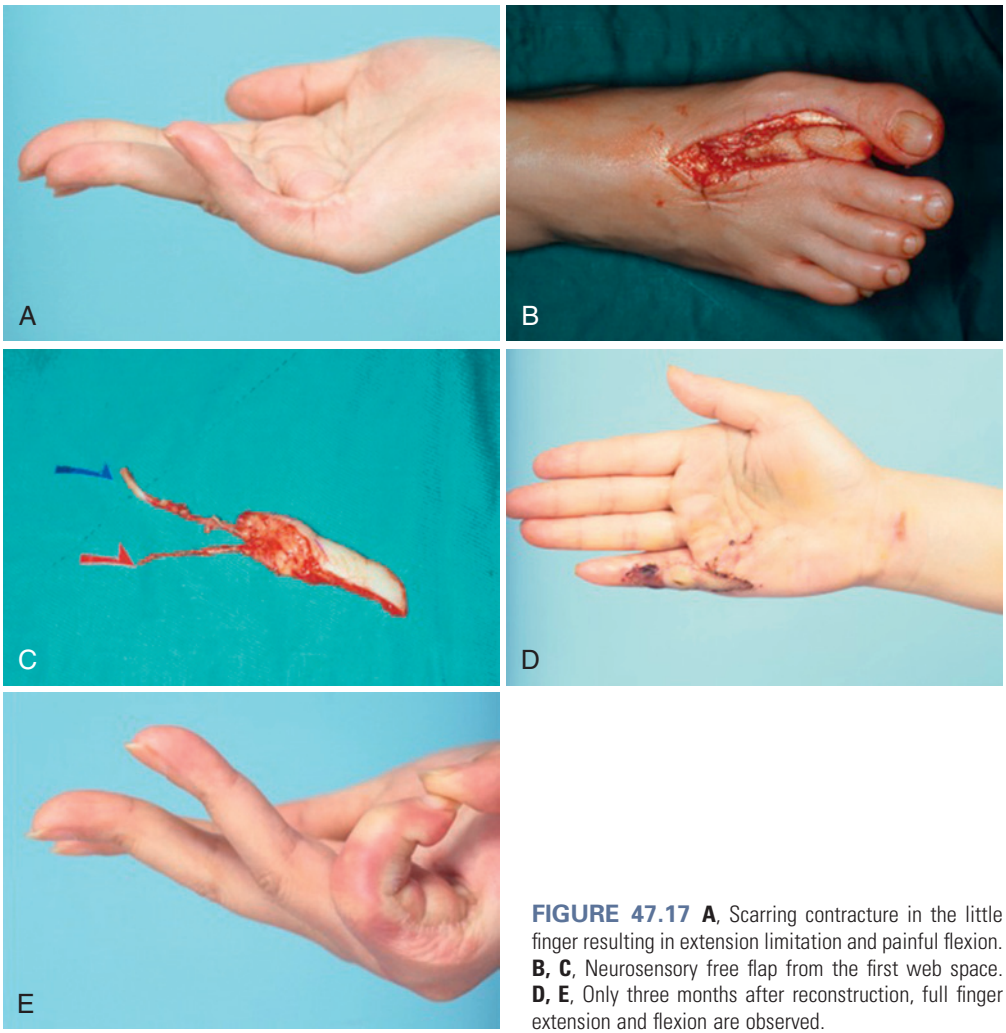

FIGURE 47.17 **A**, Scarring contracture in the little finger resulting in extension limitation and painful flexion. **B, C**, Neurosensory free flap from the first web space. **D, E**, Only three months after reconstruction, full finger extension and flexion are observed.

FIGURE 47.18 A large neurosensory skin flap harvested from the first web space can include the lateral aspect of the great toe and the medial aspect of the second toe.

obtained; if the vessel is too short, a vein graft can be used for the vascular anastomosis.[107] There is no need to abandon the procedure if the FDMA is not present. A split-thickness skin graft is used to close the donor site and is sutured in place with a tie-over dressing.

Vascularized Nail Graft

Indications

Microvascular nail transplantation is performed to ensure adequate blood inflow to the nail bed.[46,67,76] In contrast to nonvascularized nail grafts, these usually "take" better and provide adequate function and a superior aesthetic appearance. Vascularized nail grafts may be used for fingertip injuries involving the nail bed or for nail reconstruction after tumor excision. They are also a good option for replacement of nail deformities that are painful or aesthetically unacceptable to the patient (e.g., posttraumatic hook nail deformity). In most instances there is damage or loss of adjacent tissue such as the eponychial fold, pulp, and skeleton (Figure 47.19).

Technically, it is easier to transfer the whole second or third toe distal to the middle of the middle phalanx instead of trying to use nail segments with small flaps that may compromise venous outflow.[44] Whenever a larger amount of soft tissue is included with the transplanted toenail, a variable amount of normal tissue might need to be removed in the recipient finger for proper insetting.[21]

Flap Design and Elevation

The great toe usually matches the thumbnail better and may be trimmed to fit fingernails as well. Still, it is used infrequently

FIGURE 47.19 **A**, Middle and ring fingertip amputation covered with a pedicled flap. The patient's major complaint was anesthesia and nail absence in the middle finger. **B** through **D**, Results after nail reconstruction of the middle finger with partial second-toe transplantation, including the whole of the distal phalanx. Comparative views with the other intact digits are presented. **E**, Radiograph showing fixation in the middle phalanx with intraosseous wiring.

because of the secondary deformity created in the donor foot. Although the second toenail is somewhat smaller than a fingernail and has a squared shape, it looks similar to the finger counterparts, and the resultant donor defect in the foot is minor.[76] The design of the dorsal skin flap, including the toenail, should incorporate the small veins on the dorsal surface of the toe. Usually the dorsal skin flap extends from the eponychial fold up to the IP joint in the great toe and to the PIP joint in the second toe. The entire width of the nail, including both lateral eponychial folds, is harvested. The size of the pulp tissue taken is determined by the size of the defect in the finger pulp. However, for inclusion of the dorsal proper digital artery, more than half of the pulp on the medial side of the second toe (or the lateral side of the great toe) must be harvested with the vascularized nail graft. If the entire distal segment of the finger needs reconstruction, a second-toe wraparound flap is a better option (see earlier description). The proper digital nerve is included to restore nail sensation and function.

Dissection of the artery is similar to the technique described previously in the "Anatomy for Toe Dissection" section. It is

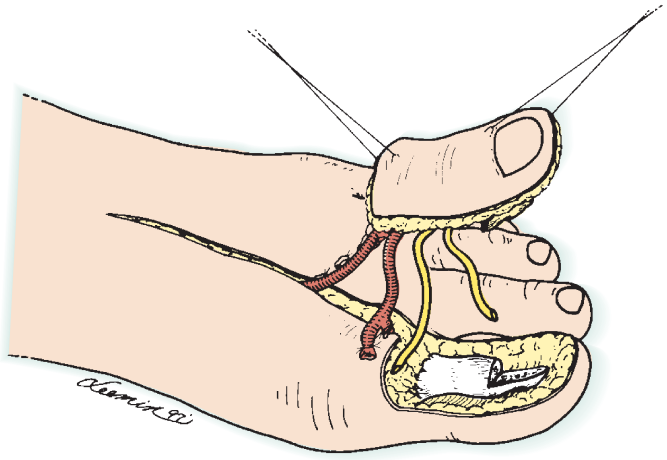

FIGURE 47.20 Vascularized nail transfer from the great toe. The nail bed is harvested through a transverse osteotomy in the distal phalanx.

important to emphasize that the small veins on the dorsal surface of the distal toe should be carefully dissected in continuity with one sizable vein tributary of the saphenous venous system to ensure dependable venous return.

After raising the dorsal flap, the extensor tendons are exposed and divided close to their insertion. Next, the nail is harvested together with the entire distal half or dorsal distal half of the distal phalanx by a transverse osteotomy of the great toe (Figure 47.20), or by including the entire distal phalanx or the entire dorsal half of the distal phalanx after DIP joint disarticulation in the second toe (authors' preferred method). In either case, the periosteum should be left attached to the nail and the skeleton exposed after reflecting the pulp flap from the distal phalanx on the plantar surface. Before doing the osteotomy, the artery, vein, and nerves in the pedicle should be protected from potential injury.

Morrison described technical modifications in which the width of the great toenail is decreased by trimming the lateral edges of the nail matrix.[67] In the great toe, the donor site defect can be closed with a cross-toe skin flap, which is divided two weeks later. In second- or third-toe vascularized nail grafts, proximal metatarsophalangeal disarticulation is favored because of the possibility of direct closure and the better appearance of the donor site. Nevertheless, if the patient's desire is to preserve the remaining toe, cross-toe skin flaps from the adjacent toe can be used to close the defect. Whenever a cross-toe flap is planned, the risk of complications and potential morbidity should be considered.

Transplantation of the Third Toe

Indications

Single transplantation of the third toe to the hand is indicated when (1) the second toe is not available or is not suitable for transfer because of previous injury, surgery, or deformity; (2) the second toe is on the same foot from which the great toe was removed (usually for thumb reconstruction in bilateral metacarpal hands) and the second toe is therefore spared for gait; and (3) the third toe provides a better size match for finger reconstruction than the second toe.[108]

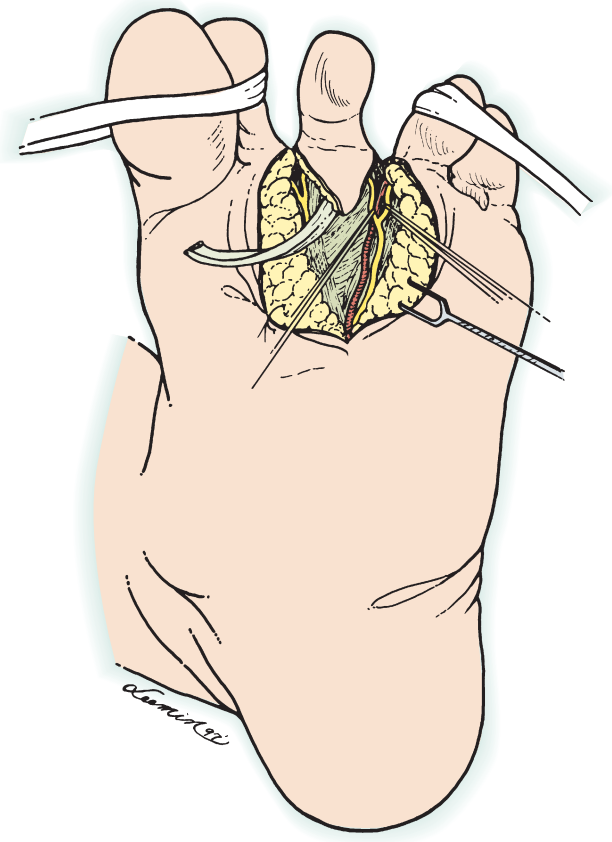

FIGURE 47.21 Dissection of the third toe depicting the third common plantar digital artery and nerve in the plantar surface.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Preoperative planning and the operative technique are similar to that for transplantation of the second toe. The third toe receives its blood supply from the second and third dorsal metatarsal arteries and the second and third plantar metatarsal arteries. Because the majority of patients undergoing transplantation of the third toe have already had or will undergo transplantation of the great or second toe, the second metatarsal pedicle is either not available or must be preserved for subsequent transfer of the great or second toe. Therefore, transfer of the third toe is usually based on the third common plantar digital artery (Figure 47.21).[108] Although this artery might be small, it is usually larger than the second or third dorsal metatarsal arteries. It is simpler and quicker to proceed directly to dissection of the plantar vascular pedicle and, if necessary, to use a vein graft for the vascular anastomosis. In most cases, however, the pedicle is long enough to reach the proper digital artery in the proximal phalanx. The donor site is closed in the same way as described for the second toe.

Combined Transplantation of the Second and Third Toes

Indications

Combined transplantation of the second and third toes is indicated for reconstruction of two adjacent fingers after traumatic amputation proximal to the digital webs.[100] With this approach, tripod pinch function, hook–grip capability, and greater lateral

stability are the result.[83,94,99,100] Additional advantages of combined transplantation of the second and third toes over bilateral transplantation of both second toes include the following:

- Only a single set of recipient vessels is required—a potentially significant advantage for severely injured hands
- Less operative time is required
- Potential morbidity in the donor site is limited to one foot, thus allowing earlier postoperative ambulation

Nevertheless, because of its length limitation, a combined transplant cannot be expected to accurately simulate the functional capabilities of full-length fingers, particularly in point pinch and arch of grasp (Figure 47.22). Optimal function is attained when the reconstructed fingers and the remaining fingers are relatively uniform in length, with the distal tip of the normal little finger used as a guide.[100] If the remaining digits extend beyond this point, tandem transplantation of the second and third toes will take less time and contribute less to smooth prehension.

The level of digit amputation is used to determine the osteotomy level of the second and third toes. If 5 to 6 mm of length is present in the proximal phalanx of the fingers, the toe osteotomy should be at the proximal phalanx. The toes are harvested through metatarsophalangeal joint disarticulation (see Figure 47.22, *C*); the bases of the proximal phalanges are shortened during toe insetting, and the periosteum is elevated to the osteotomy level. During subperiosteal dissection and osteotomy of the phalanx, all anatomic structures in the toe must be protected from injury, and excessive manipulation of the neurovascular pedicle should be avoided. Active range of motion in the MP joint of the reconstructed fingers will be similar to that observed in intact MP joints.[100]

If the cartilage surface in the metacarpal heads and the joint capsule and ligaments are intact, the tandem toes are transplanted together with the respective metatarsophalangeal joint capsule and ligaments for composite joint repair in the hand. In this case, active range of motion averaging 52 degrees (range, 30-80 degrees) can be expected.[91] In addition, when the toes are disarticulated at the metatarsophalangeal joint, the metatarsal heads and arch are preserved in the donor foot, which is important for an even weight-bearing surface and prevention of a "scissors deformity" in the donor foot.[100]

In a more proximal transmetacarpal amputation, both toes can be harvested with a transmetatarsal osteotomy. It was previously suggested that the bony arch be reconstructed with a nonvascularized bone graft after transmetatarsal amputation of both toes.[100] However, this approach is no longer recommended because no functional difference was found in a recent biomechanical gait analysis (unpublished) or in our clinical observations when no bone grafts were used to reconstruct the metatarsal defect.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Formerly, radial digit amputations were reconstructed by using combined transplantation of the second and third toes from the contralateral foot, whereas the ipsilateral toes were used for the reconstruction of ulnar digit amputations, with the aim of placing the longer second toe in a more acceptable central position.[83,100] Nowadays, when only one second- and third-toe combination is needed, we always harvest the tandem toes from the left foot because more demand is placed on the right foot in daily ambulatory activities. The right foot is selected only when the left foot is not suitable, such as when the great toe from the same foot has been or will be used for thumb reconstruction in multiple toe transplantation cases (see Figure 47.7). Skeletal length in the digits can be adjusted by the level of osteotomy in

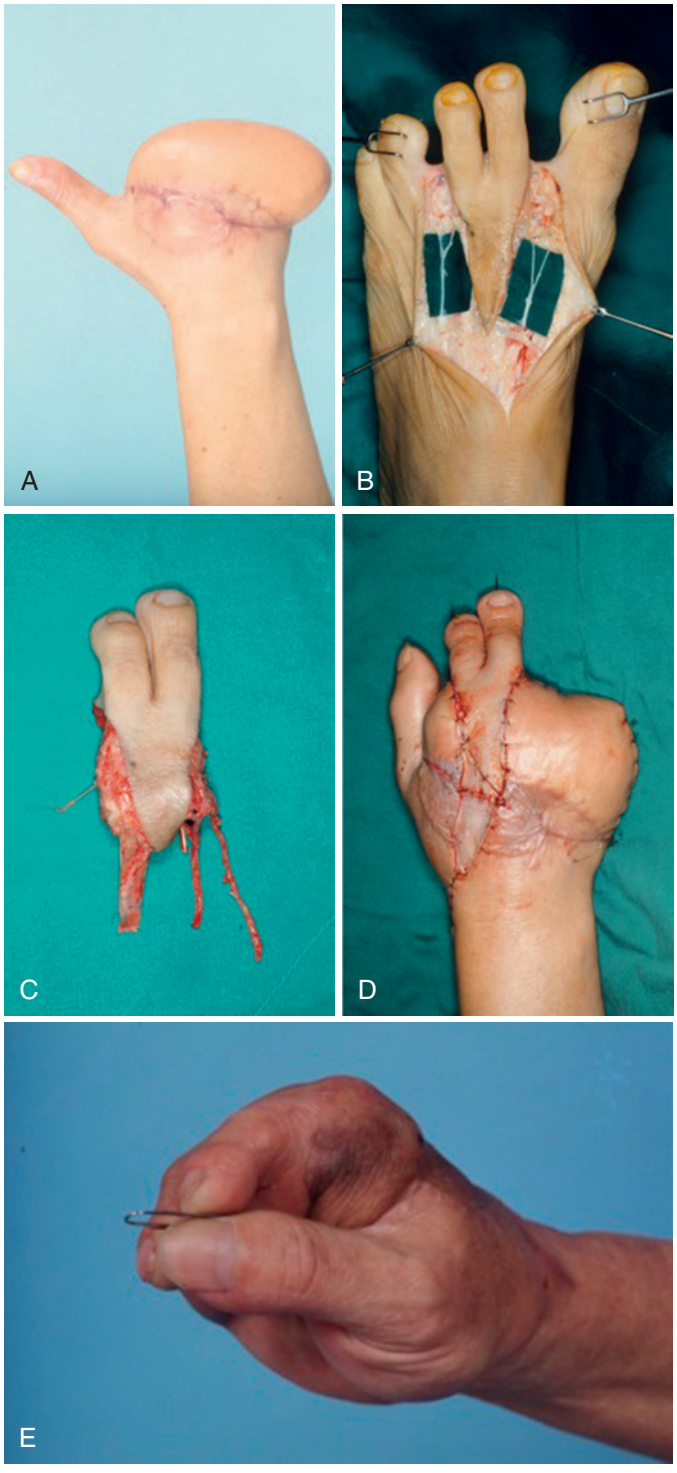

FIGURE 47.22 **A**, Metacarpal hand subtype IB. **B**, Dissection of branches of the superficial peroneal nerve in the first and third metatarsal spaces. The width of the "V"-shaped dorsal skin flap should not extend beyond the midpoint in the first web and the third web. **C**, Tandem second and third toes disarticulated in the metatarsophalangeal joint. **D**, Immediate result after inset of the transplanted unit for reconstruction of the radial fingers. **E**, Fourteen months after reconstruction, tripod pinch is adequate.

the proximal phalanges or metacarpals and the toe phalanges or metatarsals.

Skin flaps with a "V" shape are outlined on the dorsal and plantar aspects of the second and third toes. The skin incisions should not extend beyond the midpoint of the first and third web space in the foot (see Figure 47.22, *B*). By including narrow skin flaps with the toes, it is always possible to close the donor site directly without tension.

Dissection of the flap starts on the dorsal aspect of the foot, with isolation of one donor vein going to the saphenous venous system connecting all draining small veins from the second and third toes. Then the first web space is dissected to identify the dominant vascular pattern to the second toe (see "Anatomy for Toe Dissection" section). The branches of the superficial peroneal nerve to the second and third toes are dissected free (see Figure 47.22, *B*). After isolating the vessels and nerves on the dorsal surface, the extensor tendons to the second and third toes are raised and cut. To preserve the vessels communicating between these two toes, it is advisable to avoid excessive manipulation of the soft tissue connections in the second web space, especially when the bone is dissected distal to the metatarsophalangeal joint.

Next, the plantar skin flap is raised to the base of the proximal phalanx in both toes, and all fibrofatty tissue under the skin and over the plantar neurovascular bundles is carefully removed. The following three nerves are identified on this surface and included in the surgical unit:

- The proper digital nerve to the second toe, which is found in the medial aspect of the second toe
- The second common digital nerve to the second and third toes, which is located between the two toes
- The proper digital nerve to the third toe, which is in the lateral aspect of the third toe

The senior author and his colleagues assessed the arterial blood supply in 57 combined transplantations of the second and third toes in 54 consecutive cases.[13] Reexploration secondary to arterial insufficiency (i.e., vasospasm or thrombosis) was required in almost 20% of cases after revascularization using the dominant artery. Therefore, our current tendency is to preserve the second and third common plantar digital arteries and use one of these two vessels for a second arterial anastomosis, especially when arterial perfusion to the third toe is uncertain.

The osteotomy site is exposed in both toes, and all anatomic structures except the main vascular pedicle are divided and dissected a few millimeters distal to the osteotomies. The two phalanges are cut or disarticulated, and the tandem toes are allowed to reperfuse for at least 20 minutes before being transplanted. The incisions should always be closed without tension. Skin grafting on the donor site is unacceptable and can lead to severe complications in the foot.

Combined Third and Fourth Transplantation

Indications

The indications for combined third- and fourth-toe transplantation are similar to combined second- and third-toe transplantation in purpose (i.e., to establish tripod chuck pinch in the metacarpal hand with multiple-finger amputation that is proximal to the digital web); however, this combined transfer is an alternative to the combined second- and third-toe transfer and appropriate when the second toe is spared either for gait or for thumb reconstruction (i.e., in proximal thumb amputation). Another indication is when the second toe is not available or is unsuitable because of previous surgery, injury, or deformity.[82]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

The combined third and fourth toe is harvested in a similar manner to the combined second and third toe except for the following. Skin incisions are begun in the second and fourth web spaces, converging proximally to the shape of a "V" skin flap. Although the plantar system is more constant than the dorsal system, dissection starts dorsally in the second web space to identify the junction of the lateral digital artery of the second toe and the medial digital artery of the third toe. Once identified, the vessel is traced proximally to assess the second dorsal metatarsal artery. If present and of adequate caliber, further dissection to the level of the arcuate artery or the dorsalis pedis artery is done based on pedicle length requirements. If the second plantar metatarsal artery is absent or of inadequate caliber, dissection starts plantarward to identify the second or third plantar metatarsal artery.

In case of a previous injury to the second toe or when subsequent ipsilateral second-toe transfer is planned, the third plantar metatarsal artery is preferred. It is advisable in this transfer to include a "lifeboat" vessel, which is the fourth plantar metatarsal artery, because perfusion across the third web space based on a single pedicle is uncertain. All plantar metatarsal arteries are dissected no further than the level of the midtarsal shaft to minimize damage to the foot. The senior author advises that two arterial anastomoses be performed for safety; however, the decision should be made intraoperatively when any sign of arterial insufficiency is present.[10,82]

Combined Triple-Toe Transplantations

Triple-toe transplantation from the same foot, such as combined second, third, and fourth toes or combined third, fourth, and fifth toes, has been reported in the literature as case studies and mainly for the reconstruction of a bilateral metacarpal hand.[8] For these extreme transfers, the patient's level of motivation and job requirements must be carefully considered because the donor site can be problematic. Foot deformity is very conspicuous, but functional impairment is not significant when these combined toes are removed properly.

Recipient Site Preparation

A surgical approach with one team preparing the recipient site and another harvesting the toe provides several advantages:

- The proper length of all anatomic structures included in any flap from the foot can be verified before being divided.
- There is no need for extensive dissection of the foot, resulting in less morbidity in the donor site.
- Operative and anesthetic times are considerably reduced, leading to less fatigue for the patient and surgeons.

Routinely, the recipient site is prepared under a bloodless field with conventional tourniquet control, and the dissection is performed with the aid of loupe magnification.

Skin Incisions

The amputation stump is always cross-incised to create four skin flaps for exposure of the bone, tendons, and distal nerves.

The skin flaps are sufficiently undermined, and the redundant fatty tissue is properly trimmed to obtain thin skin flaps with wide mobility over the stump skeleton (see Figure 47.14, *A*). Flexibility in mobilizing the skin flaps off the underlying structures is very important for shaping them to fit smoothly with the triangular skin flaps of the toe during insetting.[94] The recipient artery can be identified by using a separate incision on the ulnar side of the proximal phalanx or distal palm, especially in distal finger reconstruction, or by extending the stump incisions proximally to this area. A separate incision in the snuffbox is usually made if the radial artery is selected. This incision must be connected with the digital stump through a wide subcutaneous tunnel to allow passage of the donor vessels without compression; otherwise, it is better to open the skin between the two incisions.

Bone and Joint Preparation

Periosteal dissection should be minimal to expose the fixation site in the recipient bone. The bony surface of the stump is smoothed to provide good contact and stability, which are essential for adequate bone union (Figure 47.23). Whenever it is going to be repaired, the joint capsule and ligaments must be carefully dissected while exposing the cartilage surface.

Tendon and Pulley Preparation

Usually the extensor tendon is located close to the bony stump, and every effort should be made not to detach it (especially in distal finger reconstruction) because extensor mechanism integrity is essential for finger function. The flexor tendons have various locations in distal and proximal finger amputations, and the pulley system must be preserved while exposing the tendon. To achieve a functional result, it is critical to have good tendon excursion, so all tendon adhesions should be removed at this stage if necessary.

Most tendons can be repaired at the midpalm level, with enough distance left from the tenorrhaphy site to the A1 pulley for smooth excursion. In distal finger reconstruction, the insertion of the FDS must be carefully exposed, together with the flexor digitorum profundus (FDP) over the middle phalanx shaft level. It is seldom necessary to repair the flexor tendon at the wrist level. If no flexor tendons are available, the FDS tendon from the adjacent finger can be transferred first.

FIGURE 47.23 Recipient site preparation. The distal end of the bone is regularized to attain stability and good bone contact with the transplanted toe.

Nerve Preparation

The proper or common digital nerves, in most cases, are close to the edge of the stump of distal finger amputation, and these are used for neurorrhaphy with the transferred toe. In deciding the proper site for neurorrhaphy in a normal or relatively normal recipient nerve, the appearance of the fascicles under the microscope is a good guide. More proximal recipient nerves in the palm, including the palmar cutaneous branch of the median nerve and dorsal sensory branches of the ulnar nerve, may be selected if the distal nerves have been avulsed. Nerve transfers from the ulnar side of the long or ring finger, or sensory branches of the superficial radial nerve on the dorsum of the hand, may be used as well.

Vessel (Artery and Vein) Preparation

The proper digital arteries at the proximal phalanx level can be used for anastomosis in distal finger reconstruction. Because of its larger size, the proper digital artery on the ulnar side is selected more often than the proper digital artery on the radial side. Common digital arteries in the palm are a good option for more proximal amputations, provided the arterial arch in the hand was not involved in the initial injury. The recipient arteries should be meticulously dissected and the adventitial layer stripped off to avoid postoperative vasospasm. If these vessels are too small for vascular anastomosis, it is advisable to select a larger artery (e.g., the radial artery in the anatomic snuffbox or the princeps pollicis artery). Vein grafts should be considered, if the donor artery is short (e.g., in a plantar-dominant system) or if the proximal arteries are required for anastomosis, rather than struggling to increase the length of the donor artery in the foot or anastomose the vessels under tension.

One vein is generally dissected on the dorsal aspect of the hand and used as a recipient vessel. More proximal veins can easily be mobilized when these are not found distally.

Toe Fixation Technique

Usually, the following sequence is suggested for insetting the transplanted toe.

Skeletal Fixation

In toe-to-hand transplantation, intraosseous wires, Kirschner wires, and rigid fixation systems have been used for bone fixation.[26,84,85,115] In addition, an intramedullary bone peg can be used in combination with wires.[52] Parallel or coronal and sagittal intraosseous wiring is used frequently. In the experience of Yim and the senior author with parallel intraosseous wiring in 68 toe-to-hand transplants in 47 patients, an overall nonunion rate of 1.5% was observed after a mean follow-up of 30

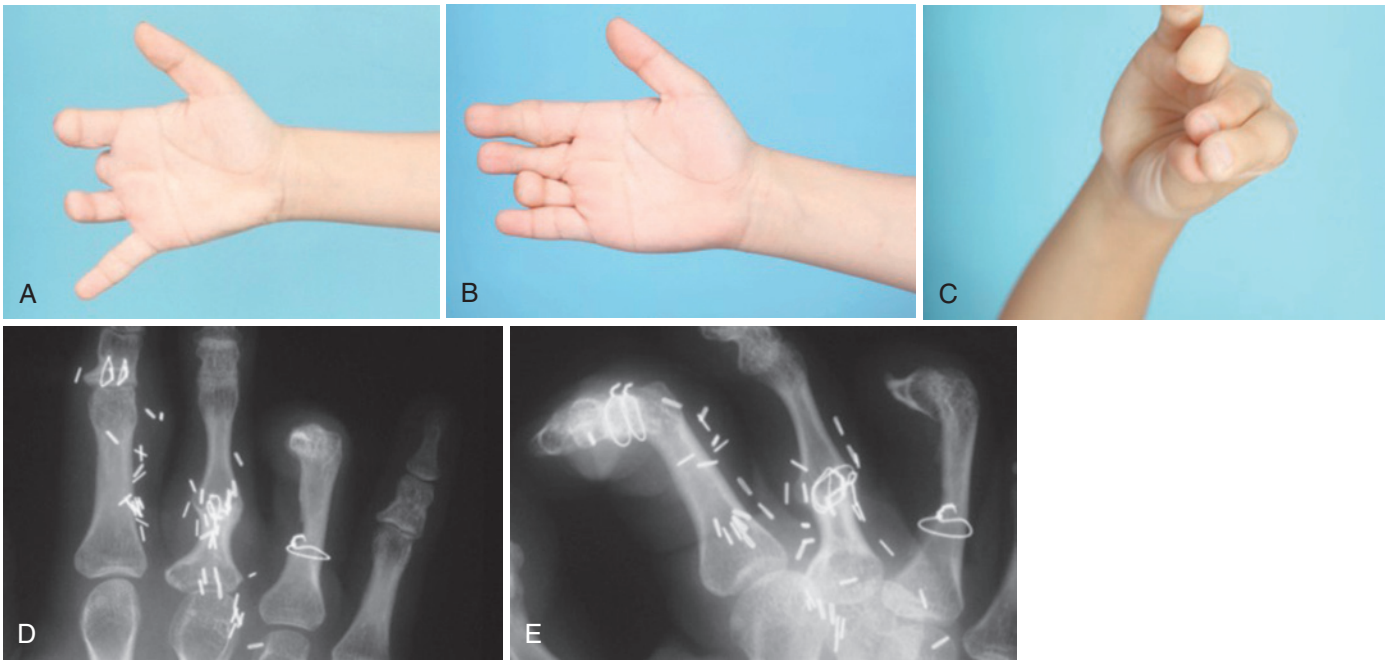

FIGURE 47.24 **A**, Multiple-digit amputation. **B, C**, Adequate tripod pinch after index finger reconstruction by partial second-toe transplantation and middle finger reconstruction by total second-toe transplantation. **D, E**, Radiographs with the index finger under extension and flexion eight months after surgery. In the index finger, 3 mm of proximal bone in the middle phalanx was used to fix the toe and preserve the proximal joint.

months.[115] Some of the advantages of this technique include the following:

- Stability is provided for early mobilization, thus preventing tendon adhesions and improving the overall range of motion in the reconstructed digit (Figure 47.24).
- Any slight angulation and malrotation can be corrected with appropriate splints during the early postoperative period (Figure 47.25).
- It is a simple, quick, and inexpensive method.
- It can be applied to a stump of phalanx as short as 5 mm (see Figure 47.24, *D*) so that the intact proximal joint can be preserved.

For intraosseous wiring, 2 mm of healthy bone between the holes and the bony edge in the skeleton stump is enough for bone healing. Two parallel 1-mm holes are made through both cortices in the distal part of the bony stump in a dorsal-to-volar direction. After placing the toe in its proper position, the angle and rotation of the toe are determined, and two parallel holes are drilled in the toe's phalanx. Next, 2-0 (28-gauge) stainless steel wires are introduced through the corresponding holes and twisted while the position of the toe is carefully adjusted. The wire ends must be placed away from the gliding extensor tendon to avoid tethering.

For composite joint repair, the volar plate and collateral ligaments of the toe are attached to the corresponding structures on the finger with nonabsorbable sutures.[78] The volar plate has to be repaired with proper tension to prevent postoperative hyperextension of the joint. This technique has been used primarily with combined transplantation of the second and third toes.[78]

Tendon Repair

After fixing the bone, the extensor tendon is repaired. It is sutured with the PIP and MP joints in full extension to minimize flexion deformity. The extensor longus tendon of the toe is sutured to the extensor of the finger using the weaving method with nonabsorbable sutures. Next, the long flexor tendon of the toe is sutured to the proximal FDP tendon stump as follows. In distal finger amputations, the FDP is repaired only to provide stability in power pinch because the insertion of the FDS is intact. So, when the proximal FDP stump is located distal to the FDS insertion, it is directly repaired; however, if the FDP stump is not present distally, the flexor tendon of the toe can be sutured to the distal portion of the FDS insertion. On the other hand, in proximal finger amputations, only the FDP is repaired, usually in zone 3, to prevent entrapment of the tenorrhaphy site by the remaining pulleys during tendon excursion. The tension between both tendons should be adjusted so that the finger forms a natural cascade with the other digits. We recommend tight extensor tendon repair and night splint application with the finger in full extension for at least a year to minimize claw deformity.[21,94]

From experience with second-toe transfer, PIP joint extensor lag is a common problem that limits the joint's range of motion.[9] At our institute, we studied the anatomy of the extensor mechanism of the lesser toe and found that the central slip of it has two different arrangements: either attenuated (type I lesser toe) or distinct central slip (type II lesser toe). In type I toes, traction on the extensor digitorum brevis and longus did not correct the extensor lag. The extension lag decreased when the metatarsophalangeal joint was flexed passively or when both extrinsic and

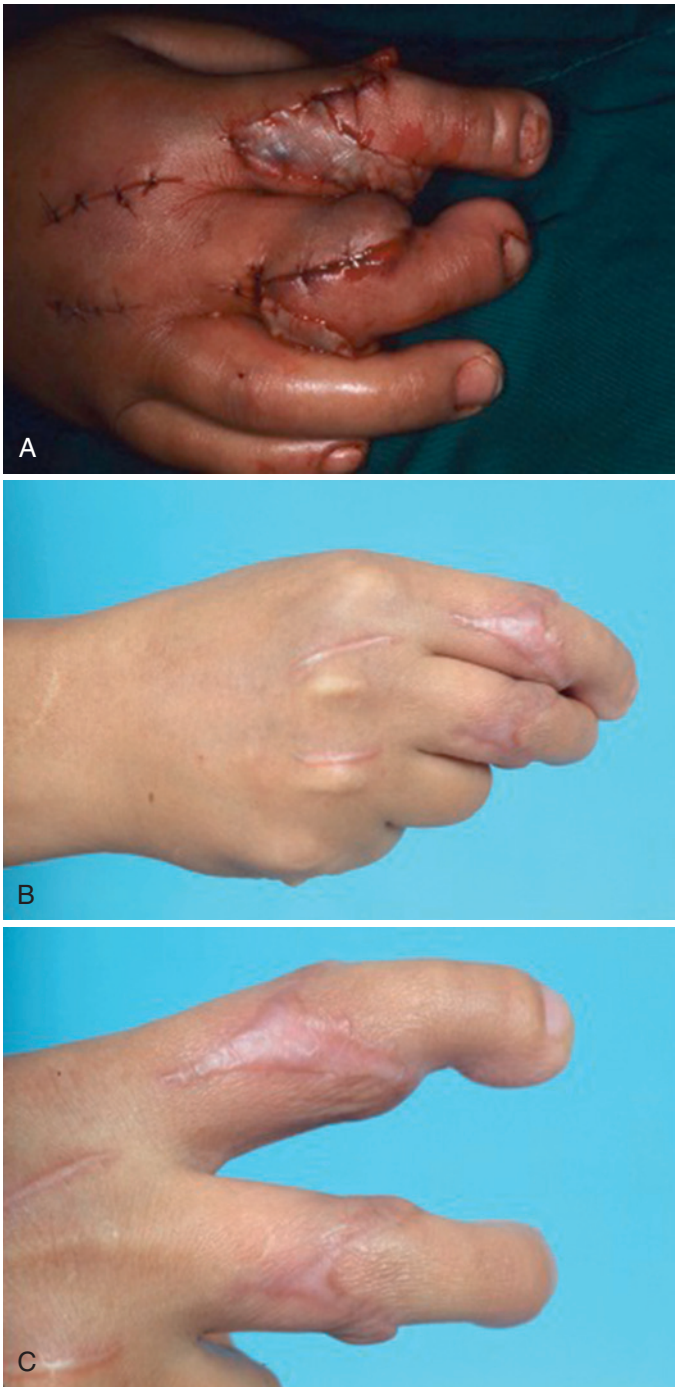

FIGURE 47.25 **A**, Bilateral second-toe transplantation. Immediately after surgery, significant rotation of the toe to long finger is observed. **B**, **C,** After rehabilitation therapy good alignment of the transferred toe has been achieved.

intrinsic tendons were pulled simultaneously. In type II toes, a full extension of the proximal interphalangeal joint was achieved when the extensor tendons were pulled with or without pulling the intrinsic tendons.

Using this information, an algorithm was constructed for a series of nine patients: (1) in a type I toe with sufficient recipient lateral bands, a centralization procedure was carried out; (2) when the lateral bands were insufficient, a modified Stack procedure was carried out. In type II toes, a tight repair of the corresponding extensor tendons was performed. The study demonstrated a total range of motion of 53.9 degrees (mean flexion, 72.2 degrees) that approximated 81.1% of the pretransfer passive range of motion at the toe proximal interphalangeal joint. These preliminary results are encouraging for wider application in lesser toe transfers.[50]

Nerve Repair

The nerves are coapted in an end-to-end fashion with 10-0 nylon. Usually only the proper digital nerves are repaired; however, if enough recipient nerves are available, the deep and superficial peroneal nerves can be individually repaired. When only one digital nerve is available proximally, various toe nerves can be sutured together with this nerve, with priority given to the proper digital nerves.

Skin Closure

The skin is adjusted and temporarily closed after ending the neurorrhaphies and before performing the vascular anastomoses. This minimizes swelling and tension during wound closure immediately after reperfusion. The four skin flaps built in the recipient stump are tailored and interposed with the triangular flaps of the transferred toe to create a smooth surface. Inadequate skin coverage in toe transplantation is a major cause of complications. Conversely, a "cobra deformity" may result when redundant skin is left at the junction between the transplanted toe and the digit, and excessive fatty tissue is a common cause of a bulbous appearance with unpleasant results.[94]

Vascular Anastomoses

The arterial anastomosis is performed first. Once completed, the venous return should be observed for several minutes. Whenever the blood outflow proves to be insufficient, the arterial anastomosis and the entire course of the vessel must be reassessed. If perfusion of the toe is suspected (e.g., into the third toe in combined transplantation of the second and third toes), a second artery can be used for anastomosis.[10]

The remaining wounds in the finger are closed, and the vein anastomosis is completed through a separate incision in the dorsum of the hand. If there is some tension while closing the skin, it is advisable to partially close the wound and use skin grafts to cover the remaining raw surface; with adequate preoperative planning, however, tension on the skin during closure is uncommon. Small silastic drains can be used to prevent hematoma accumulation, although contact of the drain with the vascular anastomoses must be avoided.

POSTOPERATIVE MANAGEMENT

The patient is hospitalized an average of five days in the microsurgery intensive care unit, where specially trained nurses can closely monitor the transplanted toe and the patient's general condition. No splints are used; rather, the proximal portion of the palm and wrist is gently wrapped with the fingers uncovered for continuous observation. The hand and forearm are kept slightly elevated atop a smooth support to reduce edema formation. Bulky dressings are not recommended because blood clots may be retained around the wounds, and dressing removal could induce vasospasm. Also, bulky dressings make it impossible to start early postoperative rehabilitation.

Beginning directly after surgery, aspirin (325 mg/d) is administered for two weeks to reduce the risk of platelet aggregation. Dextran was popularly used in the past as a rheologic agent but has lately lost favor because of its risk of systemic complications. When used, a typical dosage is an initial bolus of 100 mL of dextran 40 (low molecular weight) administered intravenously 10 minutes before completion of the arterial anastomosis, followed by a continuous infusion (25 mL/h) during the next 4 to 5 days. Likewise, heparin may be given at the time of the anastomoses and as an intravenous drip postoperatively, but it can cause a hematoma or other bleeding problems that may compromise the final outcome.

Our routine is to avoid dextran and heparin except in cases in which significant trouble was encountered during the anastomoses. Prophylactic antibiotics (cephalosporins) are used in toe transplantation. In prolonged surgical cases or potentially contaminated wounds, gentamicin is added initially, and the antibiotics are subsequently adjusted according to bacterial sensitivity in the event of an infection.

Vascular conditions in the toe are subjectively monitored by direct observation of skin color, turgor, and capillary refill; they are objectively monitored by measurement of the toe's surface temperature in comparison to the adjacent normal finger and opposite hand. In addition, arterial patency is assessed periodically by Doppler ultrasound. Another informative modality is differential pulse oximetry, in which pulse oximeter probes are placed on the transferred toe and another "control" digit; an irregular or lost waveform may signify arterial thrombosis, whereas desaturation is correlated with venous occlusion.[38]

The donor foot is gently covered with nitrofurazone (Furacin)-impregnated gauze over the wound and a light fluff dressing. No splints are used on the donor foot. Two days later the foot is uncovered, and no further dressings are used.

COMPLICATIONS

Vascular Complications

Vasospasm is probably the most commonly encountered complication in toe surgery; it most often occurs during the first three postoperative days. Therefore, vigilant observation and swift intervention are essential for a successful outcome. The smaller the vessel's caliber, the higher the chances are to develop vasospasm; thus, this complication is most likely encountered in distal-digit reconstruction with partial toe transplantation. Vasospasm can affect the flap pedicle, the recipient vessels, or both; because "prevention is the best medicine," precipitating factors should be avoided. These include consumption of caffeinated beverages or chocolate, smoking, cold room temperatures, and/or excessive manipulation of the hand. Prevention necessitates optimal systemic blood pressure throughout the surgery, adequate fluid therapy, and constant analgesia. Furthermore, dissection should be meticulous and bloodless with gentle handling of the delicate vessels, and recipient vessels located away from the zone of injury should always be chosen.

If vasospasm occurs, the following measures can be taken: warm the patient, lower the hand below heart level, and release some skin sutures. Additionally, 2 to 4% lidocaine can be intermittently instilled over the partially opened wounds. However, if no circulation is restored after observation for a reasonable time (1 h), prompt reexploration in the operating room is mandatory.

During reexploration, the hematoma is evacuated, if there is any, and the adventitia is excised. If a constricting adventitial layer or band is found, the vasospasm may be relieved by releasing or removing this. Instillation of 4% lidocaine or papaverine also may be helpful. However, in intractable vasospasm, the spasmodic vessel has to be excised and replaced with a vein graft or a flow-through venous flap.

Similarly, in the case of recipient vessel spasm, vessels at a proximal level and of a larger caliber are used with a vein graft or a flow-through venous flap. The vascular anastomosis is always checked in "takebacks" for thrombosis and revised in cases of thrombus or excised and vein grafted. If preserved, the second or third plantar metatarsal arteries can be used for a second arterial anastomosis in combined second- and third-toe transfer, provided the arterial insufficiency is secondary to inadequate proximal inflow.[10]

Venous thrombosis is uncommon and is usually related to compression of the vein as a result of inaccurate insetting or hematoma accumulation. In the majority of cases, it is possible to salvage the transplanted toe after reexploration.[10,115] However, 3.5% of cases still end in failure.[94,117] The need for reexploration and the possibility of failure must be extensively discussed with and understood by the patient and relatives before surgery, as for any other microsurgical procedure.

If failure occurs, the senior author believes that another toe transfer is possible; however, this transfer should not be done immediately. Instead, a complete evaluation of possible reasons for failure and a thorough discussion with the patient and family should precede the second surgery, and enough time to recover from the failed procedure should be given to the patient and the surgeon.

In planning for toe transfer after a failed initial attempt, and if the second toe was harvested the first time, a second toe or a great toe from the contralateral foot is usually excised. On the other hand, if the great toe was harvested in the initial surgery, the second toe from the contralateral foot should be used to minimize gait disturbance. When patients refuse a second transfer attempt, a salvage procedure with a groin flap,[70] for example, could be proposed, especially if the compromised toe is a great toe.

Other Complications

Skin coverage and wound-healing problems are probably the most common complications in toe-to-hand transplantation. Often these problems are secondary to partial necrosis of the thin skin flaps raised in the toe or at the recipient site, particularly when a groin flap was previously used. When the subjacent tendons and nerves are exposed, immediate action should be taken to provide soft tissue coverage and prevent desiccation of these structures and subsequent sequelae.

SECONDARY PROCEDURES

According to various authors, secondary procedures may be required in 20 to 70% of cases after toe-to-hand transplantation, particularly when the function or aesthetics of the transferred toe falls short of expectations.[13,15,26,31,58,85,101,112,113,116]

In a study of 133 toe-to-hand transplantations in our unit, secondary procedures for functional improvement were necessary in 19 transfers (14.3%) after an average time of 8.8 months.[116] The incidence of secondary procedures on tendon, bone, joints, and soft tissues was 9.0%, 1.5%, 2.3%, and 3.8%, respectively. Tenolysis was the secondary procedure most commonly performed (6.8%), followed by arthrodesis (3.0%) and web space deepening (3.0%). In our experience, secondary procedures yield satisfactory results, particularly flexor tendon tenolysis.

Other secondary procedures are sometimes required after toe-to-hand transplantation. These include tendon and nerve grafts, tenorrhaphies, tendon transfers, osteotomies, and capsulotomies. In addition, small revisions are used for aesthetic improvement after toe-to-finger reconstruction. Pulp-plasties are minor procedures performed under local anesthesia and are used to improve bulbous-appearing reconstructed fingers.[94,109] Scar revisions and "Z"-plasties in the junction between the transplanted toe and the recipient finger are used to correct soft tissue irregularities that result from inadequate tailoring and adjustment of the skin during toe insetting.[94]

DONOR SITE MORBIDITY AND GAIT ANALYSIS

Foot deformity is more evident after resection of the great toe or combined second and third toes than after removal of the second toe alone. Besides the alteration in appearance, a few complications, including hypertrophic scarring and partial skin necrosis, may be observed in the donor foot. Both are usually related to the elevation of very thin flaps to dissect the proximal pedicle in the dorsum of the foot and excessive tension during wound closure because of inadequate surgical planning.

Recently, biomechanical function of the foot before and after harvesting the second toe and combined second and third toes was evaluated at our institution (unpublished study). In 36 patients who experienced removal of the second toe, gait and force plate foot pressure analyses were performed during stance and walking. The results showed slightly increased loading on the first toe during stance, with the third toe becoming unloaded and the first metatarsal more loaded during walking. However, pre- and postoperative comparative results were not statistically significant.

Foot kinetics before and 6 months after combined second- and third-toe transfer were also assessed in 17 patients. The analysis revealed no significant change in gait parameters such as walking velocity, cadence, step length and width, duration of stance phase, and percentage of single- and double-limb support phases. Similar to second-toe harvesting, it was found that excising of the combined second and third toes slightly unloaded the metatarsal region and increased the load on the big toe and, to a lesser extent, the heel; this was seen as adequate compensation for the simultaneous loss of the two toes. Clinically, there were no significant complaints from the patients. It was concluded that transplantation of the second toe or combined second and third toes is associated with minimal biomechanical foot changes and problems. These findings were supported by a study using the Lower Limb Function Questionnaire, in which toe transfer patients had statistically identical scores as normal controls.[13]

Therefore, there should be no hesitation in using this surgical procedure for finger reconstruction in properly selected patients, provided the previously mentioned precautions related to toe harvesting and postoperative care of the donor site are definitely followed.

REHABILITATION

Rehabilitation after toe-to-hand transplantation is aimed at improving motor capability and sensory function of the transplanted toe.[7,62]

Motor Rehabilitation

Early controlled motor rehabilitation not only prevents joint stiffness and tendon adhesion but also enhances coordination and dexterity of the reconstructed hand. The rehabilitation program developed in our unit consists of these five stages starting on the first postoperative day.

1. *Protective stage (days 1-3).* Psychological support is provided to the patient, who is hospitalized in the microsurgery intensive care unit for observation of toe viability. During this stage, interaction between the patient and the hand therapist is established.
2. *Early mobilization stage (day 4-week 4).* Rehabilitation is directed at preventing excessive swelling and joint stiffness. From day 4-week 2 forward, the hand is kept about one foot higher than the heart level. On day 4, gentle passive range-of-motion exercises of the joints are commenced by individually moving each joint about 15 degrees. Special care is taken not to compromise the viability of the transferred toe while performing the exercises. In the subsequent weeks the controlled passive movement of all joints both proximal and distal to the osteosynthesis site is increased gradually but should not interfere with bone union. A light-pressure tubular bandage with the fingertips exposed is also applied at this time, and the patient is taught to perform gentle massage. A protective splint is provided between exercises. As a general rule, the splint should be placed in a position that prevents stress on the repaired tendons or neurovascular structures.
3. *Active motion stage (weeks 5-6).* Gentle active exercise is added to the passive exercises, and the splint is changed to a dynamic one, if necessary. During week 6, once the tendons have healed, blocking flexion and extension exercises are initiated. Compression bandages are used to help reduce edema and minimize scar formation. Ultrasound and scar massage are employed to produce a softer scar and increase the range of motion.
4. *Activities of daily living training stage (weeks 7-8).* Tasks are given that require training to strengthen muscle power and improve the joint's range of motion. According to patient capabilities, various tasks that simulate daily manual activities are assigned.
5. *Prevocational training stage (week 8 and beyond).* Vocational activities are designed to further improve muscle strength and hand dexterity and coordination. To prevent a claw deformity, the patient is encouraged to use nighttime extension splints for at least a year. The patient is encouraged to resume normal activities with the reconstructed hand and periodically attend interactive group sessions with other

patients who have received toe-to-hand transplants. Individual psychological therapy is appropriate only if required.

Sensory Rehabilitation

It is difficult to achieve functional sensory recovery after toe-to-hand transplantation without sensory rehabilitation.[17,62] Sensory reeducation is directed at helping the patient interpret the altered sensory impulses reaching the brain from peripheral nerves. This does not make axons grow faster or cause receptors to form, but it uses higher cortical functions (e.g., concentration, learning, and memory) to maximize the sensory function provided by the regenerated nerves.

The program of sensory reeducation is divided into early and delayed stages. In the early stage, reeducation focuses on facilitating the perception of touch submodalities with correct localization. Training is initiated when the patient can perceive vibrations from a tuning fork of 30 cycles per second with the reconstructed fingertip.

Late-phase sensory reeducation focuses on size and shape discrimination and object identification. This program is begun after the recovery of touch sensation. It consists of touching several objects with different textures, sizes, and shapes, the nature of which the patient attempts to appreciate with the tip of the transplanted toe instead of the adjacent normal finger's surface. It can be implemented as a home rehabilitation program, often leading to significant improvement in the final result.

In a study of sensory recovery after toe-to-hand transplantation, the senior author and his colleagues found a good relationship between the Meissner corpuscle number and two-point discrimination.[91]

Donor Site Rehabilitation

The patient is allowed to walk a few steps on the heel of the donor foot after week 2. It must be emphasized that any contact with the anterior plantar weight-bearing surface should be avoided during this recovery period. The sutures in the donor foot should not be removed earlier than week 3 after the operation. After week 4, the patient is allowed to walk with a normal gait.

OUTCOME

High success rates of more than 97%, as reported in our study series of 1841 transfers over 22 years (1985-2007), and as comparable results have been reported by our colleagues,[19,24,113] is expected in toe-to-hand surgery nowadays. Therefore, the focus currently should be on achieving near-normal function and acceptable appearance. As a result, and despite careful planning and patient selection and use of refined techniques, touch-up procedures (e.g., minor pulp-plasties and tenolyses) are still commonly performed in a second stage to enhance appearance and function, respectively. Other secondary procedures that may be needed, to a lesser degree, include flap thinning, web space deepening, scar revision, extensor tendon tightening, and arthrodesis.[89,94,109,113,116]

Sensory recovery in the transferred toe is generally adequate enough to allow the patient to have better use of the reconstructed hand compared with hand use before toe-to-hand surgery, especially in thumb reconstruction cases.[13] Delayed sensory reeducation provided for toe transplantation within a few months of toe transfer has been shown to play a key role in better sensory recovery and overall integration into the body.[11] Numerically speaking, static two-point discrimination as low as 8 mm[111,113] and moving two-point discrimination in the range of 3 to 10 mm have been reported.[32,33,43,44] Pulp pinch and sensory threshold have been studied, too, and found to be normal in reconstructed fingers.

Range-of-motion and strength recovery are still less than those of a normal finger but remain within a functional range.[29] An average range of motion of 25 degrees and 29 degrees is expected at the MP joint and PIP joint, respectively, after great toe-to-thumb transplantation.[35] In toe-to-finger transplantation, an average total range of motion of 50 to 60 degrees is expected for the PIP and DIP joints.[108,110] A slight extensor lag is common at the DIP joint; however, transfers to the distal finger typically regain nearly normal motion at the otherwise intact MP and PIP joints. Pinch strength can be restored up to 75% of the contralateral hand, and grip strength can be restored from approximately 70% of the contralateral hand when performing an immediate second-toe transfer and up to 90% with osteoonychocutaneous techniques.[13,48,49]

Compared with patients who do not undergo thumb reconstruction, toe transfer restores objective and subjective hand functioning. Thus, although normal sensation and motion are not typically achieved, toe transfer can restore function and appearance to near-normal levels.[13]

Outcomes of great toe-to-thumb transfer versus thumb replantation were also compared, and no statistically significant difference was shown except for IP motion, which was slightly better in the toe transfer group.[74] Outcomes of great-toe transfer by various techniques have been investigated in a recent systematic review of the literature. The study failed to identify any differences by technique, largely due to the heterogeneity of current data.[88]

As for integration into the body, the transplanted toe is perceived as a finger within 6 months of surgery.[12] This observation is consistent with functional MRI studies showing that motor and sensory tasks involving the transplanted toe evoke enhanced activation and cortical recruitment in the hand area of the primary sensorimotor cortex.[5] This may also be related to the observation that phantom finger phenomena are often ameliorated or eliminated after toe transfer.[12]

CONCLUSION

Between January 1985 and December 2012, a total of 2083 toes were transplanted for 1871 patients at our institution (Table 47.3): 45% (941 of 2083) were second-toe transfers, 11.5% (241 of 2083) were great-toe transfers, and 10% (209 of 2083) were combined second- and third-toe transfers. Other forms of toe transfer, including sensory pulp flaps constituted 33.5% (480 of 2083). The success rate in this series was 98%. Functional recovery, as assessed by sensation and pinch strength, was good, and patient satisfaction was high. From this experience, the authors conclude that toe-to-hand transplantation is reliable and useful for the reconstruction of missing thumbs and fingers. It replaces "like with like" that other reconstructive techniques cannot achieve. However, optimal functional and aesthetic results can be obtained only through strict adherence to the following

TABLE 47.3 Transplantations at Chang Gung Memorial Hospital

January 1985–December 2012

Type of Toe Transplant	Number of Toes
Second toe	941
Great toe	241
Combined second and third toes	209
Glabrous skin/pulp	188
Wraparound (great or lesser toes)	114
Vascularized joint	127
Third toe	44
Fourth toe	4
Combined third and fourth toes	3
Total	2083

principles: (1) proper initial management of all injured structures, (2) adequate preoperative planning, (3) selection of the appropriate transfer technique, (4) meticulous execution of the transfer, (5) thorough motor and sensory rehabilitation, and (6) performance of appropriate revision procedures.

Thumb Reconstruction

Kodi Azari

Acknowledgments: The author wishes to recognize the work of previous authors Dr. William Kleinman, Dr. James Strickland, Dr. Neil Salyapongse, and W. P. Andrew Lee for their contributions to Green's Operative Hand Surgery *and this chapter.*

> *The hand without a thumb is at worst nothing but an animated fish-slice, and at best a pair of forceps whose points don't meet properly.*
>
> ***—John Napier***[95]

Despite a long-standing recognition of the uniquely human way of using the hand, anthropologists have only recently defined the significance of the structure of the human hand that allows us to forgo an arboreal lifestyle in pursuit of vocations ranging from computer programmer to auto mechanic to surgeon. Their findings focus in large part on the anatomic features allowing three "grips" that differentiate the human hand from that of other hominids. These grips—the pad to side, three-jawed chuck, and five-jawed cradle-chuck—are possible due to the structure of the human thumb. As described by Napier, the absence of the thumb, whether due to failure of formation or loss from trauma, significantly impairs hand function.[95] In previous editions of this textbook, Drs. Kleinman and Strickland provided an excellent summary of 125 years of efforts by hand surgeons to preserve and, if necessary, reconstruct thumb function. As they predicted, many of these creative techniques have given way to the demonstrated success of microsurgery, including improved initial thumb salvage via replantation and reconstruction using free toe transfer. Unchanged from their writings is the dictum that, for a willing and motivated patient, "reconstruction of an opposable thumb should be attempted whenever possible by using whatever technical pathways are available to the surgeon."

With a few notable exceptions, techniques used to reconstruct the thumb after trauma are not unique to this digit. Skin grafts, local or regional flaps, free tissue transfer, and distraction and lengthening are all discussed at length in their respective chapters. A brief review of the evolution of thumb reconstruction outside of microsurgical techniques is provided to give the reader some perspective on the breadth of procedures developed. After this, we place the available procedures within a framework to help guide the clinician when planning thumb reconstruction. Apart from advances in microsurgery and refinements in toe transfer techniques, few changes in the procedures used for thumb salvage and reconstruction have taken place. Given this, we describe procedures unique to thumb reconstruction in detail, with attention to both preoperative planning and postoperative care.

HISTORICAL REVIEW

Although technical advances have led to changes in surgical methods, the general surgical philosophies of thumb reconstruction have remained relatively constant since their inception. In the latter part of the 19th and early 20th centuries, two distinct surgical philosophies evolved: (1) optimization of remaining function via local thumb phalangization after partial amputation, essentially a deepening of the first web space, as first described by Huguier[53]; and (2) distant pedicle flap attachment with delayed secondary detachment, first described in 1897 by Nicoladoni.[96,97] The principle of phalangization continued to evolve throughout the 20th century as techniques such as the "Z"-plasty, four-flap "Z"-plasty,[7] dorsal rotational flap,[9] and metacarpal lengthening[77] were used to provide additional web span and depth. Nicoladoni's staged great toe–to–thumb transfer and the delayed pedicle finger transfers of Luksch[75] are clearly mirrored in our current microvascular toe-to-thumb and occasional finger-to-thumb transfers.

Also during the late 19th century, the groundwork for the development of the neurovascular island flap was laid.[28] In addition to its role in plastic surgery and craniofacial reconstruction,[19] this work would become the basis for the third persistent theme in thumb reconstruction: Gosset's revolutionary concept of transfer of a digit on its own neurovascular pedicle.[40,41] In introducing this technique, Gosset not only revolutionized contemporary traumatic thumb reconstruction but also pioneered the seminal principles of reconstruction for a congenitally absent thumb. His initial recommendations involved simple lateral displacement of the index ray without bone shortening. Subsequently modified to include metacarpal recession and rotation, intrinsic muscle transfers, and skin flaps specially designed to produce a wide first web space free of scar,[12] pollicization via nonmicrovascular transfer of the long,[47,80] ring,[16,112] and little[60] fingers remains one of the mainstays of thumb reconstruction.

The fourth pathway to thumb reconstruction consisted of osteoplastic thumb creation.[99,100] Used extensively before World War II, osteoplastic reconstruction was performed in either one or two stages. The first step involved attaching the injured thumb stump to a random tubed pedicle of vascularized skin and subcutaneous tissue from the abdomen or groin; an iliac crest corticocancellous bone graft could be inserted and fixed

to the residual thumb either at a second stage (division of the tubed pedicle) or during primary formation of the pedicle. As recently as 1955, advances in osteoplastic thumb reconstruction were reported, with Moberg's introduction of the "island pedicle" transfer of vascularized, sensible cornified skin from an uninjured portion of the hand to restore stereognosis to the tactile portion of the osteoplastic thumb.[90] This technique has been widely practiced and remains a fundamental approach in complex thumb reconstruction after trauma.[19]

GENERAL CONSIDERATIONS

An ideal reconstruction of the thumb would replace "like with like," restoring both function and appearance. Replantation has demonstrated great success, in that it restores the actual lost thumb and often yields excellent functional outcomes.[61,65,125] When replantation is not possible or fails, the surgeon must re-create the likeness of the thumb. Deconstructing the ideal thumb function into its basic elements can assist the surgeon in choosing a reconstructive technique to provide an optimal outcome. Although authors differ in the specific breakdown of thumb requirements, two broad categories must be addressed: sensation and opposition. Sensation can be further divided into freedom from pain and adequate sensibility to interact with, or at least protect itself from, the environment. Opposition, the hallmark of "thumbness," necessitates length, stability, strength, and mobility.[15,18,49,130] The exact importance of each of these factors varies, depending on the individual needs of the patient: a jeweler who seeks sensibility and mobility may require different management than a manual laborer who may sacrifice mobility for stability and power.

For a patient to consistently use a reconstructed thumb, it must have painless stable skin coverage, be durable enough for normal use, and have at least protective, if not normal, sensation. Thus, regardless of the level of amputation and planned thumb length after salvage or reconstruction, every attempt should be made to restore at least an acceptable level of sensory cognition.[15,18,49,62,67,73,106,130] Procedures should be selected to provide a predictably satisfactory level of tactile perception and stereognosis. Failure to achieve this quality was the most consistent reason for patients' thumb disuse after many early reconstructive techniques (despite the fact that other functional requirements may have been met by the procedures). The use of neurovascular island pedicle techniques, sensory-innervated cross-finger flaps, and other methods of transferring innervated skin have greatly enhanced the ability to restore sensation when carrying out thumb salvage after trauma or to address congenital disorders.

First among the components of opposition is length; amputations that deprive the thumb of the distal phalanx or occur just proximal to the interphalangeal (IP) joint may not require reconstruction.[14,62,106,107] Loss at or more proximal to the shaft of the proximal phalanx, however, usually leaves a stump inadequate for pinch and grasp functions.[117] To oppose the remaining digits, a thumb of sufficient length must be antiposed (abducted, slightly extended, and pronated).[126] Whereas thumb IP flexion results in slight pronation of the distal phalanx,[49] normal motion at the metacarpophalangeal (MP) or IP joints is not mandatory. In contrast, active thumb function depends on preserving a full arc of circumduction at the carpometacarpal (CMC) joint.[15,46] If a substantial range of CMC motion cannot be attained, an essentially sensate prosthesis may be created by arthrodesing the thumb in nearly full abduction-opposition (40 degrees of abduction, 15 degrees of extension, 120 degrees of metacarpal pronation),[62] so that other mobile digits can be flexed to meet it. Thus, strength and mobility that more closely approximate normal thumb opposition may be sacrificed to provide a stable, if immobile, post for resistance during pinch and grasp.

Additional considerations when counseling a patient on the options for thumb reconstruction include the patient's age, sex, occupational demands, hand dominance, and subjective needs. Once the patient has expressed an interest in a restorative or reconstructive effort, an open and honest dialogue between the patient (and/or family) and surgeon is necessary before any final decision can be made. Rehabilitation after any reconstructive procedure is critical to obtaining a successful outcome; the patient must be motivated and should fully understand that his or her efforts during therapy will be as important as the surgery (if not more so) in regaining a functional thumb.

THUMB RECONSTRUCTION AFTER PARTIAL OR COMPLETE TRAUMATIC LOSS

Thumb function after amputation depends primarily on the remaining elements. Consequently, most algorithms for thumb reconstruction begin by stratifying the injury by level of loss.* Division of the thumb into functional levels varies slightly from one author to the next[49,67]; however, when approaching the reconstructive needs of the thumb, we prefer to stratify thumb defects after the style of Lister, as follows[67]:

1. Acceptable length with poor soft tissue coverage. These injuries are typically tip or pulp amputations that leave adequate length, functional thenar musculature, and basal joint mobility for opposition. Additional requirements for these injuries focus on sensibility or sensitivity and durability of skin coverage.
2. Subtotal amputation with questionable remaining length. This group encompasses the widest range of needs, from injuries requiring only soft tissue coverage to those demanding reconstruction analogous to total amputations. Choice of procedure is determined chiefly by the patient's perceived needs.
3. Total amputation with preservation of the basal joint. Although intrinsic thumb function is lost to varying degrees, the foremost requirement of amputations at this level is restoration of length. The extent of remaining intrinsic function, as well as the chosen reconstructive technique, determines how the new thumb is motored.
4. Total amputation with loss of the basal joint. Provision of length is critical, but functional opposition becomes more difficult. Either a substitute for the basal joint must be provided in the reconstruction, or the thumb must be arthrodesed in antiposition.

The following sections present our rationale for this division, define the differing reconstructive needs at each of these levels, and describe in detail the surgical options available.

*See references 11, 13, 15, 44, 49, 61, 63-65, 67, 68, 76, 88, 125, 130, 134.

Acceptable Length With Poor Soft Tissue Coverage

Even complete amputation of the thumb at the level of the IP joint, when treated with appropriate revision amputation, rarely results in significant functional deficit.[38] Therefore, this level has been described as the "compensated amputation zone."[30] If the skeletal and soft tissues have suffered damage sufficient to make restoration of a stable, sensate thumb tip unlikely, completion amputation and closure may provide a more immediate and equally functional outcome.[31] In this setting, it is important that closure be carried out using sound amputation principles, including avoidance of boxy stump edges and proximal resection of the digital nerves.[31,84] If these techniques are properly carried out, a good stump in the distal third of the thumb can function well with almost no functional disability.[106]

A broad spectrum of injury exists short of complete amputation or unsalvageable trauma to the distal thumb. Goals of treatment include restoration of skeletal stability; coverage of the thumb with durable, painless skin; and restoration of adequate sensory perception. The specific procedures used to accomplish these goals vary, depending on the amount and depth of tissue loss. An attempt should be made to salvage all viable tissues consistent with these objectives. Although injuries to the palmar pad of the distal phalanx of the thumb can be managed by the same coverage techniques applicable to fingertip injuries, the approach may be somewhat different as one strives to preserve length.[50,107,112,121,124]

The choice of reconstructive procedure for soft tissue deficits over the distal thumb depends primarily on the size of the defect. When the loss of skin and subcutaneous tissue from the terminal aspect of the distal phalanx is small (typically <1 cm^2) and no exposed bone is present, reasonable treatment options include allowing spontaneous healing by secondary intention, free skin grafts,[120] lateral triangular advancement flaps,[39,66] "V-Y" advancement flaps (Figure 48.1),[3,34,66] and a variety of other techniques.[52,54-56,58,101,104] For these small defects, we prefer conservative, open treatment to allow the wound to heal through secondary intention. The advantage of spontaneous healing is more favorable wound contraction, which results in a minimal defect with nearly normal sensation preserved.[62] At the time of presentation, patients undergoing conservative treatment should have the wound cleansed and covered with a nonadherent dressing. The initial dressing is removed at 24 to 48 hours, and daily dressing changes are performed thereafter until the wound has completely closed. Patients should be counseled that a few weeks may elapse before the thumb tip has healed.

Loss of greater than 50% of the distal portion of the thumb pad, tendon denuded of sheath and soft tissue coverage, and bone stripped of its periosteum may jeopardize not only the function of the injured thumb but also the preservation of thumb length. Under these circumstances, more complex reconstructive procedures such as palmar advancement flaps, cross-finger flaps, and neurovascular island or radial sensory-innervated cross-finger flaps may be warranted. Each of these techniques is considered in detail in the following sections.

Palmar Advancement Flap

Originally described by Moberg,[91] the palmar advancement flap provides a good reconstructive option for loss of greater than

FIGURE 48.1 "V-Y" palmar advancement flap. **A,** Distal thumb amputation with exposed distal phalanx. **B,** Advancement of flap to cover the defect. Note that the apex of the "V" does not cross the interphalangeal crease in order to avoid flexion contracture of the IP joint. **C** and **D,** Results 3 months after surgery.

half of the distal thumb pad.[62] It has the advantage of bringing well-innervated sensate palmar thumb skin distally to resurface the pad lesion, thereby restoring nearly normal sensory perception with durable skin and subcutaneous tissue. Resurfacing of the thumb tip is accomplished by advancement of a palmar flap containing the neurovascular structures, with or without proximal skin release and interpositional grafting.[59,86,91,105] This flap has proved most useful in covering defects ranging from slightly greater than 1 cm to "quarter sized,"[59] or as large as 2 cm.[105] The thumb is uniquely suited for this flap because the thumb IP joint can be flexed as much as 45 degrees to provide sufficient advancement of the flap. Although some authors believe this degree of flexion does not result in long-term flexion deformity,[59,105] in our practice, we have found that it does. Additionally, we have found that advancement of the flap by more than 1.5 cm is facilitated by a proximal transverse releasing incision,[2] which can decrease the need for acute IP flexion and increase the amount of tissue that can be mobilized. Although the defect created by the releasing incision can be left to heal by secondary intention, coverage with a full-thickness skin graft provides a closed wound and decreases wound contraction. The proximal flap can also be advanced by a "V-Y" technique in which the proximal incision is designed as a "V" rather than perpendicular to the thumb.

Palmar Advancement Flap Without Proximal Releasing Incision

This technique is best for terminal distal phalangeal pad defects 1.5 cm or less in length. Under tourniquet control, necrotic and ragged bone is trimmed from the distal phalanx, and thorough soft tissue débridement is carried out (Figure 48.2, *A*). Midaxial incisions are made over the radial and ulnar sides of the thumb and extended proximally from the lesion to the proximal thumb crease. Placement of the incisions across the dorsal apices of the flexion creases facilitates dissection dorsal to the neurovascular bundles. The palmar flap is carefully dissected from the underlying flexor tendon sheath; the flap should include subcutaneous tissue and both neurovascular bundles (see Figure 48.2, *B*). The mobility of the flap is tested by distal traction to determine whether any additional soft tissue undermining or releases are necessary. If tension is too great, the midaxial incisions can be extended proximally onto the thenar eminence. The MP and IP joints of the thumb are flexed 30 to 45 degrees. The distal edge of the flap is sutured to the remaining nail, nail bed, or terminal skin remnant, and radial and ulnar sutures are used to complete skin closure (see Figure 48.2, *C*). Figure 48.2, *E* to *G*, shows a clinical example of the palmar advancement flap without a proximal incision in a patient who suffered a distal thumb amputation during an altercation.

Palmar Advancement Flap With Proximal Releasing Incision

Use of a proximal releasing incision allows the palmar advancement flap to cover defects up to 2.5 cm long. As in the case of a palmar flap without a releasing incision, appropriate bone and soft tissue débridement should be carried out under tourniquet hemostasis (Figure 48.3, *A*). Dissection begins at the radial and ulnar edges of the wound via midaxial incisions. How far proximal these midaxial incisions are carried depends on the method chosen to close or cover the wound created by the relaxing incision. If the necessary advancement is only slightly greater than that achievable without a relaxing incision, options such as ending each incision as a "Z"-plasty over the thenar eminence or creating a "V-Y" advancement flap just proximal to the proximal thumb crease may allow primary closure of all wounds. More often, however, when significant advancement is required, the midaxial incisions should be carried to the level of the proximal third of the proximal phalanx. At this point, a transverse incision should be used to connect the proximal ends of the incisions. The neurovascular bundles must be identified, protected, and carefully mobilized (see Figure 48.3, *B*). It is more convenient and simpler to raise the flap in a distal-to-proximal direction, maintaining a plane of dissection just superficial to the flexor sheath. On reaching the proximal portions of the midaxial incisions, the flap consists of skin, subcutaneous tissue, and both neurovascular bundles. This "islandized" flap can be advanced to the thumb tip and sutured into place (see Figure 48.3, *C*). As when insetting the standard palmar advancement flap, it may be necessary to flex both the IP and MP joints to relieve tension on the closure. The resulting gap between the proximal end of the flap and the proximal releasing incision is covered with a full-thickness skin graft harvested from the medial arm (preferred), hypothenar eminence, antecubital fossa, or groin (see Figure 48.3, *D*).

At the conclusion of either palmar advancement flap, a dressing consisting of antibiotic ointment, nonadherent gauze, fluffed cotton gauze, and a thumb spica splint is applied. Care should be taken in shaping the thumb spica to maintain the flexion applied to achieve a tension-free closure. The splint and dressings are removed to allow inspection of the flap and skin grafts (if used) after 7 to 10 days. Thereafter, a removable Orthoplast thumb spica splint is applied to prevent overextension of the thumb. After 3 weeks, the patient begins active range-of-motion exercises; if necessary to regain full extension, dynamic splinting can begin at around 4 weeks.

CRITICAL POINTS *Palmar Advancement Flap*

Indications

- Palmar thumb pad defects greater than 1 cm but less than 2 cm long
- Exposed distal phalanx devoid of periosteum

Technical Points

- Perform thorough débridement of the defect.
- Incise skin in the midaxial line beginning at the wound and extending proximally on the radial and ulnar aspects of the thumb up to the proximal thumb crease.
- Dissect the flap, containing the subcutaneous tissue and both neurovascular bundles, from the flexor sheath.
- Test tension on the flap by providing distal traction.
- If additional length is necessary, extend incisions or dissection onto the thenar eminence.
- Flex thumb MP and IP joints to 30 to 45 degrees.
- Suture the distal flap to the remaining nail, nail bed, or skin.
- Apply nonadherent dressing and a thumb spica splint.

Postoperative Care

- Inspect the wound at 7 to 10 days.
- Switch to a thermoplastic thumb spica splint.
- Begin active range-of-motion exercises at 3 weeks.
- If necessary to achieve IP joint extension, dynamic splinting can start at 3 to 4 weeks.

Although these flaps are used primarily in acute situations, they can also be employed for thumb resurfacing at a later time when inadequate coverage exists.[86,91,103] Choosing the appropriate wound for reconstruction with these flaps provides the best chance for a successful outcome. The required advancement should not exceed 2.5 cm and should include, if at the upper end of this distance, plans for a proximal releasing incision. Despite the excellent dorsal vascularity of the thumb, it is possible to induce ischemia in the ungual area, particularly in smokers; therefore, it is advisable to avoid dissecting the pedicle too far. Other risks worth mentioning during preoperative counseling include sloughing of bits of bone or nail during the immediate postoperative period[59] and the possibility of flexion contractures of the IP joints.

CRITICAL POINTS *Palmar Advancement Flap With Proximal Releasing Incision*

Indication

- Same as for the standard palmar advancement flap, with defects greater than 2 cm and less than 2.5 cm long.

Technical Points

- Perform thorough débridement of the defect.
- Incise the skin in a midaxial line beginning at the wound and extending proximally on the radial and ulnar aspects of the thumb up to the proximal third of the proximal phalanx.
- Connect the midaxial incisions via a transverse palmar incision.
- Identify and mobilize the neurovascular bundles.
- Dissect the flap, containing the subcutaneous tissue and both neurovascular bundles, from the flexor sheath.
- Test tension on the flap by providing distal traction.
- If additional length is necessary, extend incisions or dissection onto the thenar eminence.
- Flex thumb MP and IP joints to 30 to 45 degrees.
- Suture the distal flap to the remaining nail, nail bed, or skin.
- Apply a full-thickness skin graft to the proximal thumb flap harvest site.
- Apply nonadherent dressing and a thumb spica splint.

Postoperative Care

- Inspect the wound at 7 to 10 days.
- Switch to a thermoplastic thumb spica splint.
- Begin active range-of-motion exercises at 3 weeks.
- If necessary to achieve extension, dynamic splinting can start at 3 to 4 weeks.

Heterodigital Flap Reconstruction

Loss of the entire palmar surface of the thumb distal phalanx presents a wound too great to be covered with a palmar advancement flap. Simple skin grafting may preserve length, but it does not restore durable, painless skin. Initially developed for coverage of exposed tendon or bone and for loss of a significant amount of skin and subcutaneous tissue from the palmar surface of the fingers,[43] a cross-finger flap designed from the dorsal proximal phalanx of the index finger often provides excellent coverage of these lesions, with satisfactory skin and subcutaneous tissue and adequate recovery of sensation.[26,29,62,82,106,115,123] This flap, and its innervated variations, substitutes a delayed skin flap from an adjacent digit for flaps historically based on cross-arm, thoracic (Figure 48.4), or abdominal donor sites. The reliability and ease of performance of these flaps have made them the mainstay for larger tissue losses in the distal third of the thumb, despite the development of numerous more elaborate techniques, including transfer of the tip of the fifth finger,[123] free toe pulp transfers,[108,118] a one-stage advancement–rotational flap combination,[52,56] "kite" or "flag" flaps from the index finger,[33,54,114] a dorsal flap based on the first web space,[79] or a flap hinged on the ulnar side of the thumb and rotated distally, as popularized by Brunelli[10] (Figure 48.5).

Occasionally, irreparable damage to the digital nerves of the thumb, resulting in permanent sensory loss in the palmar tactile pad, accompanies soft tissue loss in the distal third of the thumb. A patient with this wound may suffer substantial disability

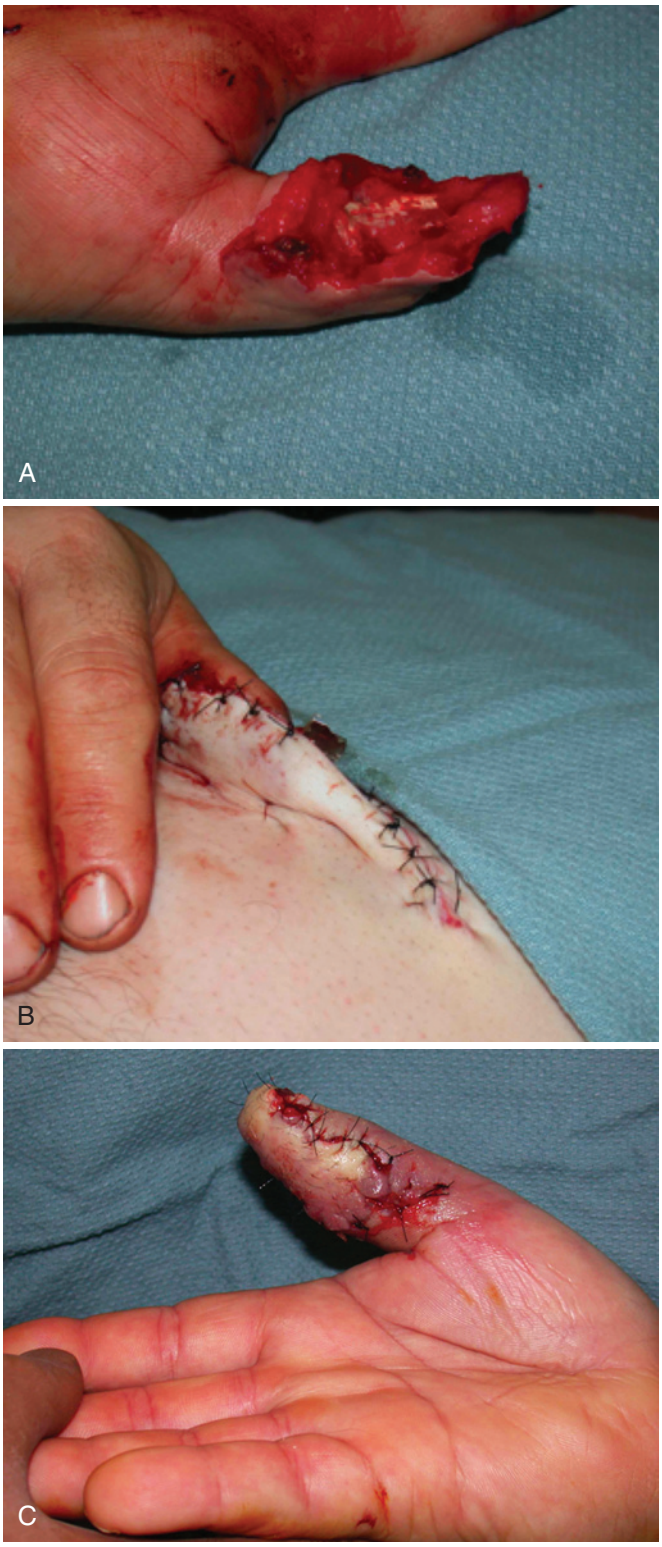

FIGURE 48.4 A thoracoepigastric flap is shown here for historical purposes because much better reconstructive options exist. **A,** Large volar thumb defect sustained from a table saw. **B,** After débridement, the thumb defect is secured to a random-pattern thoracoepigastric flap. **C,** Division of the flap 3 weeks later.

owing to impairment of pinch and grasp function. Under these circumstances, it may be appropriate to use a neurovascular island pedicle transfer, as first suggested by Moberg[91] and Littler.[72] This technique is very demanding, however, and the quality of sensory return has been challenged.[93]

Cross-Finger Flap to the Thumb

Under tourniquet hemostasis, acute wounds should be thoroughly débrided and the wound margins excised. Some attempt to convert the lesion into a square or rectangular defect may facilitate flap design and inset; however, this should not take precedence over preservation of viable palmar skin, especially along the radial aspect of the thumb, which represents the most distal aspect of the cross-finger flap. Blotting the wound with a sterile piece of paper produces a template corresponding in size to the defect. This template can be cut from the paper and traced onto the dorsal radial aspect of the index finger after adducting the thumb against the side of the index finger to determine the appropriate level for the base of the flap (Figure 48.6, *A*). Because of the unique rotational motion of the thumb, the base of the flap originates palmar to the midaxial line of the index finger and extends across the dorsum of the proximal phalanx as far as the defect size requires. A slightly oblique configuration of the donor flap aids in positioning it against the pad lesion.

Incisions are made along the proximal, ulnar, and distal borders of the flap through the skin and subcutaneous tissue down to the level of the paratenon. The flap is raised in an ulnar-to-radial direction in the plane just superficial to the extensor paratenon. As dissection proceeds radially toward the base of the flap, the cutaneous ligaments of Cleland must be incised to increase mobility of the flap. Dorsal veins running in the subcutaneous tissue can be divided with bipolar cautery, but small veins in the radial corner of the flap should be preserved to ensure its viability (see Figure 48.6, *B*). On completion of dissection, the tourniquet is deflated, and hemostasis is achieved using bipolar cautery.

A full-thickness skin graft is patterned slightly larger than the donor defect and harvested from the ipsilateral medial arm (preferred), antecubital fossa, or groin. The graft excess is applied to the base of the flap as it spans the space between the apposed thumb and index finger. Inset of the flap to the proximal, radial, and distal thumb wound is performed using fine (5-0) nonabsorbable monofilament sutures. The skin graft is applied to the donor defect and sutured in place with fine (5-0) plain gut suture. The inset of the skin graft is completed by suturing to the ulnar aspect of the thumb defect, thereby creating a closed wound (see Figure 48.6, *C* and *D*). The skin graft and flap should be covered with antibiotic ointment, a nonadherent dressing, followed by cotton gauze. The gauze overlying the skin graft should be conformed to the wound to serve as a bolster. These dressings are held in place by rolled cotton gauze, and the thumb and index finger are immobilized in a palmar splint extending across the hand and wrist.

Motion is permitted in the ulnar three fingers to prevent stiffness, and a dressing change at 5 to 7 days is used to assess the viability of the flap and the "take" of the graft. The flap can be safely divided after 14 to 21 days. Some recommend elevation of the wound edges and inset of the flap, as well as closure of the index donor site during division of the flap. Although this is possible, the wounds will heal just as effectively by secondary intention, without the risk of constricting either finger by attempting inset and closure. Daily dressing changes to the divided flap wounds are performed until complete closure has occurred. Active and passive range-of-motion exercises are begun immediately after division of the flap.

FIGURE 48.5 Brunelli flap reconstruction of the dorsal thumb. **A,** Squamous cell carcinoma of the nail bed. **B,** Total excision of the nail complex and distal phalanx dorsal cortex with clear surgical margins. **C,** Marking of the flap and the course of the dorsal ulnar artery of the thumb pedicle. **D,** Elevation and rotation of the flap. **E,** Flap inset and closure of the donor site with a rotation flap. **F,** Results 6 weeks after surgery.

Satisfactory sensory return has been reported in several long-term studies of cross-finger flap performance.[103] The technique is reliable and well tolerated by patients and provides sufficient padding for long-term heavy thumb use (eFigure 48.1). Disadvantages and complications include a potentially unsightly defect over the dorsum of the index finger, which may be particularly annoying to children and women, and some occasional problems with digital joint stiffness or thumb web contracture.

Innervated Cross-Finger Flap

Protective sensation and two-point discrimination return most predictably after cross-finger flaps in patients younger than 20 years; in patients older than 40, nearly half fail to regain protective sensation. In an attempt to improve on these outcomes, large cross-finger pedicle flaps that carry a sensory branch of the radial nerve have been described.[6,37,88,110,131] With the exception of the axial, bipedicled neurovascular island flap developed by Paneva-Holevich and Holevich,[102] each of these flaps differs from a traditional cross-finger flap primarily in that additional dissection over the first web space is used to facilitate inclusion and transposition of a dorsal sensory branch of the radial nerve.[6,37] Walker and colleagues[131] determined that the ultimate sensibility of these flaps is a mixture of the median and radial nerves, and Hastings[48] described a "dual innervated cross-finger" or island flap that coapts the dorsal sensory branch of the index radial digital nerve to the ulnar digital nerve of the thumb in an effort to improve cortical recognition of the flap as a thumb. Other variations have also been described,[23,51,88,110] and though it is rarely required, the procedure has a definite place among the reconstructive options for restoring thumb sensibility.

CRITICAL POINTS *Cross-Finger Flap*

Indication

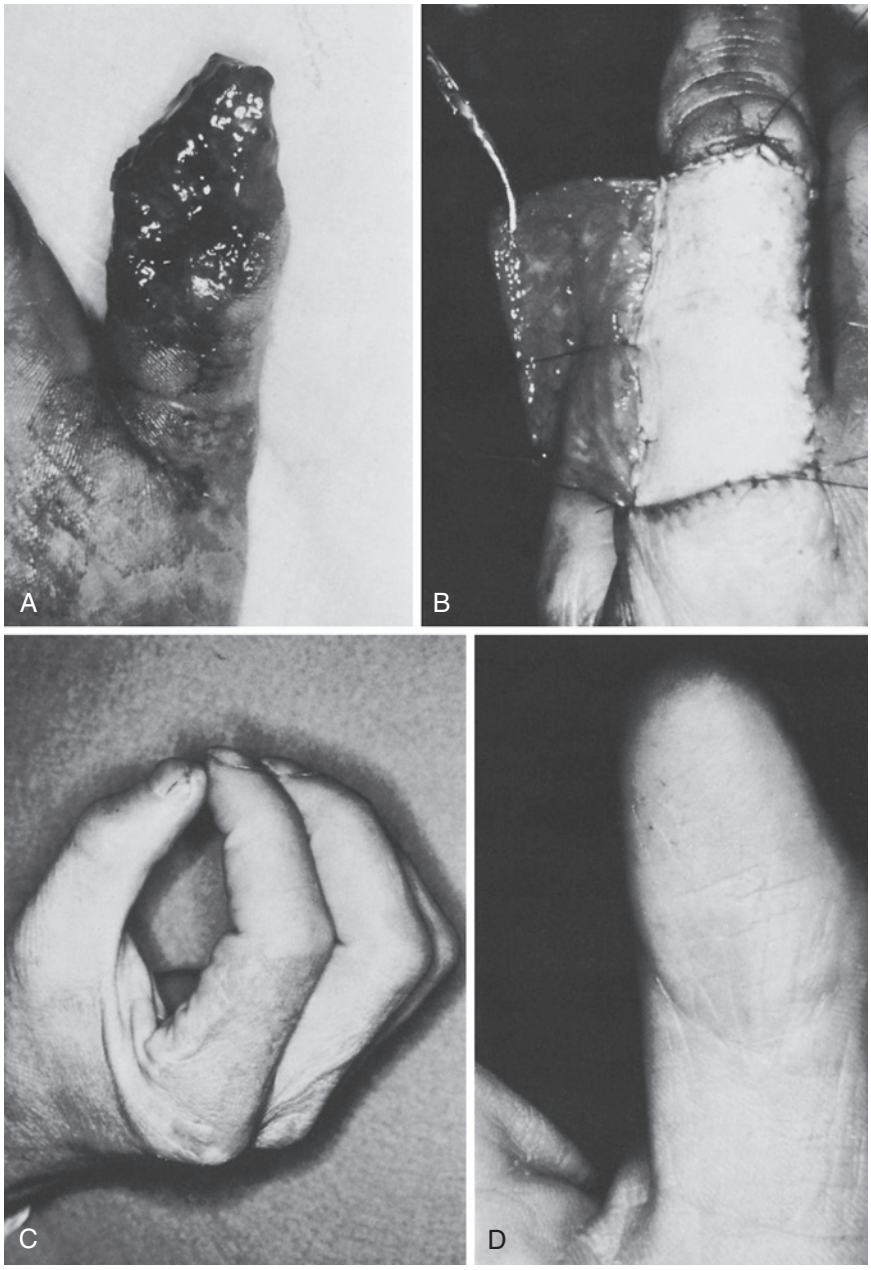
- Loss of the entire palmar surface of the thumb distal to the IP joint

Technical Points

- Thoroughly débride the wound.
- Blot the wound with sterile paper to form a template.
- Align the thumb with the radial aspect of the index finger to determine the level for the base of the flap.
- Trace the template onto the dorsal index finger.
- Incise the proximal, ulnar, and distal borders of the flap.
- Preserve the small veins in the radial corner of the flap.
- Raise the flap in a plane just superficial to the extensor paratenon.
- On the radial aspect of the flap, divide the Cleland ligaments to increase mobility of the flap.
- Deflate the tourniquet and achieve hemostasis before flap inset.
- Inset the flap along the proximal, radial, and distal margins of the wound.
- Harvest a full-thickness skin graft (medial arm) and inset this in the donor site using 5-0 plain gut sutures.
- Apply antibiotic ointment and a nonadherent gauze dressing to the flap and graft.
- Immobilize the thumb and index finger via a palmar splint crossing the hand and wrist.

Postoperative Care

- Inspect the wound in 5 to 7 days.
- Divide the base of the flap at 10 to 14 days.
- Allow the divided bridge to heal by secondary intention.
- Begin active range-of-motion exercises immediately after flap division.



eFIGURE 48.1 Cross-finger flap coverage of a large thumb defect. **A,** Large avulsion defect involving the entire palmar aspect of the distal phalanx of the thumb. **B,** Large cross-finger flap designed from the dorsum of the proximal phalanx of the index finger. The donor site has already been covered with a skin graft. **C,** Appearance of the thumb and donor defect at 3 months. **D,** Cosmetic appearance of the thumb pad at 3 months, with satisfactory sensation and durable coverage. (From Strickland JW: Restoration of thumb function following partial or total amputation. In Hunter JM, Schneider LH, Mackin EJ, et al, editors: *Rehabilitation of the hand*, St Louis, 1978, CV Mosby.)

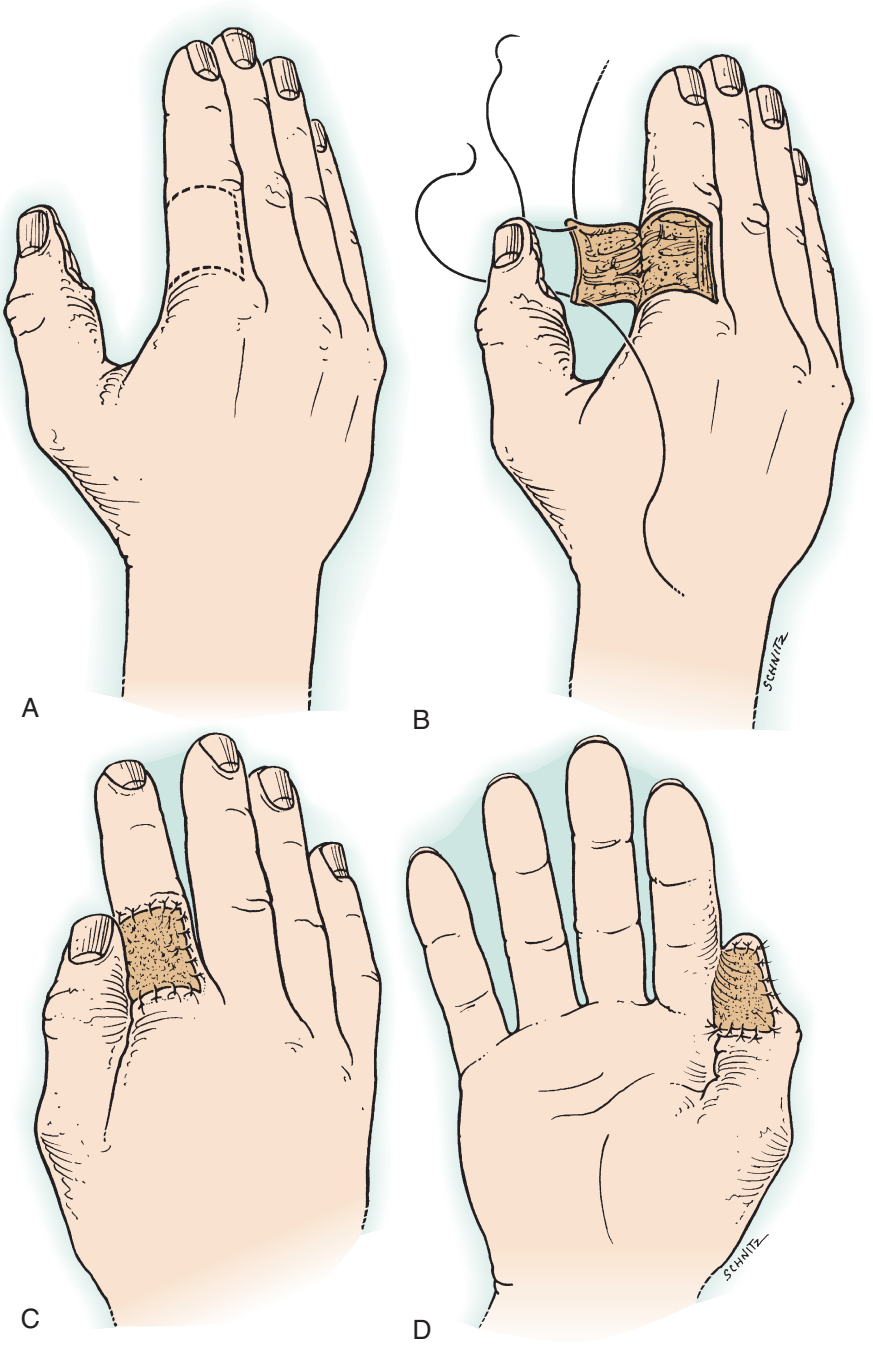


FIGURE 48.6 Cross-finger flap from the index finger to the thumb. **A,** Large defect involving most of the distal pulp of the thumb, and outline of the cross-finger flap on the proximal phalanx of the index finger. **B,** Placement of the flap on the thumb defect. **C** and **D,** Position of the thumb and cross-finger flap with a free graft covering the donor defect.

Radial-Innervated Cross-Finger Flap. After appropriate débridement under tourniquet hemostasis, a pattern matching the size of the acute defect or the defect to be created to provide sensory restoration to the denervated thumb is created. Markings for the size and location of the cross-finger flap are carried out in a manner identical to that described for the noninnervated cross-finger flap. If necessary, the flap can be extended over the MP joint for the resurfacing of larger defects. Beginning at the midpoint of the proximal transverse outline of the flap, an oblique incision extends proximally over the dorsal ulnar border of the first web space to a level several centimeters proximal to the midportion of the thumb web (Figure 48.7, *A*). A large dorsal sensory branch of the radial nerve may be identified on the muscle fascia in the proximal portion of this incision and traced distally into the proximal margin of the flap. Complete mobilization of the nerve from the proximal edge of the flap to the base of the web space incision is necessary to prevent undue tension on the nerve after transposition. Small branches of the nerve encountered during mobilization should be divided.

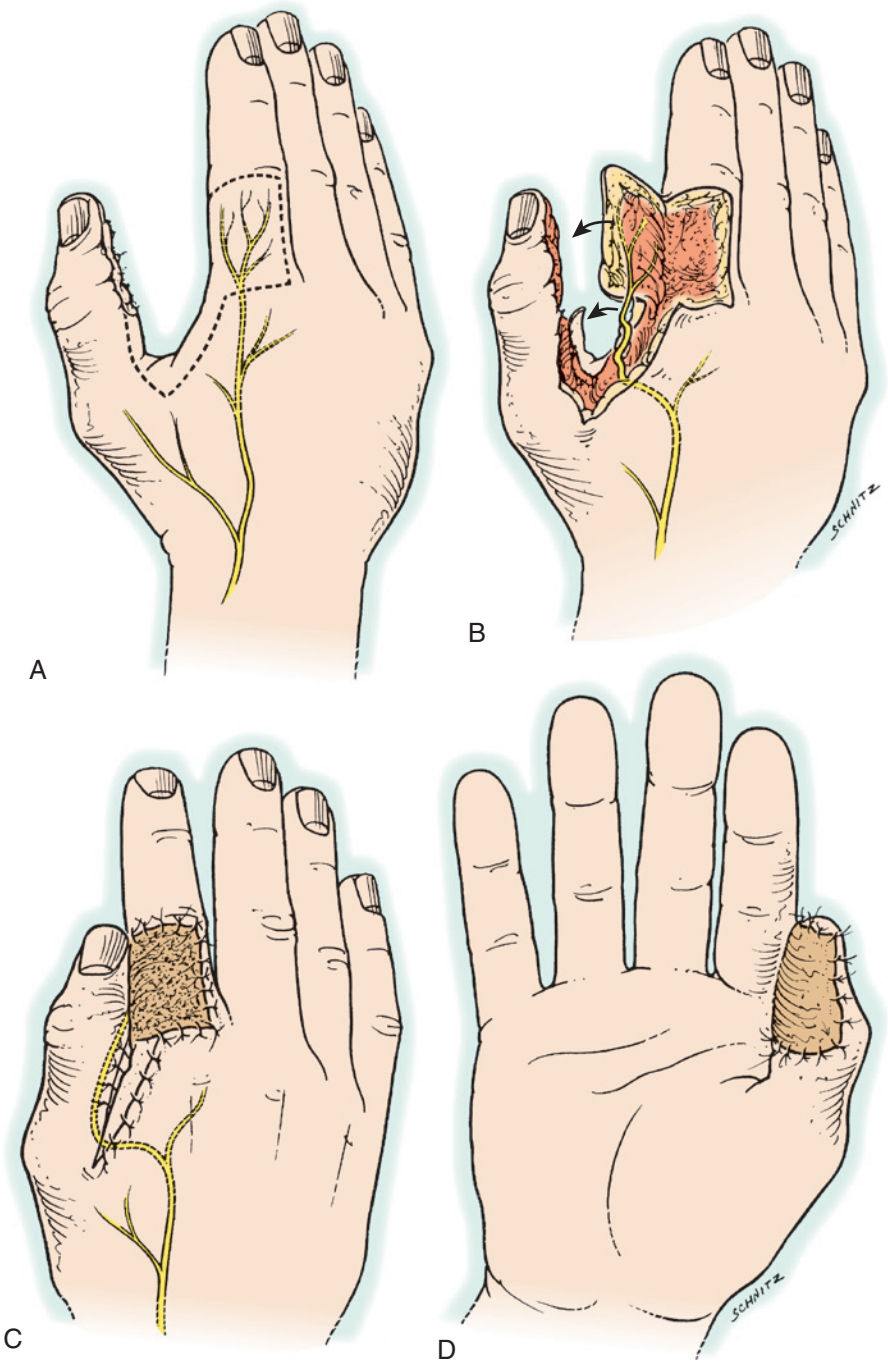

FIGURE 48.7 Sensory radial nerve–innervated cross-finger flap. **A,** Outline of the cross-finger flap with dorsal web incisions connecting to the thumb defect. The incision is made dorsal and proximal to the thumb web to prevent a subsequent scar contracture. The position of the dorsal sensory radial nerve is depicted. **B,** Reflection of the flap after dissection of the nerve branch. **C** and **D,** Position of the thumb and transferred flap, with closure of incisions and free graft coverage of the donor defect.

Once the radial sensory branch has been mobilized, the cross-finger flap is incised and elevated, as for a standard cross-finger flap. A solitary but significant difference from the standard flap is that care must be taken when incising the proximal transverse border of the flap to avoid injury to the radial sensory branch as it enters the flap. When the flap has been mobilized to its base, the thumb is brought along the side of the index finger to check the positioning of the flap into the recipient defect (see Figure 48.7, *B*).

A connecting incision is made along the midaxial ulnar border of the thumb and carried proximally to the previous oblique incision extending from the flap. At the time of flap attachment, the nerve is carefully transposed from the dorsum of the index ray to the ulnar thumb incision after undermining has provided a satisfactory trough in which it can lie without tension. Suturing of the ulnar thumb incision and the connecting dorsal radial index incision secures the position of the nerve, and the defect over the dorsum of the proximal phalanx is

covered with a full-thickness skin graft. As in the standard cross-finger flap, enough graft is harvested to provide coverage of the exposed pedicle by suturing into the free ulnar edge of the thumb defect (see Figure 48.7, *C* and *D*).

A dressing and splint identical to that described for the standard cross-finger flap are applied. Flap monitoring and division are also as described earlier. In addition to active and passive motion rehabilitation, a protocol of gradually increasing pressure stimuli is added, with the goal of increasing appropriate cortical recognition of the transferred flap. Risks inherent in using the innervated cross-finger flap include those related to damage to the mobilized branch of the radial sensory nerve secondary to undue tension or manipulation. Sensory return may be only protective, and the patient may continue to interpret thumb sensation as that of the dorsal index finger. Nonetheless, the radial-innervated cross-finger flap is a useful procedure when one is faced with irreparable sensory damage to the thumb and no other source is available for reconstruction (eFigure 48.2).

CRITICAL POINTS *Radial-Innervated Cross-Finger Flap*

Indications

- Similar to those for the cross-finger flap
- Damage to the terminal digital nerve with tissue loss, as for the standard cross-finger flap

Technical Points

- Débride, create a template, and outline the flap, as for the standard cross-finger flap.
- Incise the skin obliquely, beginning at the midportion of the proximal flap incision and extending along the ulnar border of the first web space.
- Stop the incision a few centimeters proximal to the midportion of the thumb web.
- Bluntly dissect a branch of the radial sensory nerve, typically found running deep on the muscle fascia.
- Trace the nerve up to the flap.
- Dissect the flap as for the standard cross-finger flap, taking care not to divide the nerve as it enters the flap.
- Incise from the proximal margin of the thumb wound along the radial aspect of the first web space.
- Stop this incision at the proximal end of the incision used to identify the radial sensory nerve branch.
- Deflate the tourniquet and achieve hemostasis.
- Bluntly dissect and elevate the radial sensory nerve branch.
- During inset of the flap, transpose the nerve to the incision created on the ulnar aspect of the thumb.
- Harvest a graft large enough to allow coverage of the harvest site as well as the nerve pedicle at the proximal flap inset.

Postoperative Care

- Same as for the standard cross-finger flap

Dual Innervated Cross-Finger Flap. Under tourniquet hemostasis, thumb débridement, pattern creation, and flap design are carried out as described for the standard cross-finger flap. An incision is made from the proximal aspect of the flap along the radial aspect of the index metacarpal to the recess between the base of the index metacarpal and the extensor pollicis longus. A second incision is extended distally along the dorsal ulnar aspect of the thumb metacarpal to the MP joint and the more distal thumb defect just palmar to the midaxial line (Figure 48.8, *A*).

Flap elevation is initiated along the distal and ulnar incisions on the index finger. As the incision is carried down to the level of the paratenon, small veins are divided with bipolar electrocautery. The flap is elevated in a dorsal-to-palmar direction while preserving the paratenon of the extensor mechanism and including all neurovascular structures within the flap. Along the incision coursing proximal over the index metacarpal, flaps are elevated superficial to the neurovascular structures. No attempt is made to separately dissect out the two to four terminal branches of the dorsal sensory radial nerve to the dorsal index finger. The subcutaneous tissue surrounding the dorsal sensory radial nerve contains veins and, in most instances, the first dorsal intermetacarpal artery; a narrow 0.5- to 1-cm-wide strip of this subcutaneous tissue should be raised down to the level of the investing muscle fascia to incorporate these nerve branches and, if the flap is to be transferred as an island pedicle, the artery and veins (see Figure 48.8, *B*). If an island flap is planned, the first dorsal intermetacarpal artery should be identified proximally before raising the subcutaneous portion of the flap to ensure that it is contained in the pedicle. Although, as stated by Foucher,[33] the artery most often runs superficial to the fascia, it may run deep to the fascia in 15% of cases or consist of two vessels, one superficial and one deep, in 10%.[48] At the level of the MP joint, the dorsal branch from the index radial digital nerve (median nerve distribution) is identified and dissected back to its origin. The connecting incision to the thumb is completed, and the ulnar digital nerve amputation stump proximal to the thumb defect is identified.

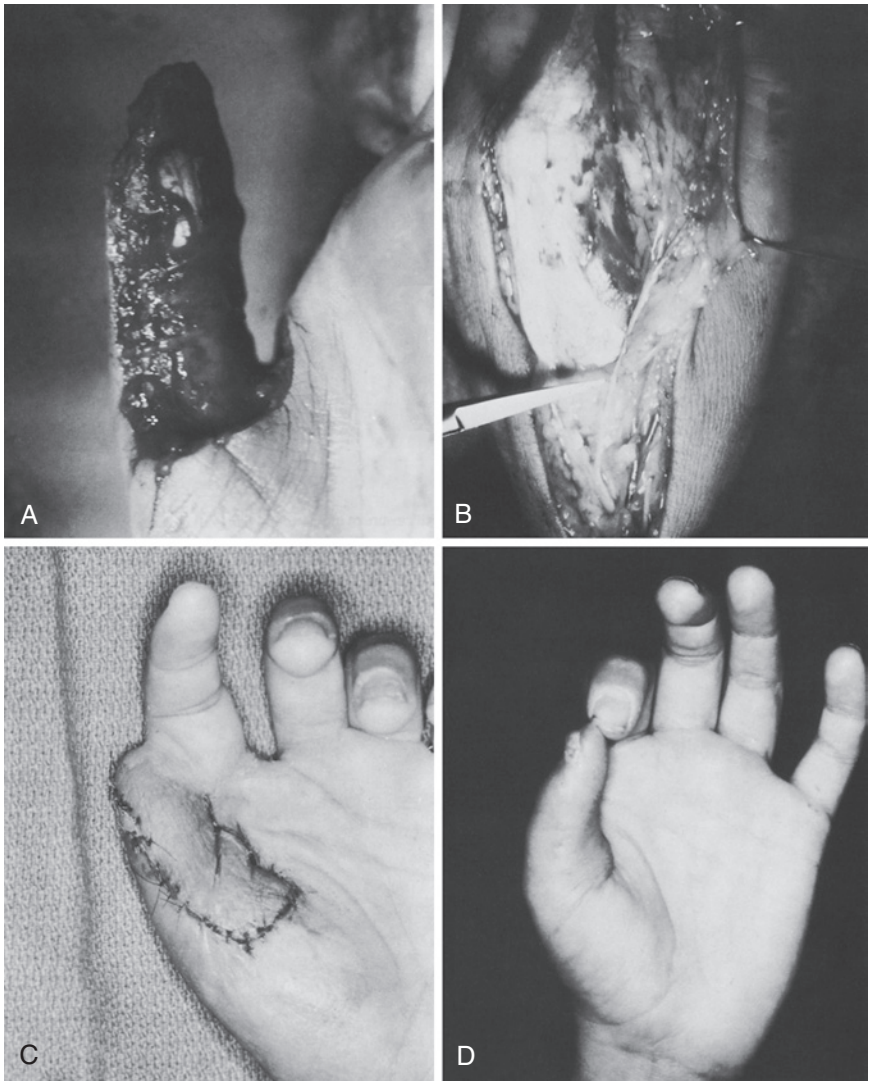
Transposition of the flap with the dorsal sensory radial nerve branches is accomplished as described earlier, and the inset begins radially (see Figure 48.8, *C* and *D*). Before completion of the proximal and distal inset, neurorrhaphy of the palmar ulnar digital nerve of the thumb to the more distal dorsal sensory nerve branch of the transposed flap is accomplished under the operating microscope (eFigure 48.3). The connecting incisions are closed, and skin grafts are applied to the donor area.

Postoperative care, flap division, and rehabilitation are identical to these steps for the radial-innervated cross-finger flap previously described.

First Dorsal Metacarpal Artery Island Flap

The first dorsal metacarpal artery (FDMA) flap was popularized as a pure island flap (kite flap) by Foucher in 1979.[34] In many ways, this flap is similar in design to the radial-innervated cross-finger flap. However, it is transferred as a pure island flap carrying the FDMA, subcutaneous veins, and branches of the radial sensory nerve in a single stage, thus eliminating the need for prolonged immobilization and potential long-term stiffness. The FDMA island flap can reach the volar and dorsal aspects of the distal thumb and is considered a versatile workhorse flap for innervated distal thumb soft tissue coverage.

As with the other described procedures, the operation begins with appropriate débridement. Then a pattern matching the size of the defect is drawn on the dorsum of the index finger



eFIGURE 48.2 Large sensory radial nerve–innervated cross-finger flap. **A,** Avulsion of the entire palmar thumb after forceful removal of a circumferential pipe. **B,** Use of a large sensory-innervated cross-finger flap from the index finger and second metacarpal. proximal phalanx (Figure 48.9). To avoid scar contracture, the proximal limit of the flap is the MP joint, and the distal limit is the proximal IP joint. The course of the FDMA is mapped with the aid of a handheld pencil Doppler from the radial aspect of the index MP joint to its proximal pivot point, located at the juncture of the proximal first and second metacarpals. Under tourniquet hemostasis, the flap is elevated in the loose areolar plane above the extensor tendon paratenon. Dissection generally moves from distal to proximal and from the ulnar to the radial side. Extreme care must be taken at the radial border of the MP joint because this is where the FDMA enters the flap's subcutaneous network.

FIGURE 48.9 Sensate first dorsal metacarpal artery (FDMA) flap. **A,** Thumb amputation following débridement. **B,** Skin markings indicating the course of the FDMA, outlined such that the skin of the metacarpophalangeal joint is preserved. **C,** The flap is raised proceeding from distal to proximal and ulnar to radial. Care is taken to leave the extensor tendon paratenon intact to ensure skin graft "take." The flap pedicle contains the fascia of the first dorsal interosseous muscle, two large dorsal veins, the FDMA, and radial sensory nerve branches. **D** to **F,** Results 2 months after surgery. **G,** The preferred alternate teardrop-shaped skin incision.

At the level of the MP joint, a teardrop-shaped incision (preferably) (see Figure 48.9, *G*) or a lazy-"S" proximal incision is made, and the skin is elevated in the deep dermal plane superficial to the adipose tissues. The pedicle is dissected by incising the interosseous fascia at the radial edge of the muscle and second metacarpal periosteum at the ulnar edge. The deep periosteal incision is carried radially and deep to the muscle fascia. The dorsal veins and sensory branches of the radial nerve that typically enter the flap over the ulnar border of the MP joint are included in the pedicle. The pedicle is dissected back to the pivot point at the juncture of the first and second metacarpals.

The tourniquet is released, and the vascularity of the flap is assessed. Once viability is assured, the flap is passed to the defect through a subcutaneous tunnel and sutured. In our experience, we have found that the subcutaneous tunnel is often too narrow and must be opened to avoid unnecessary tension on the flap. The teardrop flap design allows a tension-free closure in this instance and is recommended. The index finger dorsal donor site defect is covered with a full-thickness skin graft obtained from the medial arm. The skin graft is covered with a nonadherent dressing and moist gauze; a bulky dressing is applied to the entire hand. The dressing over the distal tip of the thumb should be opened to expose the most distal portion of the flap and allow monitoring of viability. A full dressing change is carried out at 7 to 10 days, and motion is permitted.

Potential complications include flap vascular compromise and index finger donor site morbidity, such as stiffness, cold intolerance, hypertrophic scarring, and neuroma.

Neurovascular Island Pedicle Flap

Although developed before the innervated cross-finger flap, the neurovascular island pedicle flap now plays a smaller role in the armamentarium of hand surgeons. This stems not only from the greater technical difficulty of the procedure but also from the need to sacrifice palmar sensation along the ulnar aspect of another digit. As a result, important preoperative considerations include selection of a donor digit and determination of

the amount of digital skin and subcutaneous tissue to be brought with the pedicle. The main factor in choosing the donor digit is the status of the median nerve; if median nerve function is intact, the ulnar aspect of the long finger provides a long neurovascular pedicle that can facilitate transposition of the flap. In the absence of median nerve function, an ulnar-innervated digit must be chosen; under these circumstances, the ulnar aspect of the ring finger may serve as a donor.

In either setting, the ulnar aspects of the digits do not participate in pinch, making the sacrifice of tactile surface an acceptable deficit. In general, the size of the flap should correspond to the deficit created by adequate débridement of the scarred and insensate tissue along the thumb defect; occasionally, it may be reasonable to use an "extended" neurovascular island transfer that consists of almost the entire ulnar palmar half of the donor digit to provide the widest possible areas of sensory restoration.[93,109,119,129] Thompson[128] emphasized that it is not necessary to apply the flap to the absolute tip of the thumb unless it is required for soft tissue coverage and that the position should favor the ulnar side of the thumb.

Variations have involved attempts to improve innervation, as well as the creative use of extended flaps. Some authors have advocated suturing the divided proper digital nerve of the neurovascular island pedicle flap to the distal stump of a previously severed thumb digital nerve to improve sensation and help prevent neuromas.[1] Chen and Noordhoff[20] reported one case in which the entire distal phalanx of the thumb was resurfaced with twin neurovascular island flaps taken from the ulnar and radial sides of the middle and ring fingers.

Before beginning, it is necessary to determine the size of the thumb defect to be resurfaced; this measurement mandates the size of the flap. Because most clinical conditions warrant the use of an extended flap involving the entire length of a donor digit, this technique is described here (Figure 48.10, *A*).

Under tourniquet hemostasis, the flap is outlined on the ulnar aspect of the donor digit; it extends from well out on the pad of the distal phalanx along the midline of the palmar aspect of the digit and terminates just short of the proximal digital crease. Small darts are created at the IP creases, and the flap extends posteriorly beyond the midlateral line to the dorsal aspect of the digit. A midlateral proximal continuation is used to connect the digital incision with a series of palmar zigzag incisions. A paper template with the exact size and configuration of the flap is used to outline the recipient area on the palmar aspect of the thumb. A proximal connection into the palm is also provided in this area to facilitate passage of the flap. Under magnification, the dissection begins in the palm, and the neurovascular bundle to the web space is identified. The digital artery to the radial side of the adjacent finger is identified and ligated well distal to the arterial bifurcation. The digital nerves to the adjacent sides of the long and ring fingers are carefully teased apart well into the midpalm. The artery and nerve to the ulnar side of the donor finger have now been isolated as far as the base of the finger and are dissected distally into the island flap. Incisions are made about the entire periphery of the flap, and dissection is performed distally and carefully continued in a proximal direction while incorporating skin, subcutaneous tissue, and the neurovascular bundle, which should be protected by the surrounding soft tissue. The flap is freed on its neurovascular pedicle to the level of the midpalm. Small vascular branches are transected during this dissection using bipolar electrocautery.

Skin and scar tissue within the previously outlined recipient site on the thumb are excised, and a bridge between the proximal thumb incision and the proximal end of the palmar incision is carefully undermined in an area just deep to the palmar aponeurosis (see Figure 48.10, *B*). A suture placed in the distal end of the island pedicle flap is used to gently pull the flap from the palmar wound into the thumb wound, with great care taken not to damage or twist the pedicle (see Figure 48.10, *C*). It is important to create some redundancy of the pedicle and a generous subcutaneous pocket to prevent tension and ensure flap survival.

The transferred flap is loosely tagged in place in the recipient defect, and the tourniquet is released. Any bleeders are ligated, and the vascularity of the flap is assessed. Completion of flap suture and repair of the palmar and proximal digital wounds are carried out at this time. A full-thickness skin graft taken from the medial arm (or groin) is sutured into the donor defect (see Figure 48.10, *D*).

The skin graft is covered with a nonadherent dressing and moist gauze; a compressive dressing is applied to the entire hand. The dressing over the distal tip of the thumb should be opened to expose the most distal portion of the flap and allow monitoring of viability. A full dressing change is carried out at 7 to 10 days, and motion is permitted at 3 to 4 weeks.

Potential complications include partial or complete flap necrosis, failure of the graft, or stiffness of the donor finger. Obviously, the loss of sensate skin in the donor finger is considerable; however, when the indications are appropriate, the restoration of good palmar sensory skin to the critical tactile pad of the thumb is functionally justified. Few adults will convert sensory recognition of the transferred flap to that of the thumb.[93]

Summary: Reconstruction of Soft Tissue Defects of the Thumb

The primary goal in treating tissue loss of a thumb of adequate length is to provide or improve skin coverage while optimizing the chance for the return of satisfactory sensation without pain. Although providing additional length is not necessary at this level, techniques directed at preserving stump length or covering significant palmar soft tissue losses may be useful. The choice of procedure is dictated primarily by the size of the defect. For defects less than 1 cm^2, healing by secondary intention provides adequate coverage, with no additional donor wound. For defects less than 2.5 cm long, the palmar advancement flaps offer excellent coverage with minimal morbidity and no need for sensory cortical reorganization. Larger lesions may require one of the heterodigital flaps. Circumferential soft tissue loss with preservation of the underlying skeletal and tendinous structures often requires reconstruction using local and regional flaps for hand coverage (see Chapter 44). A secondary but important consideration is the extent of nerve damage. Radial sensory-innervated cross-finger flaps and neurovascular island pedicle flaps are occasionally used for acute thumb injuries with loss of skin, subcutaneous tissue, and one or both digital nerves. Although these procedures result in varying degrees of impairment to their respective donor areas and often involve some difficulty in terms of patients' cortical interpretation, they

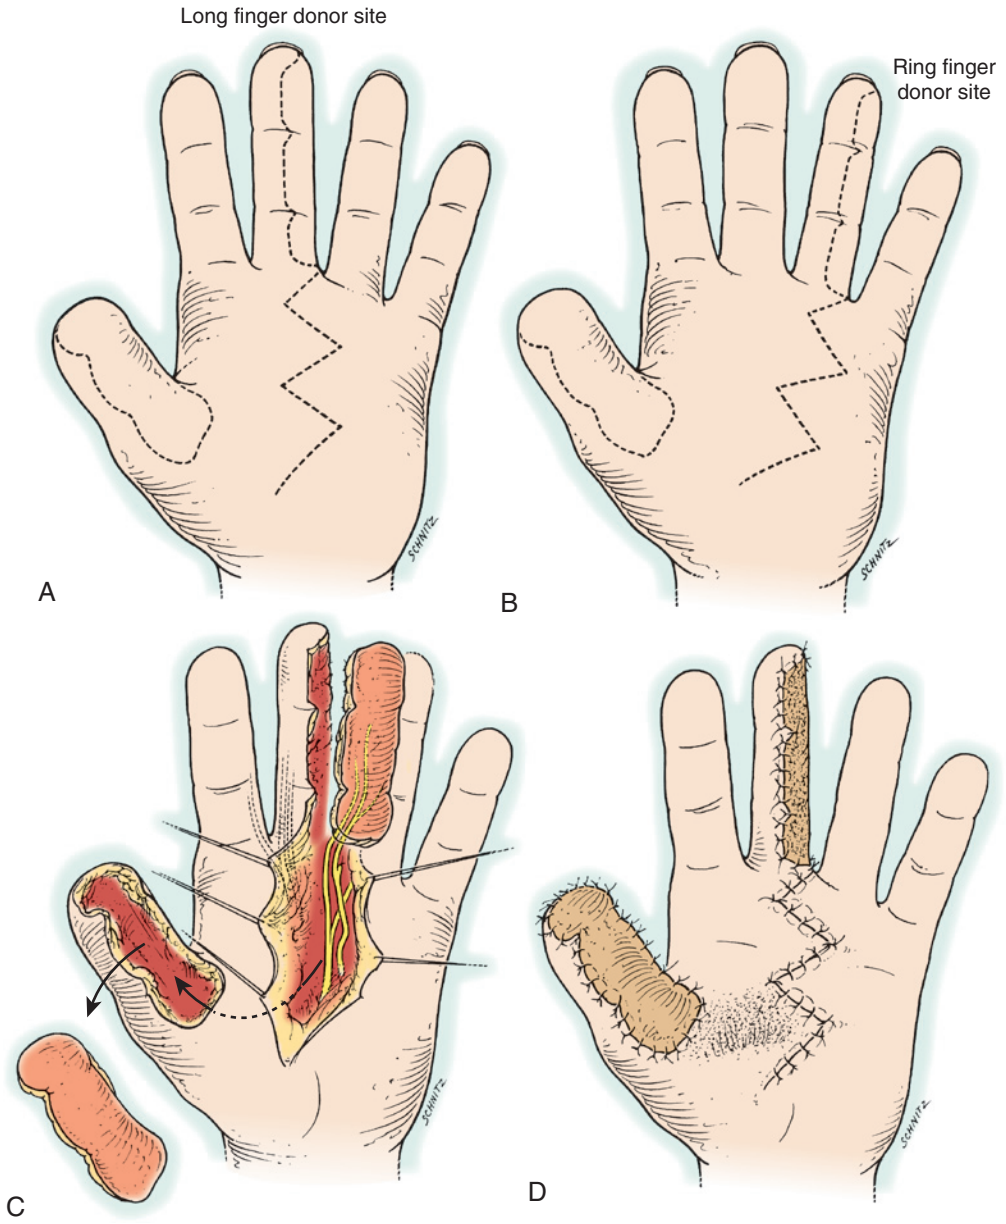

FIGURE 48.10 Neurovascular island transfer from either the long finger or the ring finger to provide sensate coverage of the thumb. **A,** Neurovascular island flap using the ulnar side of the long finger. An extended island flap is designed with an identical defect patterned over the palmar aspect of the thumb. **B,** Use of the ulnar aspect of the ring finger, which is designed and transferred in a similar manner. **C,** Mobilization of the island flap on its neurovascular pedicle, and preparation of the recipient bed on the thumb. Note the areas of undermining required between the palmar and thumb incisions (*dotted arrow*). **D,** Completed transfer of the neurovascular island flap with a free graft on the donor area of the long finger. Care must be taken to avoid a longitudinal scar along the palmar aspect of the donor finger. (Modified from Reid DAC: Reconstruction of the mutilated hand. In Rob C, Smith R, Pulvertaft RG, editors: *Operative surgery: the hand*, ed 3, London, 1977, Butterworth.)

are time-honored methods of improving function in certain cases of devastating palmar thumb loss and are best used as secondary restorative methods.

Subtotal Amputation With Questionable Remaining Length

Amputations of primarily the palmar soft tissues can be managed as described in the preceding section; however, if the tissue loss extends to the bony structures, the presence of a thumb of adequate length for opposition becomes questionable. Although the provision of extra thumb length can be performed in the setting of acute injury,[127] the surgeon is more commonly presented with a patient who has already undergone completion amputation and now seeks advice regarding reconstructive options. Under these circumstances, it is imperative that the choice of reconstruction, ranging from none to microvascular toe transfer, be carefully tailored to the patient's needs. Minimal bone loss, up to the level of the thumb IP joint, is unlikely to significantly impair function. In contrast, loss of length proximal to the midportion of the proximal phalanx decreases the hand span, making it difficult to grasp large objects and causing problems with dexterous pinch. After amputation at this level, most thumbs retain acceptable CMC rotation and an adequate thumb–index finger cleft. Functional

CRITICAL POINTS *Neurovascular Island Pedicle Flap*

Indications

- Extensive loss of the palmar thumb pulp
- Loss of terminal digital nerve innervation, particularly of the ulnar thumb

Technical Points

- Choose a donor digit based on remaining intact innervation: either the ulnar long finger (median nerve intact) or the ulnar ring finger (ulnar nerve intact).
- Determine the size of the defect to be resurfaced and create a template.
- Outline the template on the ulnar aspect of the donor digit, extending from the distal palmar pad to just short of the proximal digital crease.
- Center the template such that the donor flap begins at the midpalmar aspect of the digit and extends onto the dorsum of the donor digit.
- Add small darts to the flap design at the IP creases.
- Connect the proximal flap via an incision along the midlateral aspect of the digit to a series of zigzag incisions on the palm.
- Create the palmar thumb defect to fit the flap design.
- Extend the recipient site via an incision into the palm in a similar fashion to the donor digit extension, leaving a skin bridge of 1 to 2 cm between the donor zigzag incision and the thumb proximal incision.
- Identify the common digital artery and nerve to the donor web space.
- Ligate the proper digital artery to the adjacent (nondonor) finger's radial aspect at least 5 to 10 mm away from the bifurcation.
- Tease apart the common digital nerve into the proximal palm, separating the donor ulnar nerve from the adjacent radial sensory branch.
- Dissect the donor artery and nerve to the base of the flap.
- Incise the margins of the flap.
- Raise the flap, including skin, subcutaneous tissue, and the neurovascular bundle.
- Undermine the skin bridge between the two proximal extending incisions just deep to the palmar aponeurosis.
- Place a suture in the distal flap and pass this through the tunnel into the thumb defect wound.
- Gently pull the flap through into the thumb defect.
- Tag the flap in place and release the tourniquet.
- Achieve hemostasis.
- Inset the flap with fine, nonabsorbable sutures.
- Harvest a full-thickness skin graft and inset this into the donor defect using fine chromic sutures.
- Apply a nonadherent dressing and moist gauze; leave the thumb tip of the dressing open to facilitate monitoring of the flap.
- Apply a volar resting splint from fingertip to distal forearm and a gentle compressive dressing.

Postoperative Care

- Inspect the flap and graft at 7 to 10 days.
- Begin active range-of-motion exercises at 3 to 4 weeks.

Expected Outcomes

- Improved padding and sensibility of the thumb
- Potential scarring in thumb and palm
- Potential stiffness of the donor finger

requirements at this level therefore include added length; preservation of sensibility, mobility, and stability; and a pain-free thumb.

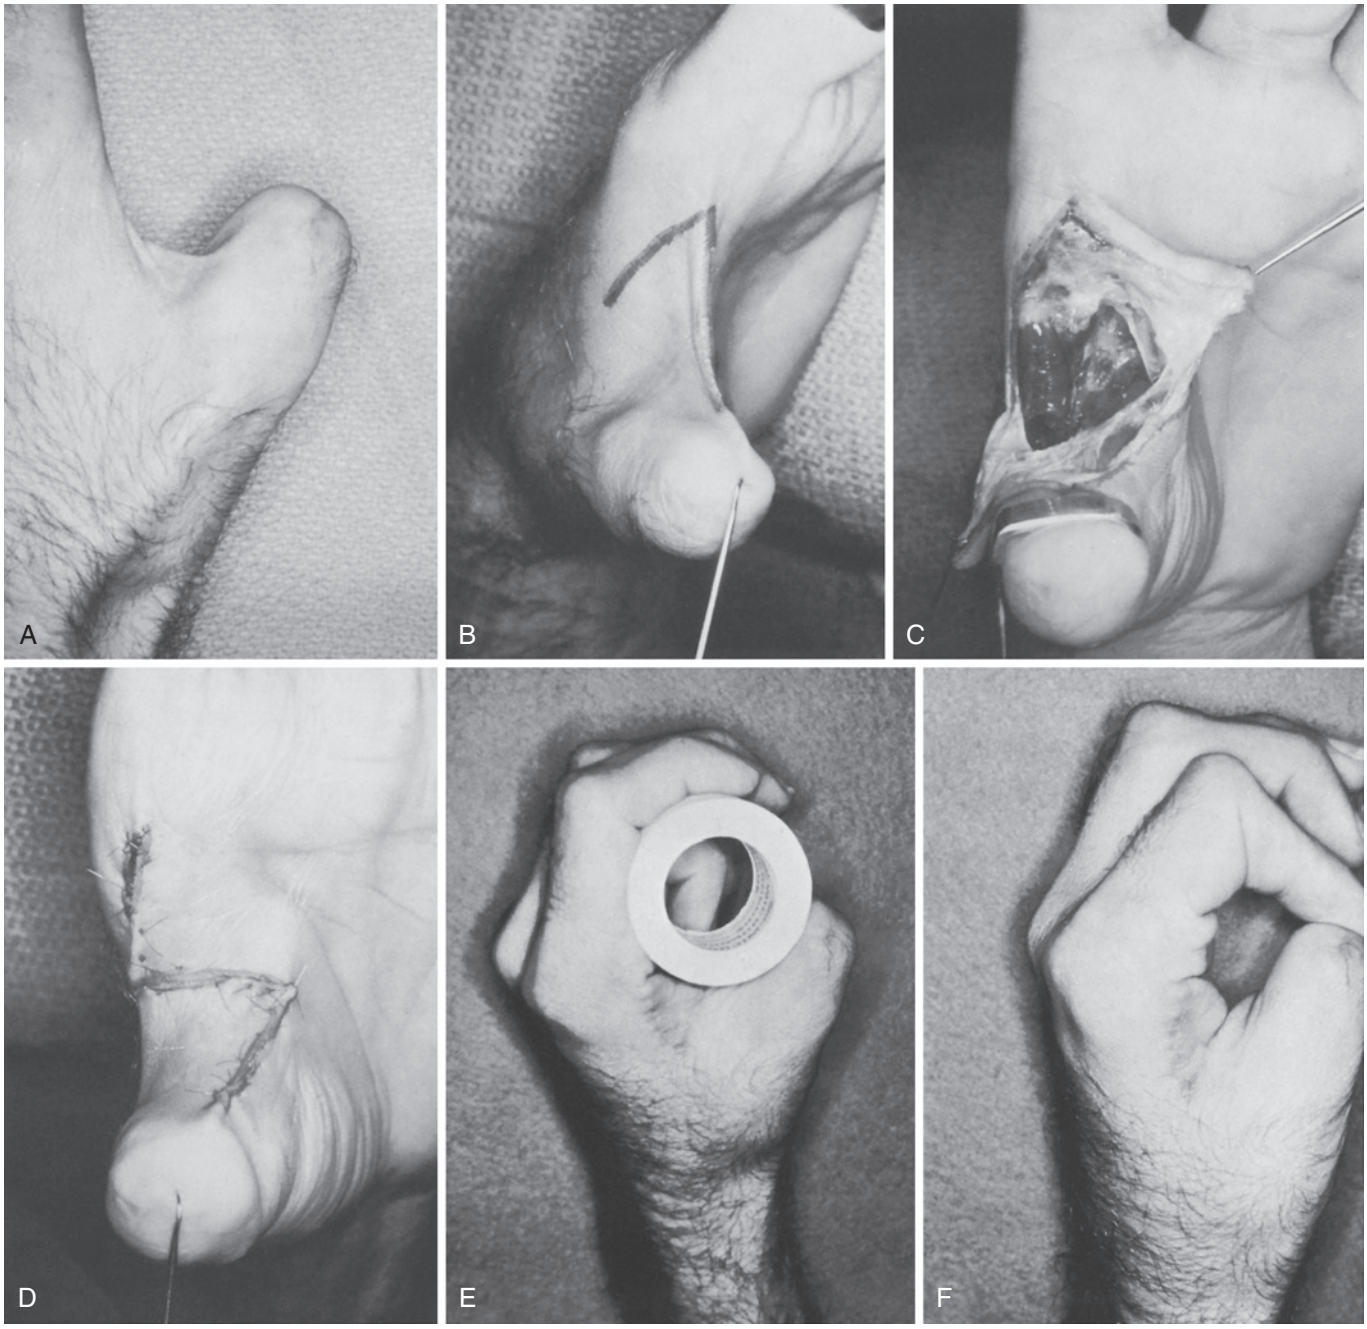
When unsalvageable thumbs are amputated near the distal portion of the proximal phalanx, satisfactory function can usually be achieved by procedures designed to deepen the first web space and create a widened thumb–index finger interval. These procedures have been called phalangization, and they use methods that deepen the interdigital cleft so that the first metacarpal and remaining proximal phalanx are relatively lengthened.[9,29,70,87,94,98] This can be accomplished by simple scar-lengthening techniques; local, regional, or distal pedicle flaps; or, when necessary, free tissue transfer. The indications for these techniques vary according to residual thumb length, amount of first web contracture, mobility of the first metacarpal, and condition of the web space skin and muscle.[9,69,87,94] Apart from their use in thumb reconstruction, these techniques also prove useful when contracture of the first web space occurs after thumb reconstruction by another procedure, such as free toe transfer.

"Z"-Plasty Procedures

"Z"-plasty techniques are designed to lengthen the distance between the apices of the "Z" at the cost of narrowing the distance between the endpoints of the "Z." The simple and four-flap "Z"-plasties take advantage of both actions to increase the thumb–index finger span and simultaneously deepen the first web space. Prerequisites for effective web space deepening via "Z"-plasty include the following: (1) at least half the proximal phalanx remains, (2) the skin is minimally scarred, (3) the first metacarpal is mobile, and (4) there is minimal muscle contracture. The following sections discuss the concepts of "Z"-plasty, including proper flap design, mobilization, and repositioning as applied to the first web space.

Simple "Z"-Plasty of the Thumb Web. Under tourniquet hemostasis, the central limb of the planned "Z" is marked on the distal ridge of the first web space, extending from the proximal digital crease of the thumb to approximately 1 cm proximal to the proximal digital crease of the index finger, at a point that corresponds with the radial confluence of the proximal and middle palmar creases. Using these landmarks as guidelines decreases the likelihood of extending the flap onto the ulnar thumb or radial index finger. Oblique proximal palmar and distal dorsal limbs oriented at 60-degree angles to the central limb are designed, with their length corresponding to the length of the central limb. Local scar, previous incisions, or possible approaches for other reconstructive procedures may result in the need to reverse the direction of the two oblique limbs (proximal dorsal and distal palmar). Either combination seems to work satisfactorily (Figure 48.11, *A*), but the combination of proximal palmar and distal dorsal parallels the interthenar crease and affords excellent cosmesis to the closure.

After incising the skin, dissection is carried down to the level of the muscle fascia. The flaps are carefully undermined just superficial to the muscle fascia to avoid vascular compromise. Care should be taken during dissection to avoid injuring (if present) a distal arterial connection between the indicis radialis and princeps pollicis vessels. Deepening of the web space is facilitated by incision of the fascia over the first dorsal interosseous muscle and partial division of its distal mass (see Figure 48.11, *B*). Abducting the thumb tends to begin transposing the flaps; as the span between the thumb and index finger increases, the distance across the web space, from dorsal to palmar, decreases. This decrease is compensated for by recession of the first dorsal interosseous muscle. Once the flaps are reversed and sutured in place, the result is an increased web span and deepened web space (see Figures 48.11, *C* and eFigure 48.4).



eFIGURE 48.4 Simple "Z"-plasty of the thumb web. **A,** Limited thumb–index finger cleft following amputation through the midproximal phalanx. **B,** Design of the "Z"-plasty. **C,** Reflection of flaps with partial recession of the first web musculature. **D,** Appearance of the "Z"-plasty after reversal and suture of flaps. **E** and **F,** Effective deepening of the thumb web 3 months postoperatively. (From Strickland JW: Restoration of thumb function following partial or total amputation. In Hunter JM, Schneider LH, Mackin E, et al, editors: *Rehabilitation of the hand*, St. Louis, 1984, CV Mosby.)

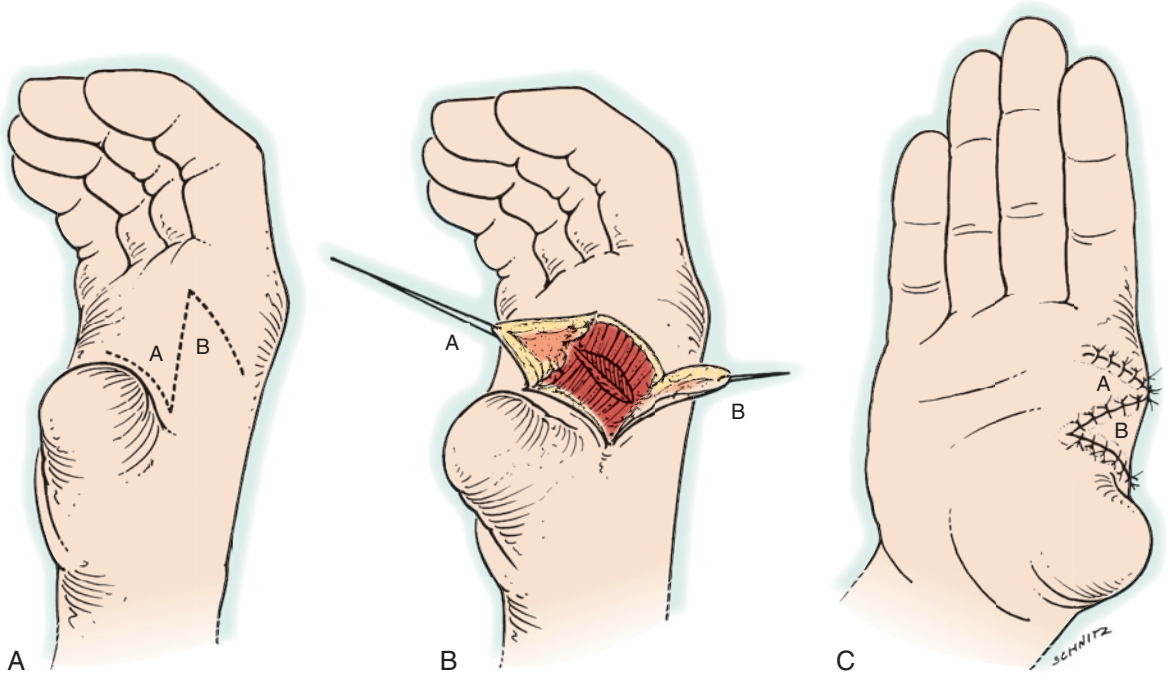


FIGURE 48.11 Simple "Z"-plasty of the thumb web. **A,** Design of the "Z"-plasty. The preferred angles are approximately 60 degrees. **B,** Flaps reflected with partial recession of the web space musculature. **C,** Appearance of the flaps after reversal and suture. Comer sutures are preferred in the tips of the flaps.

Four-Flap "Z"-Plasty of the Thumb Web. Under tourniquet hemostasis, the central limb of the "Z"-plasty is drawn on the distal edge of the thumb web ridge, as described for the simple "Z"-plasty. Proximal palmar and distal dorsal limbs at angles varying from 90 to 120 degrees relative to the central limb are made, with their lengths equaling that of the longitudinal incision. The angles formed by these three limbs are bisected by oblique lines, equal in length to the prior limbs, extending from their apices and yielding four angles ranging from 45 to 60 degrees (Figures 48-12, *A* to *C*, and 48.13, *A*). The flaps are reflected on their bases by gentle undermining, and a small recession of the thumb web musculature can be carried out to provide additional depth.

The flaps are transposed so that the common border of the two middle flaps previously formed by the central limb now lies against the proximal and distal incision sites (see Figure 48.12, *D* and *E*). The proximal palmar and distal dorsal flaps are rotated to the midline, and their medial edges, previously formed by the oblique bisecting incisions, are joined. The flaps are sutured in place without tension. Completion of flap transposition should result in a substantial increase in web depth (see Figures 48.12, *F*, and 48.13, *B*).

At the conclusion of the procedure, the wound is dressed with nonadherent gauze and a compressive dressing consisting of adequate gauze to maintain the expanded web space is applied. The wound is examined at 10 to 14 days, at which time the bulky dressing is exchanged for a static, custom-fitted splint. Therapy consisting of active and passive range of motion begins after this initial dressing change; the patient continues to wear the web spacer splint when not performing range-of-motion exercises. The patient is gradually weaned from the splint over the next few weeks, based on his or her individual progress in therapy.

CRITICAL POINTS *Four-Flap "Z"-Plasty*

Indications

- Amputation near the midportion of the proximal phalanx
- Minimal scarring of the first web skin
- Absence of first web muscle contracture
- Mobile first metacarpal

Technical Points

- Mark the central limb of the planned "Z" on the distal ridge of the first web space, beginning at the proximal digital crease of the thumb and extending to 1 cm proximal to the proximal digital crease of the index finger.
- Design the proximal palmar and distal dorsal limbs at an angle between 90 and 120 degrees relative to the central limb; the combined length of these limbs should equal the length of the central limb.
- Add two more limbs, each equal in length to the proximal and distal limbs, and each positioned to bisect the angle between the proximal or distal limbs and the central limb.
- Incise the skin along the markings, and gently undermine the flaps.
- If necessary, incise the musculature to deepen the web space.
- Transpose the flaps so that the common border of the central flaps (the central limb) lies against the proximal and distal incision sites.
- Transpose the proximal palmar and distal dorsal flaps so that their medial edges (previously the bisecting limbs) are joined.
- Inset the flaps with fine, nonabsorbable suture.
- Apply nonadherent gauze and a gentle compressive dressing.

Postoperative Care

- Examine the wound at 10 to 14 days.
- Switch to a thermoplastic splint to maintain the web space.
- Begin active and passive range-of-motion exercises immediately after the first dressing change.
- Wean the patient from the web spacer splint over the course of a few weeks.

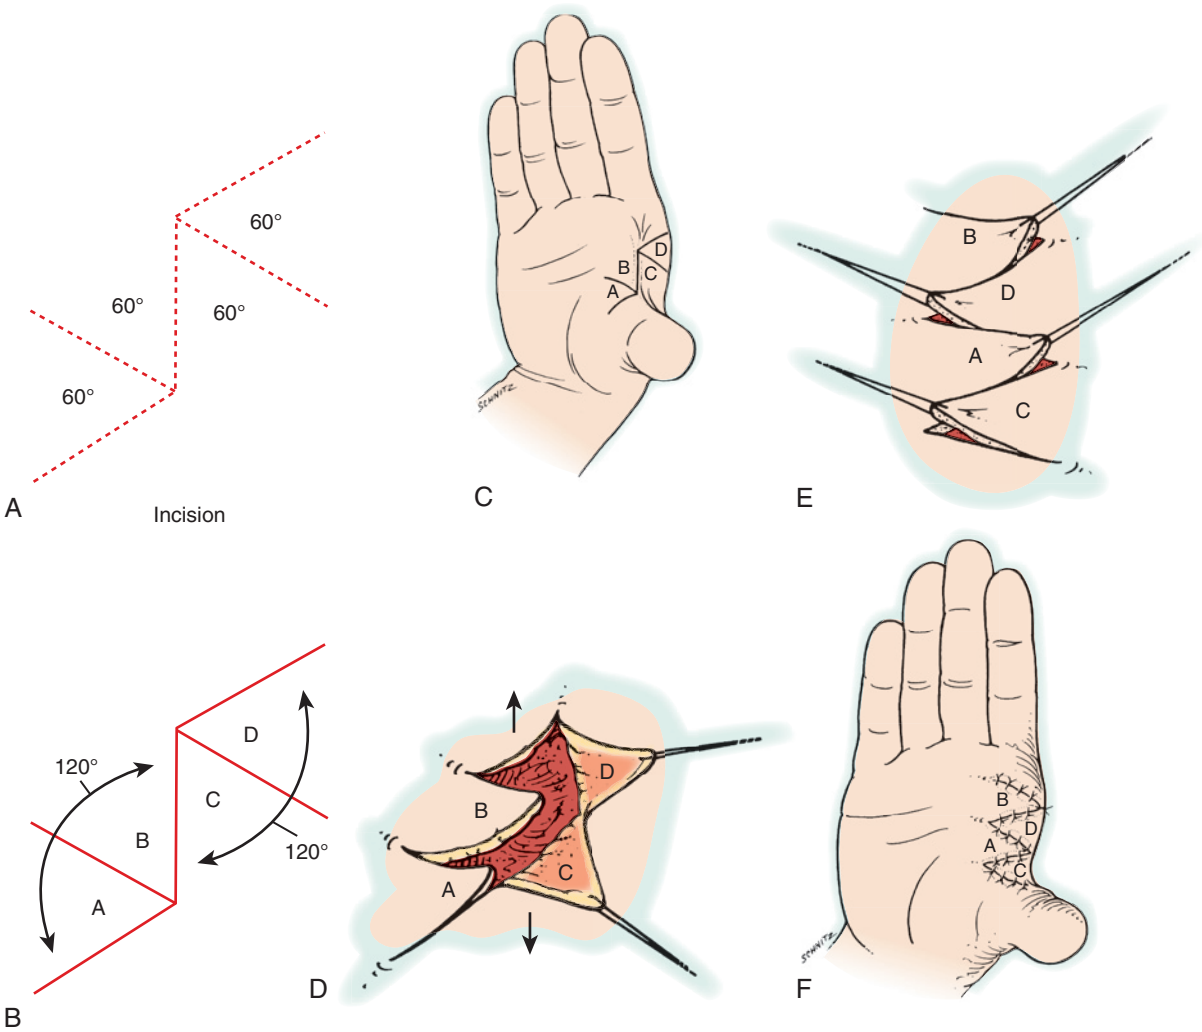

FIGURE 48.12 Four-flap "Z"-plasty of the thumb web. **A** and **B,** Two 120-degree-angle opposing incisions are bisected to form four 60-degree flaps. **C,** Design of the flaps in the first web space. **D,** Incision, elevation, and undermining of the flaps. **E,** Flap position after interposition. **F,** Appearance of the thumb web after interposition of the flaps. (Modified from Broadbent TR, Woolf RM: Thumb reconstruction with contiguous skin-bone pedicle graft. *Plast Reconstr Surg* 26:494–499, 1960.)

These simple skin mobilization techniques, occasionally combined with short distal muscle recession, can provide reliable deepening of the thumb web and relative lengthening of the shortened thumb. When measured, the gain in depth varies from 1.5 to 2 cm, which should result in an improved ability to grasp large objects. The main potential complication with these techniques is necrosis, either partial or complete, of the flaps; the risk can be minimized with careful planning and dissection of the flaps.

Dorsal Rotational Flap

When at least half the proximal phalanx of the thumb remains but extensive scarring of the first web skin or an adduction contracture of the first metacarpal exists, "Z"-plasty techniques are no longer useful. To phalangize the residual thumb stump, sequential division of all restraining skin, muscle, scar, and capsular adhesions may be necessary. Such extensive mobilization is likely to result in a significant skin deficit over the first web. Several dorsal rotational flap techniques have proved effective in deepening the first web space and mobilizing and resurfacing the metacarpal-phalanx unit.[9,32,103,116,120] Advantages of web space coverage by a dorsal rotational flap include excellent skin quality and sensory perception in the web.

Phalangization of the First Metacarpal With Dorsal Rotational Flap Coverage. With the use of tourniquet anesthesia, a continuous linear dorsal and palmar incision is carried through the first web, beginning dorsally at the level of the trapeziometacarpal joint and extending along the ulnar border of the first metacarpal to the first MP joint, where it passes through the thumb web and continues volarly into the palm at the base of the thenar eminence (Figure 48.14).

Sharp dissection is continued just ulnar to the extensor pollicis longus. With careful technique to protect sensory branches of the radial nerve, the origin of the first dorsal interosseous muscle is stripped from the metacarpal; alternatively, if the muscle is scarred or fibrotic, it is divided. The radial artery must be identified as it dips between the two heads of the first dorsal interosseous muscle just beyond the trapeziometacarpal joint. By following the artery distally, the princeps pollicis artery can be identified and protected as the border of the adductor

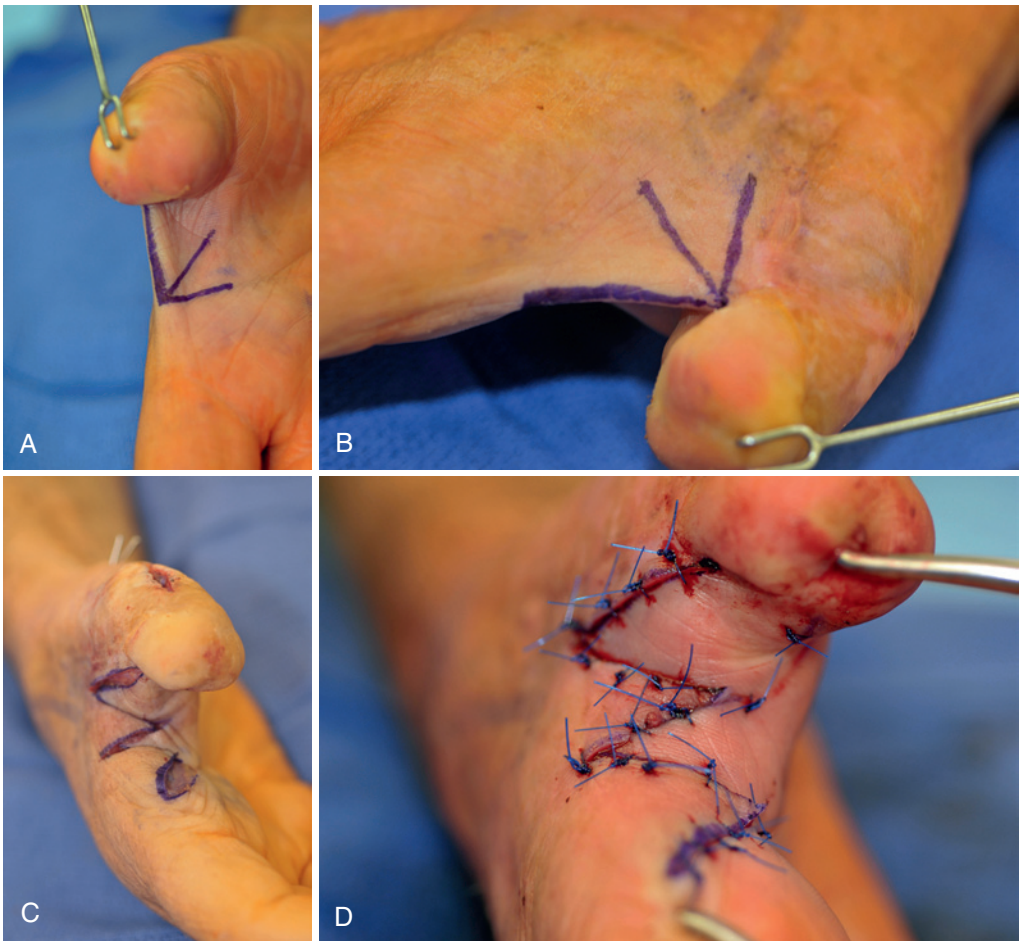

FIGURE 48.13 Four-flap "Z"-plasty of the thumb web. **A,** Design of the flaps (see also Figure 48.12). **B,** Appearance of the thumb web immediately after transposition and suture of the flaps.

pollicis is defined. Both the oblique and transverse heads of the adductor are divided, and by gentle abduction traction on the first metacarpal, the adequacy of mobilization of the first ray can be evaluated. Stripping of the opponens pollicis muscle may be required to mobilize a severely contracted first metacarpal. In some cases, muscle release does not result in complete mobilization of the first metacarpal, and release of the CMC joint capsule or occasionally trapezial excision may be necessary. The capsule of the trapeziometacarpal joint is opened transversely through a palmar incision, and a similar capsulectomy on the dorsal ulnar side of the joint is sometimes used. The mobilized thumb is stabilized in the corrected position by transfixing the first and second metacarpals through their proximal segments with two nonparallel Kirschner wires (see Figure 48.14, *D*) or with an external fixator (Figure 48.15). The tourniquet is released at this point; all brisk bleeding vessels are controlled, and the vascularity of the thumb is confirmed before reinflation. Trial rotation of a paper pattern placed over the dorsum of the hand can help determine the proper size and configuration of the flap. The incision is continued from the ulnar aspect of the first web dorsally across the radial aspect of the MP joint of the index finger and onto the dorsum of the proximal phalanx of that digit. It is brought proximally over the dorsum of the hand to approximately the base of the fourth metacarpal; the exact configuration can best be determined by the paper pattern technique just described (see Figure 48.14, *B* and *C*). The dorsal flap is dissected free from the peritenon overlying the extensors of the fingers, and although there is minimal interference with the dorsal veins of the hand, a few sizable veins should be ligated distally and brought with the flap (see Figure 48.14, *C*). Gentle undermining is carried out, and an occasional additional dorsal ulnar skin release may be necessary to bring the flap into the proper position to cover the defect. The flap is sutured in place, and the resulting triangular defect over the dorsal radial aspect of the hand is covered with either a dissected, nearly full-thickness graft from the groin or a split-thickness graft taken with a dermatome (see Figure 48.14, *D*).

Nonadherent gauze and a saline-moistened cotton dressing are used over the graft. Kirschner wires are bent and trimmed, and a compressive dressing is applied to the hand, wrist, and forearm. The flap and grafts are first checked at 7 to 10 days, and the sutures are removed at 2 weeks. Active and passive therapy for digital mobilization begins at 2 to 3 weeks; during this initial rehabilitation, a custom-made first web splint is worn to maintain the web space. The pins are removed at 4 to 6 weeks, after which the patient is gradually weaned from continuous use of the web splint. Continual monitoring of the status of the web space is necessary for 1 year, and night

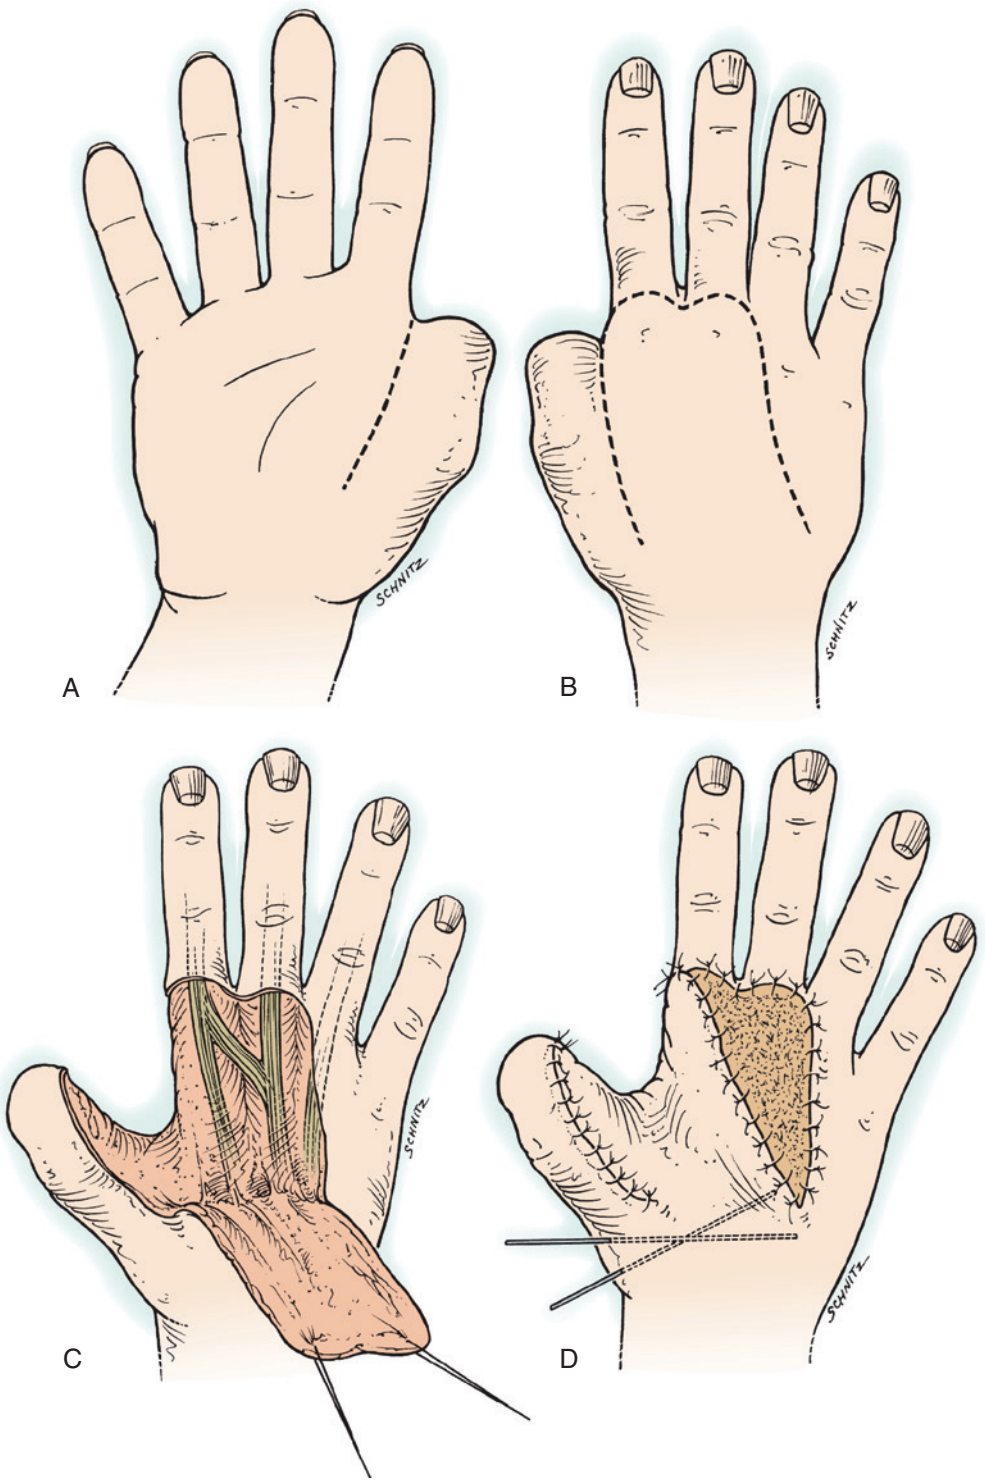

FIGURE 48.14 Release of adduction contracture of the first web space with dorsal rotational flap coverage. **A,** The palmar web-dividing incision is a continuous linear incision from the first web space to the thenar crease, paralleling the medial margin of the thenar musculature. **B,** Linear incision over the dorsum of the first web with approximate outline of the dorsal rotational flap. **C,** First web defect after division of restraining skin, soft tissue, and muscle with abduction of the first metacarpal. Elevation of the dorsal rotational flap down to the peritenon overlying the extensor tendons is complete. **D,** Appearance of the first web after coverage with the dorsal rotational flap. Kirschner wires hold the thumb in abduction during healing, and a free skin graft is used to cover the donor defect. (Modified from Brown PW: Adduction-flexion contracture of the thumb: correction with dorsal rotation flap and release of contracture. *Clin Orthop Relat Res* 88:161–168, 1972.)

The use of a mini–external fixator is depicted. **A,** Purchase pins in the lateral aspect of the first metacarpal and dorsum of the second metacarpal, with a transfixing bar used to stabilize and maintain the web. **B,** Transverse section to depict the position of the fixator pins in the metacarpals. **C,** Alternatively, a mini–distraction device can be applied and gradually distracted, as in this case, in which the mutilated hand was reconstructed with a rectus free flap, adductor release, and first web space distraction. **D,** Application of mini–distraction device.

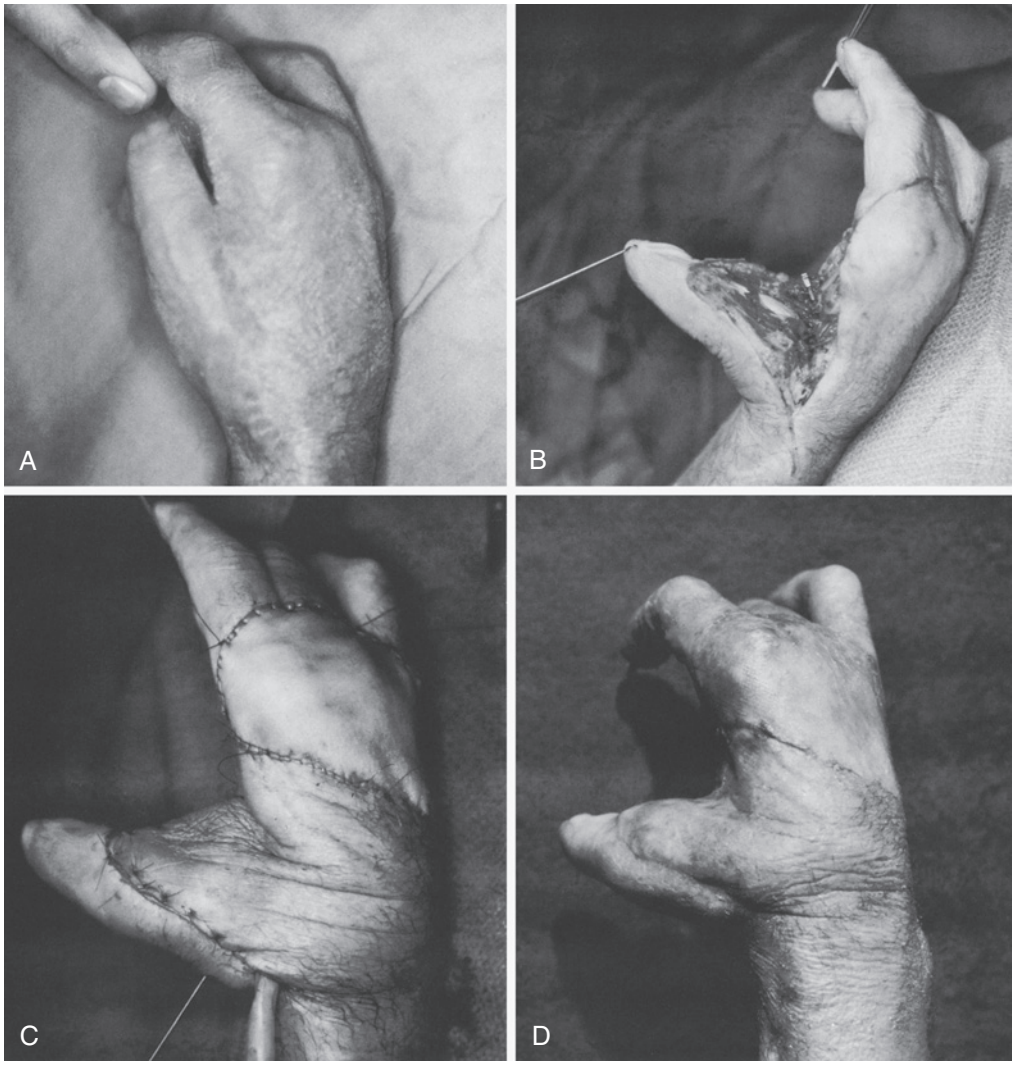
splinting with a web spacer may be necessary throughout that period.

Long-standing severe adduction contracture of the first metacarpal is a crippling deformity, particularly when a portion of the distal thumb has been lost. Surgical release of the deformity is accomplished by meticulous sequential division of all contracting elements, which results in a substantial skin and soft tissue deficit. This defect can be well covered by a rotational flap from the dorsum of the hand (eFigure 48.5).

Potential complications include hematoma formation, flap loss, graft failure, or recurrent adduction contracture. If the surgical procedure is carried out carefully, with attention to technical detail, and if proper postoperative care is given, the incidence of these problems should be minimal. Additional reconstructive procedures such as tendon transfers may be necessary to further enhance thumb function; however, restoration of the web space and improvement in thumb posture alone should have a profoundly favorable influence on hand performance.

Regional and Distant Flaps

Just as damage to the first web skin and muscle contractures render the simple "Z"-plasty inadequate for thumb phalangization, damage to the skin overlying the dorsum of the hand removes the possibility of deepening the web space with a dorsal rotational flap. In this setting, a remote pedicle source must be sought to provide quality coverage after releasing procedures. A variety of regional and distant flaps have been employed to cover defects on the hand, and these flaps may serve equally well to release contractures of the first web space and provide greater hand span. Because the locations and techniques for elevating these flaps are described in detail in other chapters, they are



eFIGURE 48.5 Phalangization of a severely contracted first metacarpal with a dorsal rotational flap. **A,** Severe, long-standing adduction contracture of the thumb after amputation through the proximal phalanx. **B,** Appearance of the thumb web after release of skin, soft tissue, web space musculature, and the basal thumb joint. **C,** Coverage of the thumb web with a large dorsal rotational flap. **D,** Appearance of the thumb web at 3 months.

mentioned only briefly here. The distally based radial forearm flap[29] and posterior interosseous flap[25] are both capable of reaching the first web space and providing excellent soft tissue coverage to allow web space deepening and expansion. When trauma to the arm has rendered both of these regional flaps unusable, free tissue transfer either alone, as in the lateral arm flap,[111] or as an adjunct to free toe transfer can be used to augment the first web space.

Although seldom used owing to the awkwardness of positioning and the inconvenience of even simple activities such as donning a shirt, distant pedicled flaps, such as the groin flap, pectoral flap, or cross-arm flap,[94,122] can provide excellent resurfacing of the first web space. Unlike the groin and pectoral flaps, the limited size of the cross-arm flap makes it less useful for general hand wound coverage; however, the flap can provide thin, supple skin for web space resurfacing, and the contour of the arm is excellent for maintaining the web space while the pedicle is being vascularized.[94] The medial aspect of the arm bears the thinnest skin and a thin subcutaneous layer, making it the preferred donor site for the flap. Given its potential use in phalangization and web space creation, we include a description of the cross-arm flap technique here.

First Web Space Deepening With Cross-Arm Flap Coverage. Release of the first web space is carried out in a manner identical to that described for the dorsal rotational flap (Figure 48.16, *A*; see also Figure 48.14). The abducted position of the thumb is maintained by Kirschner wires crossed between the bases of the first and second metacarpals or by an external fixator. The hand is brought into place against the opposite arm in such a manner that the ulnar border of the hand rests against the anterior medial surface of the forearm, with the thumb comfortably placed around the inner aspect of the upper arm. Patterns are used to design a proximally based triangular flap for resurfacing the dorsal half of the divided web space (Figure 48.16, *B*). The flap is meticulously elevated, including skin and subcutaneous tissue, and temporary split-thickness skin coverage is placed on the arm and palmar hand defects. Moist cotton stent dressings over the graft are important, and the position of the arm is maintained by a plaster Velpeau dressing. At 2 to 3 weeks the patient is returned to the operating room, and a corresponding triangular flap is designed proximally; this is dissected out and turned into the palmar defect after the free graft is excised. Defatting of the flap is not usually necessary, and excellent restoration of the web space can be achieved in this manner (see Figure 48.16, *C*). A bulky dressing to maintain the web space is applied and changed at 7 to 10 days. Suture removal and web space splinting with a custom-fit spacer are performed at 2 weeks. Rehabilitation and pin removal occur on the same schedule as for the dorsal rotational flap. Likewise, monitoring for web space contracture may be necessary for up to 1 year, and night splinting with the web spacer may be required.

The cross-arm flap can provide excellent coverage after release of the first web space in patients with thumb amputation through the middle third of the first ray. The procedure restores excellent skin and subcutaneous tissue both palmarly and dorsally, without the need to use the frequently compromised dorsal hand skin. A disadvantage is the resulting defect on the opposite arm, and although this procedure can generally maintain the hand in a position of function, upper limb function is limited during the period of obligatory immobilization.

Nonetheless, it has proved to be an effective technique for web space widening and deepening and relative thumb lengthening in certain cases where microvascular free tissue transfer is not available.

Subtotal amputations at or proximal to the midportion of the proximal phalanx are unlikely to achieve adequate length solely through phalangization procedures. At this level, the reconstructive options overlap with techniques used to provide an opposable thumb in the setting of total amputation with preservation of the basal joint.

Total Amputation With Preservation of the Basal Joint

Although not the only possible reconstruction at this level, the reliability of free toe transfer procedures, the availability of microsurgical instrumentation, and the familiarity of most hand surgeons with the techniques make free toe transfer the optimal choice for these amputations. Either great toe or second toe transfer is often an excellent restorative option that can provide the necessary length, mobility, and sensibility for a functional thumb. Given the excellent outcomes with free toe transfer (see Chapter 44),[22,132,133] the majority of patients seeking thumb reconstruction who require additional length are candidates for these procedures. There may be occasional patients who are unwilling to accept the cosmetic alteration of the foot or for whom athletic performance may be compromised after sacrifice of a toe. Alternative methods include metacarpal distraction or lengthening techniques, osteoplastic reconstruction, and pollicization of an injured or partially amputated digit.[85] Distraction osteogenesis, as discussed elsewhere, may be useful when the amputation has spared a substantial amount of the first metacarpal. Under optimal conditions, progressive metacarpal distraction can safely result in 3 to 4 cm of additional length for patients with traumatic thumb amputation. Although distraction can add length, motoring of the digit depends on the residual function of the intrinsic muscles of the thumb. With increasingly proximal amputations, motor function may need to be provided through tendon transfers.

Osteoplastic Reconstruction

Osteoplastic reconstruction, or thumb reconstruction by means of a bone graft covered with a pedicled flap, was first attempted by Nicoladoni in 1897.[96] Early reports of successful thumb reconstruction using bone graft and tubed pedicle techniques made this the preferred method of thumb reconstruction during the first half of the 20th century[27,42,96]; however, results were plagued by the inability to provide adequate sensory perception to the reconstructed thumb and significant resorption of the bone graft inside the pedicle. Moberg[89] and Littler[71] improved sensation by suggesting that a neurovascular island pedicle transfer become part of osteoplastic reconstruction of the thumb, and the use of large, extraperiosteal, tricortical iliac crest grafts may have reduced the extent of bone resorption.[67,92] Although toe-to-thumb transfer procedures have largely supplanted osteoplastic reconstruction, it may still prove useful when there is good basal joint motion, the fingers are normal or too badly damaged for transfer, and toe transfers or lengthening techniques are not appropriate.[68]

Variations on the osteoplastic theme include the Gillies "cocked-hat" flap, which uses local tissue to cover the bone graft (Figure 48.17), and composite flaps based on the pedicled radial forearm flap.[5,8,17,24,78,135] Biemer and Stock[5] described a one-stage total thumb reconstruction using a composite flap containing skin and subcutaneous tissue, a segment of radial bone, a length of the lateral cutaneous nerve of the forearm, and two veins. The elevated flap is turned 180 degrees, and the radial bone is fixed to the first metacarpal. The digital nerves of the thumb are sutured to the nerves in the flap, and vein anastomosis is optional. Foucher's technique varies, in that it restores sensation by means of a neurovascular island pedicle flap.[35]

Two-Stage Osteoplastic Reconstruction of the Thumb

Stage 1. In the first stage (Figure 48.18, *A* to *D*), a groin flap that includes the superficial circumflex iliac artery is patterned and raised on the same side as the hand whose thumb is to be reconstructed (see Chapter 44). The flap should have a width of 7.5 cm and a minimum length of 12 cm, with its free end positioned over the lateral prominence of the underlying iliac crest. A large extraperiosteal tricortical bone graft is taken from the iliac crest; the graft should be 7 to 8 mm thick, 5 to 6 cm long, and 1.5 cm wide (see Figure 48.18, *B*).

Under tourniquet hemostasis, adequate débridement of scar, skin, and any necrotic bone from the distal metacarpal is carried out. A cuff of viable skin over the first metacarpal should be reflected to increase the vascular contact area of the flap. A small curet is used to fashion a hole in the medullary canal of the metacarpal, and the bone graft is shaped with a motorized bur to produce a stout cortical stem 2 cm long. The graft is inserted and secured in the metacarpal so that its flattened raw edge is facing the index finger in opposition with the first metacarpal (see Figure 48.18, *C*). Lister[67] has suggested that the fit of the graft peg into the metacarpal should be tight enough to enable lifting of the arm by the graft after insertion; however, fixation is typically secured by longitudinally or obliquely placed pins. The distal tip of the graft is shaped with a rongeur to remove any sharp edges and approximate the length of the IP joint of the normal thumb.

The substantial amount of subcutaneous fat present in most groin flaps necessitates defatting of the distal tip of the flap before inset. After careful removal of an adequate amount of fat, the flap is tubed along most of its length. The donor defect is undermined and closed without excessive tension, and the bone graft is inserted into the tube with the suture line coming to lie palmarly in preparation for insertion of the neurovascular island flap during the second stage. The free end of the pedicle is sutured to the expanded metacarpal skin defect (see Figure 48.18, *D*). Care is taken to avoid tension, twisting, or "kinking" of the pedicle, and a low-suction drain is placed in the groin wound for 24 to 48 hours. A soft Velpeau-type restraining dressing is used to comfortably immobilize the arm. Throughout the period of neovascularization of the flap, the patient is instructed to move the untethered fingers and wrist through a full range of motion. The debate over how long to wait before pedicle division and performance of the second stage ranges from just over 8 days (provided an ischemic preconditioning protocol has been followed)[21] to 4 weeks.[113] Useful methods to assess the readiness of the flap for division include fluorescein testing[83] and laser Doppler flowmetry.[21] Whichever testing modality is used, if flap viability is still questionable at 10 to 14 days, partial division of the flap and ligation of the superficial circumflex iliac artery can be performed with the patient under local

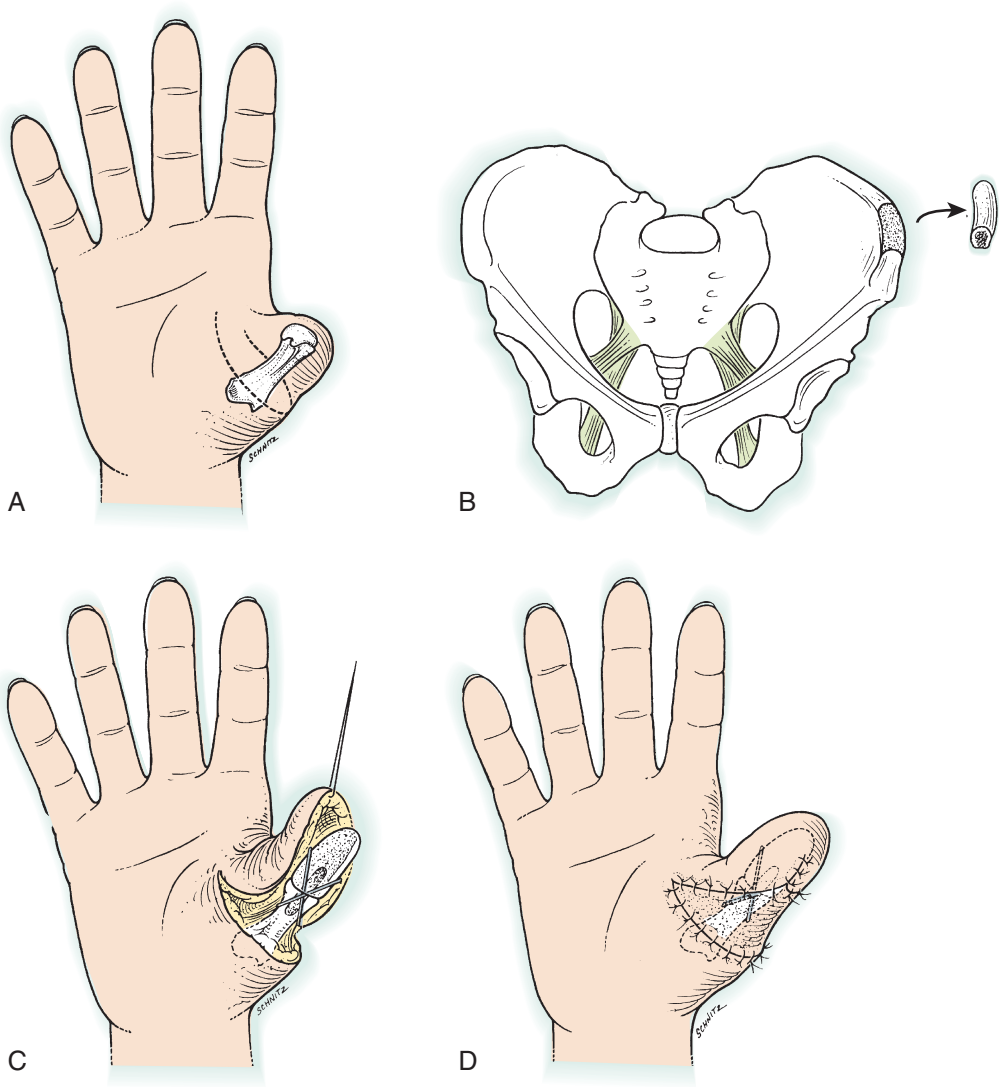

FIGURE 48.17 Gillies "cocked-hat" flap. **A,** Outline of the incisions around the base of the thenar eminence. **B,** Tricorticocancellous iliac bone graft to elongate the first metacarpal. **C,** The flap is reflected, and the graft is held in place with crossed Kirschner wire fixation. The graft may be stemmed for insertion into the metacarpal, or a cortical peg may be used to bridge the graft-metacarpal interval, as shown here. **D,** The flap brought back to cover the bone graft. A free skin graft covers the thumb defect. (Modified from Reid DAC: Reconstruction of the mutilated hand. In Rob C, Smith R, Pulvertaft RG, editors: *Operative surgery: the hand*, ed 3, London, 1977, Butterworth.)

anesthesia to effect a "delay" of the flap and improve its vascularity.

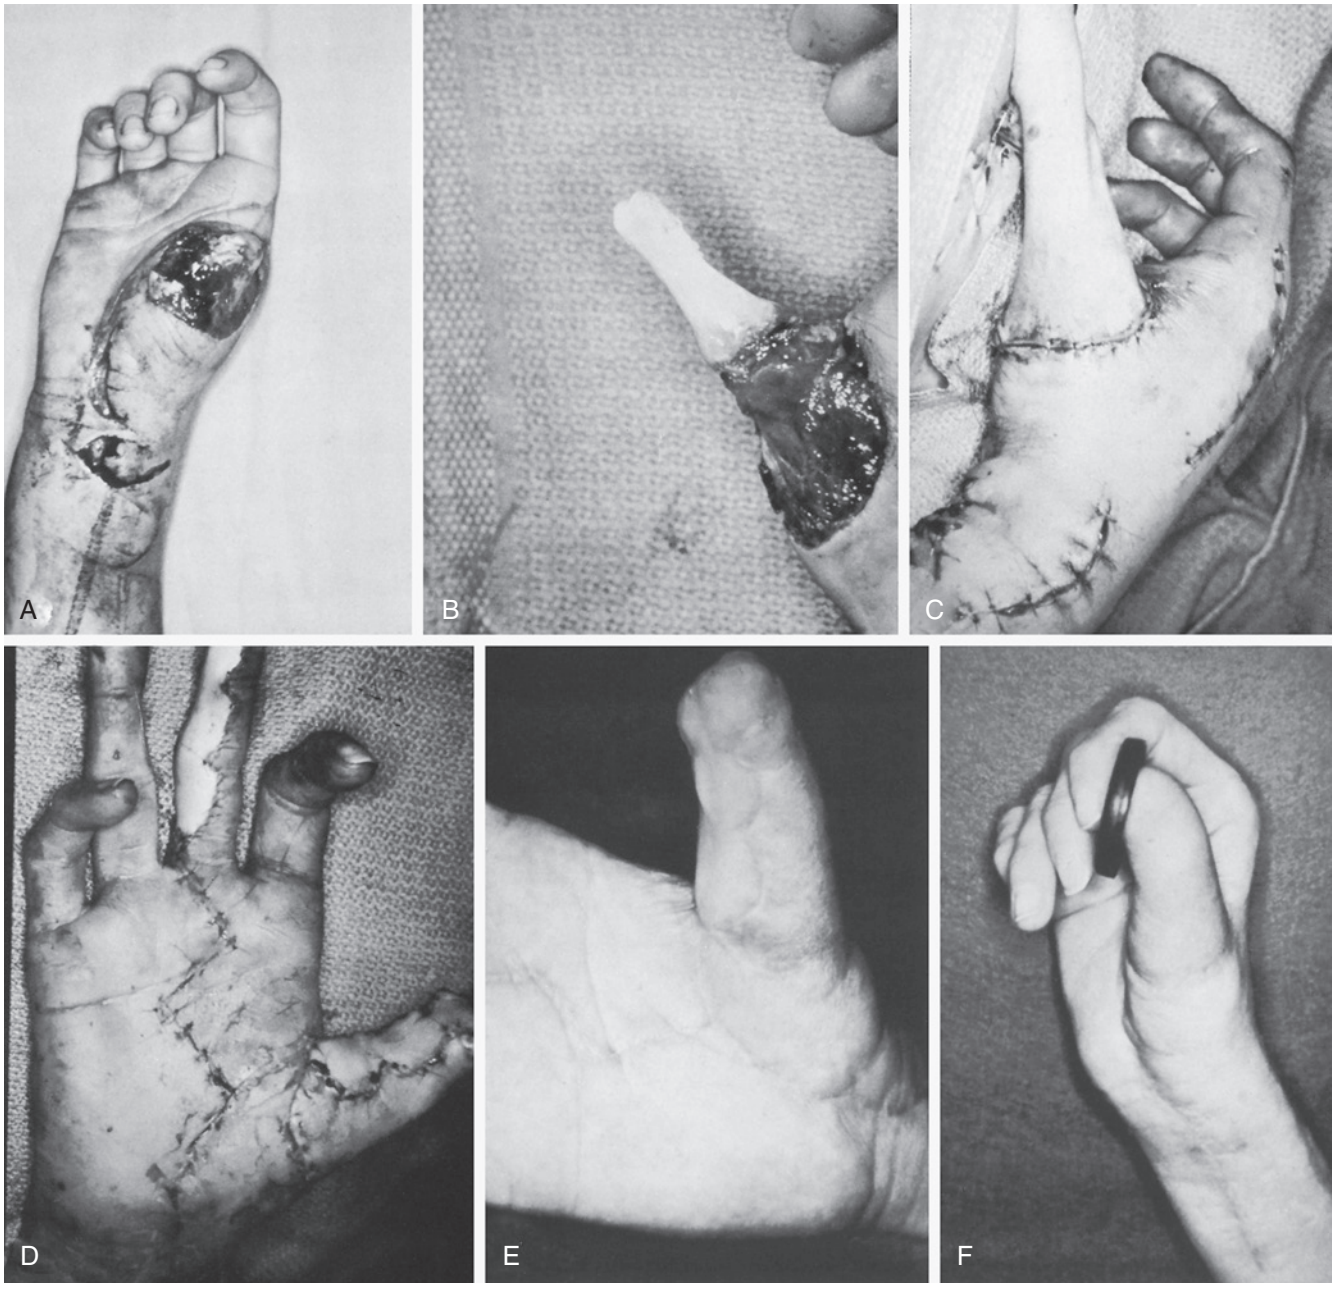
Stage 2. At the time of complete tube release, whether at the initial assessment or after the partial delay procedure, an extended neurovascular island flap is raised from the ulnar aspect of the long finger and dissected well into the palm as described earlier (see Figure 48.18, *E* to *H*). When re-creating the defect into which the flap will be placed, the surgeon should extend the defect over the distal aspect of the bone graft and dissect down to the raw bone on the palmar side of the graft (see Figure 48.18, *F* and *G*). Passage, inset, and donor site closure are identical to the techniques used for the standard neurovascular island flap (see Figure 48.18, *H*).

A plaster-reinforced compressive dressing is used postoperatively for 7 to 10 days, and cast immobilization is continued until bony union is complete at 6 to 8 weeks. Gradually increasing use of the reconstructed thumb is then permitted.

Although rarely necessary, this type of thumb reconstruction is fairly rapid and does not require the use of other digits or toes (eFigure 48.6). Its disadvantages lie in the obligatory insult to the long finger and the tendency to continue to perceive the reconstructed thumb unit as the long finger, although this may be a less bothersome phenomenon with the passage of time. The potential complications are numerous and include partial necrosis of the groin flap, loss of blood supply or diminished sensory perception in the neurovascular island flap, failure of the free graft to the long finger, and nonunion or resorption of the bone graft.

Composite Radial Forearm Island Flap

This procedure has the advantage of providing a well-vascularized skin and bone flap and, with the addition of an extended neurovascular island pedicle flap, avoiding the staging necessitated by conventional osteoplastic methods. Preoperative



eFIGURE 48.6 Osteoplastic reconstruction of an amputated thumb. **A,** Traumatic amputation of the thumb through the first metacarpal. **B,** Bone graft using the preserved proximal phalanx of the amputated thumb. **C,** Application of a thin, tubed upper abdominal pedicle flap. **D,** Transfer of an extended neurovascular island pedicle flap from the ulnar aspect of the long finger at the time of pedicle flap detachment. **E** and **F,** Appearance of the thumb unit at 9 months, with satisfactory pinch and grasp functions. (From Strickland JW: Restoration of thumb function following partial or total amputation. FIGURE 48.18 Osteoplastic reconstruction of the thumb. **A,** Thumb amputation through the metacarpophalangeal joint. **B,** Site of removal of extraperiosteal tricorticocancellous iliac crest bone graft. **C,** Preparation of the recipient site with insertion of the iliac crest graft into the first metacarpal, shown here with Kirschner wire fixation. **D,** Bone graft coverage with a tubed groin flap. **E,** Incisions for the use of an extended neurovascular island pedicle flap to provide vascularized and innervated skin on the palmar aspect of the reconstructed thumb. **F,** Transfer of the neurovascular island flap to the palmar thumb defect at the time of flap detachment. **G,** Severance of the digital artery to the opposite web and careful intraneural separation of the common digital nerve in preparation for tension-free transfer of the neurovascular island flap. **H,** Completion of neurovascular island transfer with a free skin graft to the donor defect in the long finger. (Modified from Simonetta C: Reconstruction of the thumb by tube pedicle, bone graft and island flap. In Reid DA, Gosset J, editors: *Mutilating injuries of the hand*, New York, 1979, Churchill Livingstone.)

requirements are those of the standard radial forearm flap (see Chapter 44), including a patent ulnar artery and palmar arch. The finding of a predominantly radial blood supply or the absence of an ulnar artery precludes the use of this procedure.

The flap is designed from the palmar and radiodorsal aspect of the forearm, beginning several centimeters proximal to the radial styloid. It should be 7 to 8 cm long and 6 to 7 cm wide (Figure 48.19, *A*). After preparation of the distal thumb stump, the flap, including the radial artery and its venae comitantes, is carefully raised. Great care is taken not to damage the cutaneous branches of the radial nerve or the blood supply to the radius just proximal to the styloid process. One or more small branches from the radial artery should be identified entering the pronator quadratus muscle and extending down to the periosteum of the radius. These vessels must be protected, which often necessitates leaving a small amount of muscle attached to the radius. A bone flap measuring from 2 to 4 cm is patterned on the lateral side of the radius and designed to include the perforating branches from the radial artery. The bone is osteotomized with either powered or conventional bone instruments, taking care to protect the radial artery and perforating vessels. After ligating the radial vessels proximally, the entire flap is mobilized as a composite unit to the level of the anatomic snuffbox. The abductor pollicis longus and extensor pollicis brevis tendons are freed proximally by releasing the distal portion of the first dorsal compartment. The composite bone-skin preparation is passed in a palmar-to-dorsal direction beneath the skin and over the abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus. Whichever way the pedicle is taken, however, one must be mindful to prevent kinking of the vascular bundle. The flap is passed under the skin bridge of the first web space to the level of the distal thumb wound. Connecting incisions are often used if scar tissue makes this passage difficult. The segment of bone is secured to the metacarpal with its cancellous raw edge facing the index finger and the first metacarpal in opposition. Fixation is secured by longitudinal or obliquely placed pins or by the use of a small plate. Distal shaping and trimming of the graft ensure a smooth configuration. The forearm skin now provides coverage in a nearly circumferential fashion around the graft and the distal aspect of the remaining metacarpal or proximal phalangeal bone (see Figure 48.19, *B*).

At this point, an extended neurovascular island pedicle flap taken from the ulnar side of either the long or ring finger can be placed on the palmar aspect of the bone graft to provide sensory perception and complete the reconstruction (see Figure 48.19, *D*). A split-thickness skin graft taken from the opposite anterior thigh is used to close the forearm donor area after adjacent muscle has been mobilized over the defect created by the removal of radial bone. The tourniquet should be released before application of a dressing to ensure a sufficient blood supply to both flaps, and exploration of the vascular pedicle must be carried out if any problems exist.

A plaster-reinforced compressive dressing is applied over the forearm; however, the dressing should be loose around the wrist and hand, and sufficient portions of both flaps are left exposed to allow continuous monitoring of their vascularity. A dressing change is carried out at 1 week, and a plaster short-arm thumb spica cast is applied at 2 weeks and continued for 6 weeks. Additional immobilization may be necessary, depending on bone healing.

Advantages of the composite radial forearm island flap include the elimination of staging and the excellent vascularity achieved with both flaps, which helps minimize the possibility of flap failure. Because the bone segment is vascularized, this technique should theoretically prevent bone resorption, which is probably the most significant disadvantage of osteoplastic thumb reconstruction. Bone grafts (even vascularized ones) placed out in "space" and not spanning a gap often show some resorption of the distal portion over time, however.

Disadvantages of the procedure include a considerable cosmetic defect created in the area of forearm flap harvest and the possibility of distal radius fracture. The risk of fracture can be decreased by making the initial osteotomies on the radius at a sharp angle, creating a "canoe-shaped" graft. This avoids the stress risers associated with osteotomies performed at right angles and may help prevent fractures at these sites. Although no microvascular anastomoses are required, the dissection must be carried out under loupe magnification to ensure that no damage occurs to the radial artery or its venae comitantes and to maintain the vascular supply to the bone graft. When carried out correctly, this procedure seems to be the most effective means of osteoplastic thumb restoration (eFigures 48.7).

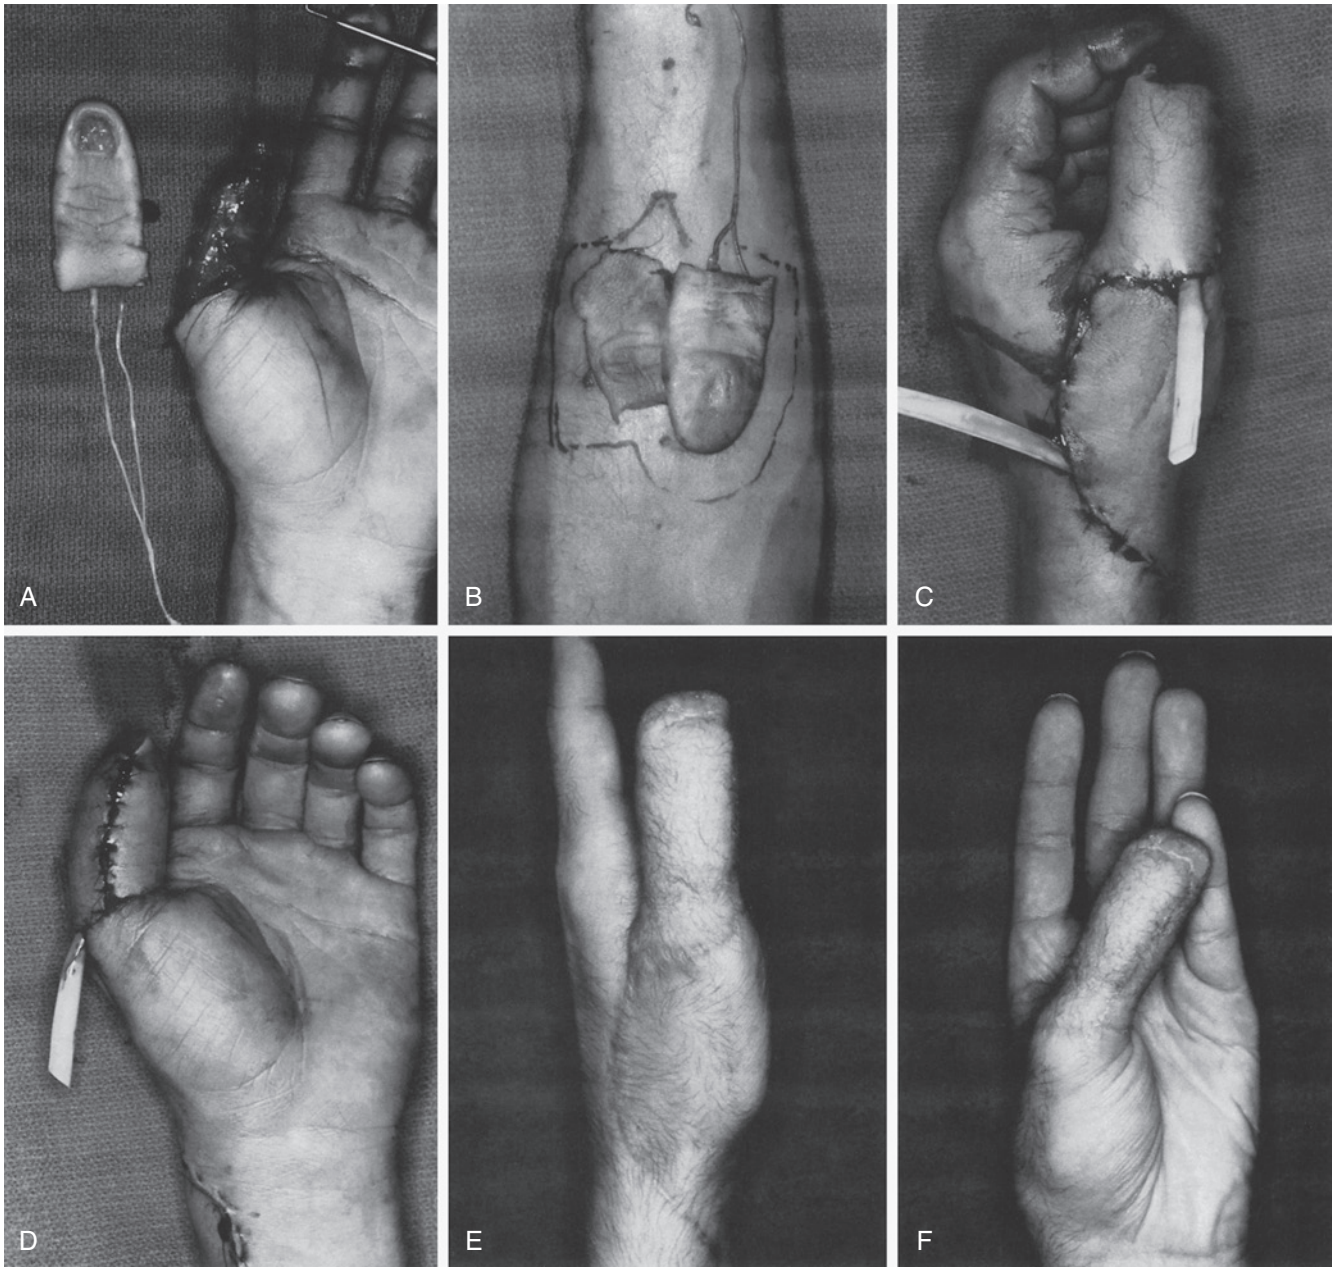
Pollicization of an Injured Digit

Not infrequently, injuries that result in loss of the thumb also cause partial destruction or amputation of adjacent digits. This creates the possibility for transfer of an injured digit or distal metacarpal to the base of the proximal phalanx of the thumb or to the first metacarpal to restore length and sensory perception.[18,19,45,57,81,109,123] The most common digital injuries associated with thumb loss are partial or complete amputation of the index finger or index and long fingers. This creates an ideal situation for pollicization of the index or long finger stump to the thumb remnant. This procedure not only adds length to the thumb but also widens and deepens the first web space by providing a ray resection of the second metacarpal.

When both the thumb and the index finger have been lost and the long finger has been damaged or partially amputated, transposition of the stump of the long finger can be carried out by techniques almost identical to those described for pollicization of the index stump. Occasionally, satisfactory index function is preserved with damage to or amputation of the long finger, thus making it the best candidate for transposition. Although transfer of an injured ring or small finger may occasionally be indicated, concomitant damage to the index and long fingers makes them much more frequent candidates for transfer, and the techniques described here are limited to these two digits.

Pollicization of an Index or Long Finger Stump. Under tourniquet hemostasis, an incision is designed circumferentially around the base of the index finger, at about the level of the MP joint, to join as a "V" over the dorsal hand proximal to the midportion of the second metacarpal. An incision originating from the tip of the "V" curves transversely to the ulnar aspect of the first metacarpal. This creates a flap that can be used to cover the new first web (Figure 48.20).

Skin flaps are carefully raised, with the initial dissection carried out palmarly. Under magnification, the digital nerve to



eFIGURE 48.7 Coverage of a degloved thumb with a patterned radial artery forearm flap. **A,** This thumb was totally degloved from the metacarpophalangeal joint distally, including skin and digital nerves. **B,** The avulsed skin was used as a pattern for the radial artery forearm flap. Note the oversizing of the skin pattern to ensure adequate coverage. **C** and **D,** The thumb immediately after completion of radial forearm flap coverage. **E,** Appearance of the thumb at 3 months. **F,** The reconstructed thumb demonstrating pinch to the small finger. Sensation can be enhanced with a dual innervated cross-finger flap or an extended neurovascular island pedicle flap. (Courtesy of Hill Hastings II, MD.)

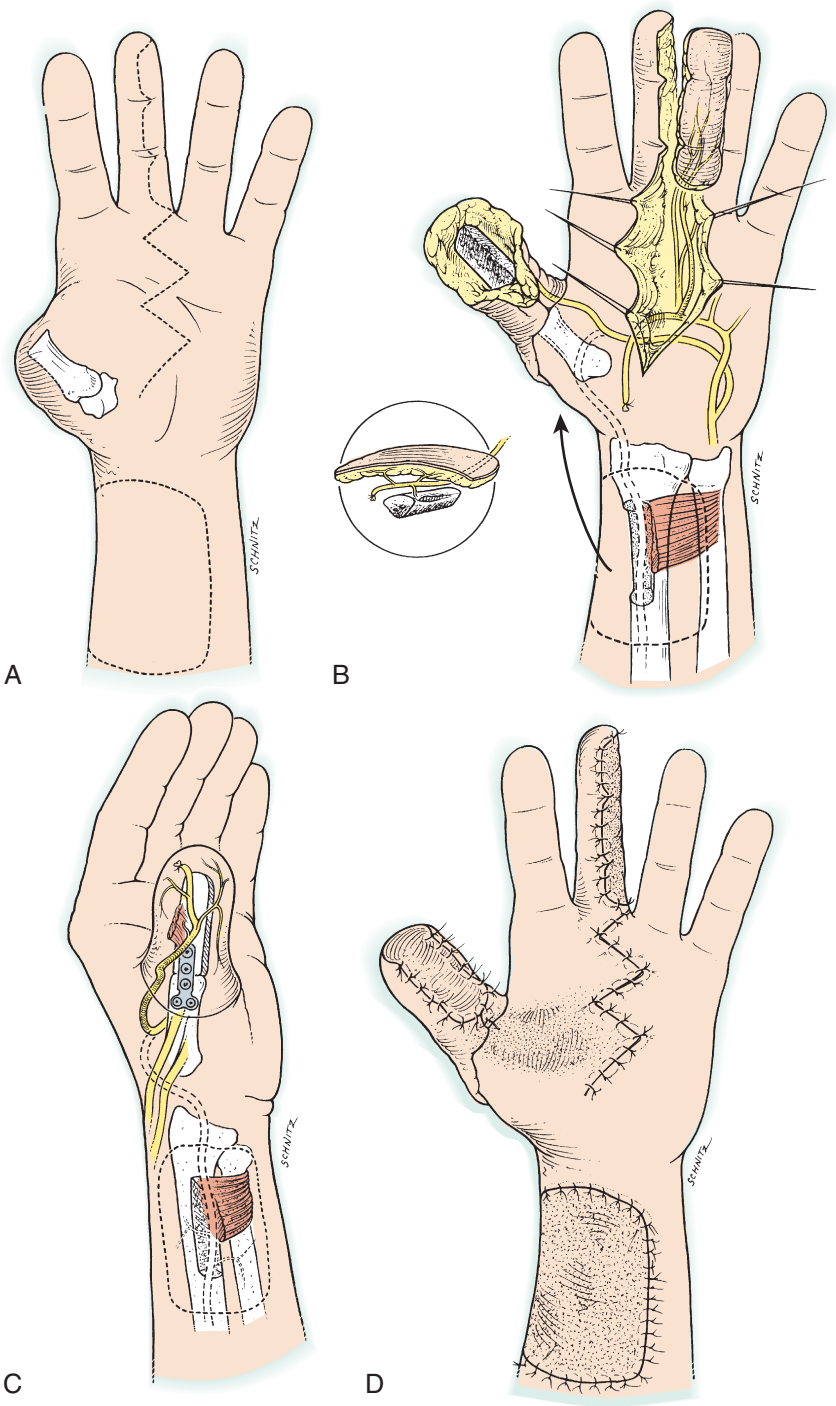


FIGURE 48.19 Composite radial forearm island flap. **A,** Incisions used for thumb reconstruction entailing a composite radial forearm island flap and neurovascular island flap taken from the ulnar side of the long finger. The radial flap is approximately 7 by 7 cm and is raised from the distal volar lateral forearm. **B,** Elevation of the flap together with a segment of the distal radius, with careful preservation of radial artery communications between the skin and the bone graft (*inset*). The artery is ligated proximally, and the flap is tunneled under the first dorsal compartment. The positions of the bone graft and the flap are shown. The neurovascular island pedicle flap is raised in preparation for palmar resurfacing of the reconstructed thumb. **C,** Dorsal appearance of the composite radial forearm flap and bone graft in position; a small "T"-plate is used for fixation. Note the position of the radial artery. **D,** Completion of the thumb reconstruction, with skin grafts used to cover the radial side of the long finger and the volar forearm. CRITICAL POINTS *Composite Radial Forearm Island Flap*

Indications

- Indications are few, given the success of toe-to-thumb microvascular transfer.
- Loss of the thumb at the mid to proximal metacarpal level
- Intact remaining digits, making sacrifice for pollicization less desirable
- Patency of the ulnar artery and superficial palmar arch

Technical Points

- Design a flap 7 to 8 cm long and 6 to 7 cm wide over the volar, radiodorsal aspect of the forearm.
- Débride the distal thumb stump.
- Raise the flap as for a standard, distally based radial forearm flap.
- As dissection approaches the radial styloid, identify a branch of the radial artery coursing to or through the pronator quadratus and the underlying radius periosteum.
- Osteotomize a corticocancellous bone graft 2 to 4 cm long and 1.5 cm wide, including the entry point of the feeding vessel from the radial artery.
- Ligate the radial vessels proximally, and elevate the composite flap to the level of the anatomic snuffbox.
- Incise the distal portion of the first dorsal extensor compartment to release the abductor pollicis longus and extensor pollicis brevis tendons.
- Pass the composite flap over the abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus tendons and under the overlying skin bridge into the dorsal aspect of the thumb wound.
- Avoid kinking or twisting of the pedicle during passage; if passage is difficult, create connecting incisions in the skin to facilitate passage.
- Orient the cancellous portion of the osseous part of the flap so that it faces the index finger, with the residual thumb metacarpal in opposition.
- Secure the bone portion of the flap to the thumb metacarpal using a small plate or Kirschner wires.
- Harvest a neurovascular island pedicle flap and transpose to the palmar aspect of the composite flap in the standard fashion.
- Release the tourniquet, achieve hemostasis, and inspect the transferred flaps for viability.
- Inset the flaps using fine, nonabsorbable suture.
- Harvest a split-thickness graft and inset this in the radial forearm harvest site.
- Harvest a full-thickness skin graft and inset this in the neurovascular island flap defect.
- Apply nonadherent gauze, a gentle compressive dressing, and a volar resting splint.

Postoperative Care

- Inspect the flaps at 1 week.
- Apply a short-arm thumb spica cast after the initial dressing change.
- Continue cast immobilization for 6 weeks (possibly longer, depending on bone healing).
- On cessation of casting, begin active and passive range-of-motion exercises.

Expected Outcomes

- Improved length and function of the thumb
- Adequate padding and sensation (with a neurovascular island flap)
- No motion in the thumb
- Potential donor site problems (skin graft "take," fracture of the radius, unattractive scar on the forearm)

the radial side of the index finger is identified, together with the radial digital artery. The flexor tendons are identified, and the neurovascular bundle to the index and long fingers is delineated. Careful dissection isolates the digital artery to the radial side of the long finger, which is clamped and ligated well beyond the bifurcation of the common digital artery. Under magnification, the digital nerves to the adjacent sides of the index and long fingers are carefully teased apart, well back into the palm (see Figure 48.20, *B* and *D*).

By alternating dissection from the palm to the dorsum, the second intermetacarpal space is developed beginning in the web and proceeding proximally. The transverse intermetacarpal ligament is divided, and the interossei in the cleft are separated down to the proximal part of the intermetacarpal interval by blunt dissection. Flexor and extensor tendons are left undisturbed.

The index metacarpal is now completely exposed subperiosteally, and a reciprocating saw is used to divide it obliquely at its base. The amount of additional metacarpal to be removed depends on the exact level of thumb loss, but this is usually just proximal to the metacarpal neck for amputations at the MP joint level. The stump to be pollicized should now be quite mobile, attached only by its two neurovascular pedicles and the flexor and extensor tendons.

At this point, the thumb stump is prepared by removing all scarred bone and cartilage. At the time of transposition, a small bone peg may be fashioned from the removed section of the second metacarpal and used to traverse the bony juncture (see Figure 48.20, *E*). The limiting factor in the transfer is the length of the neurovascular pedicles, and great care must be taken to avoid putting these structures under tension. Obliquely placed Kirschner wires or a small compression plate is used to secure fixation of the transferred digit (see Figure 48.20, *F*). The tourniquet is released to ensure hemostasis and the vascularity of the transferred digital stump. Skin defects are closed by transposing the lateral flap into the cleft created by transposition (Figure 48.21; see Figures 48.20, *G* and *H*).

Postoperatively, the hand is kept in a large plaster-reinforced compressive dressing for 2 weeks, and a plaster cast is continued until bony union occurs. A lightweight splint that will maintain the web space should be worn at least intermittently for several additional months.

In the setting of a functional index finger, pollicization of a long finger stump differs slightly from the technique of index transfer. Dorsal incisions are similar, but the palm is approached through an additional zigzag incision (Figure 48.22, *A* and *B*). Through the palmar incision, the digital arterial bifurcations are identified, and the proper digital arteries to the ulnar side of the index finger and the radial side of the ring finger are exposed and carefully ligated and divided well away from the bifurcations (see Figure 48.22, *C*). The common digital nerves are carefully separated from each other well back into the palm. Dissection, exposure, and division of the third metacarpal proceed as for the index technique (see Figure 48.22, *D*). Transfer of the digit differs, in that after ensuring that the neurovascular bundles have been mobilized well into the palm, a subcutaneous tunnel is made to the distal aspect of the first metacarpal, which has been cleared of scar tissue and trimmed to strong, well-vascularized bone. The isolated middle finger stump is passed through the tunnel, and additional tailoring of

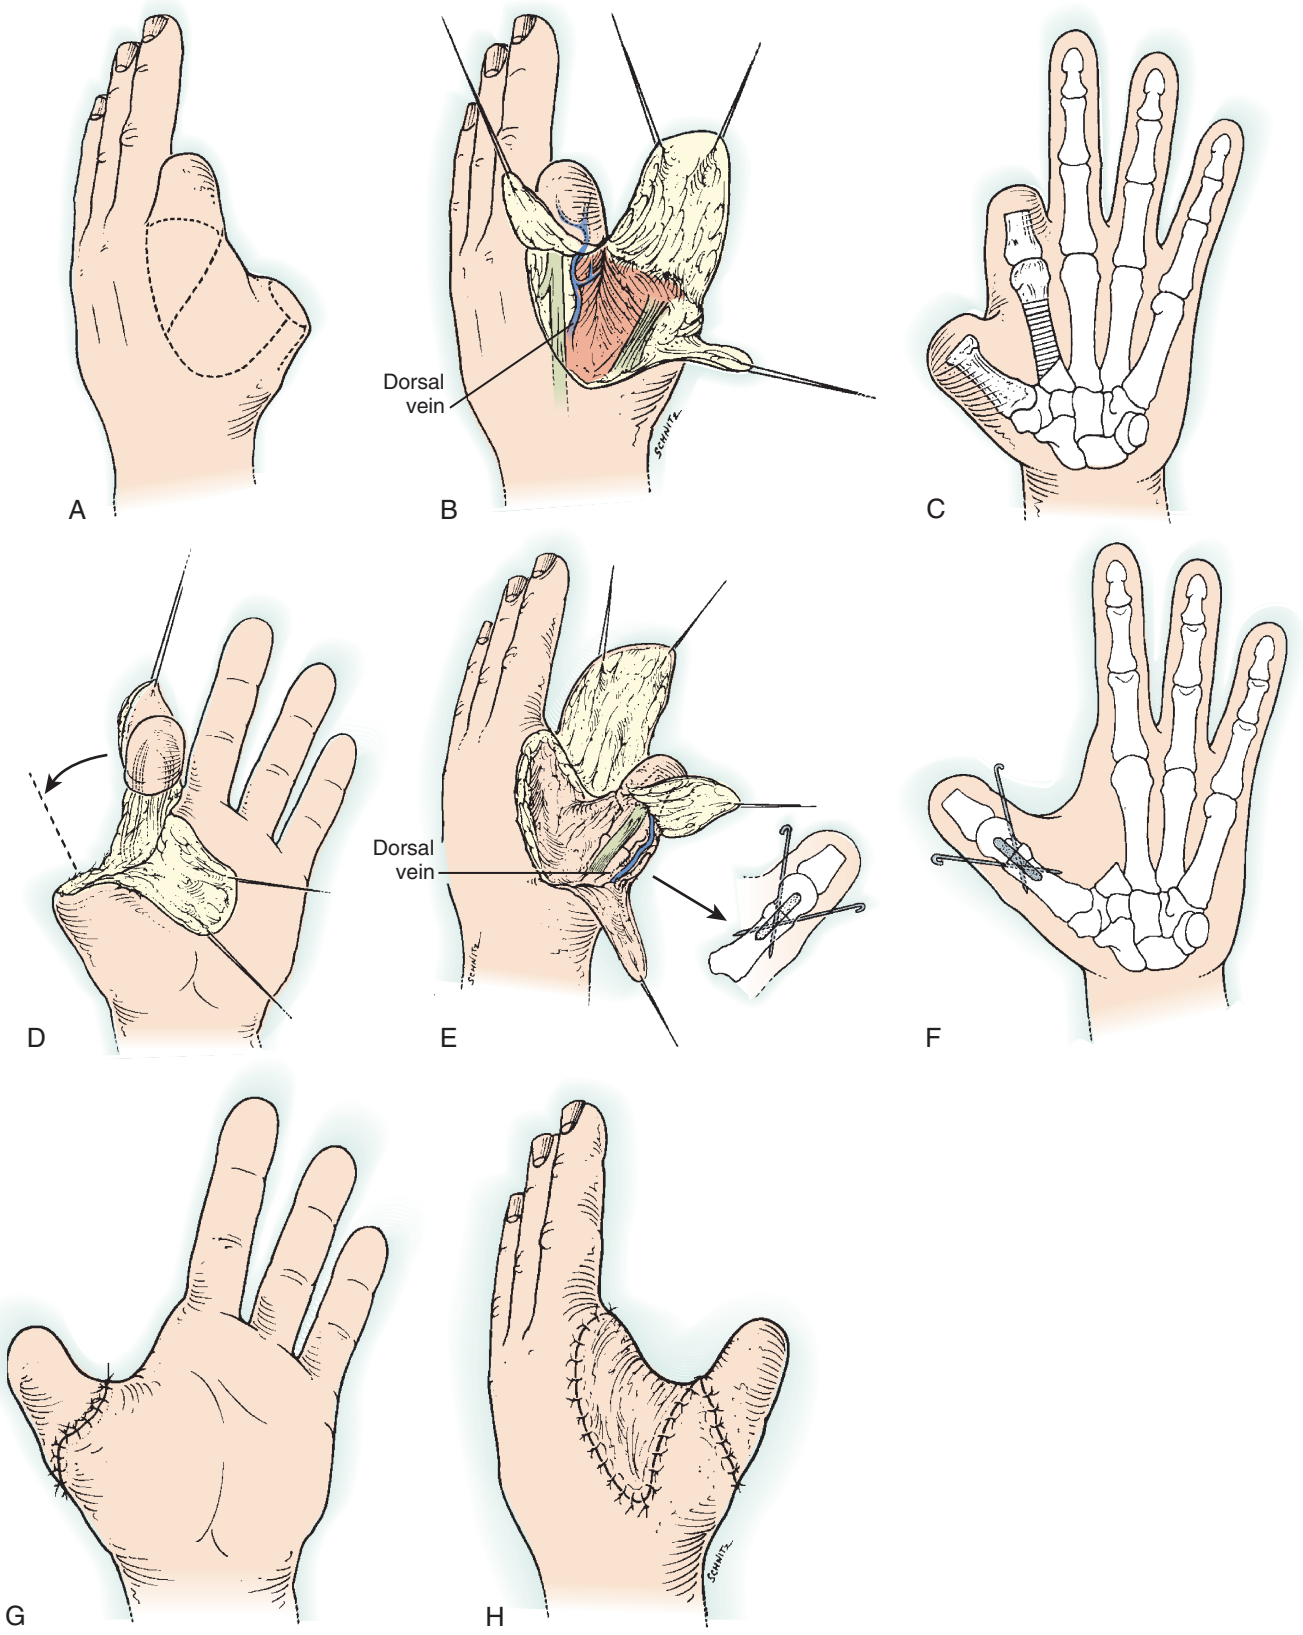

FIGURE 48.20 Pollicization of an index finger stump. **A,** Incisions used for index stump transposition. **B,** Elevation of flaps and mobilization of the second ray. A dorsal vein is identified. **C,** Diagram depicting the areas of the second metacarpal to be divided and excised (*stripes*) before transfer of the distal metacarpal and proximal phalangeal stump. **D,** The palmar flap with intact neurovascular bundles and flexor tendons following division of the radial digital artery to the long finger. **E,** Transfer of the index stump to the first metacarpal, again with preservation of a dorsal vein. Fixation by means of a bone peg and crossed Kirschner wires is shown. **F,** First and second metacarpal fixation with proximal deletion of the second metacarpal. **G,** Wound closure on the palmar surface of the transposed index stump. **H,** Use of the palmar flap to create a thumb–long finger cleft. (From Reid DAC: Reconstruction of the mutilated hand. In Rob C, Smith R, Pulvertaft RG, editors: *Operative surgery: the hand*, ed 3, London, 1977, Butterworth.)

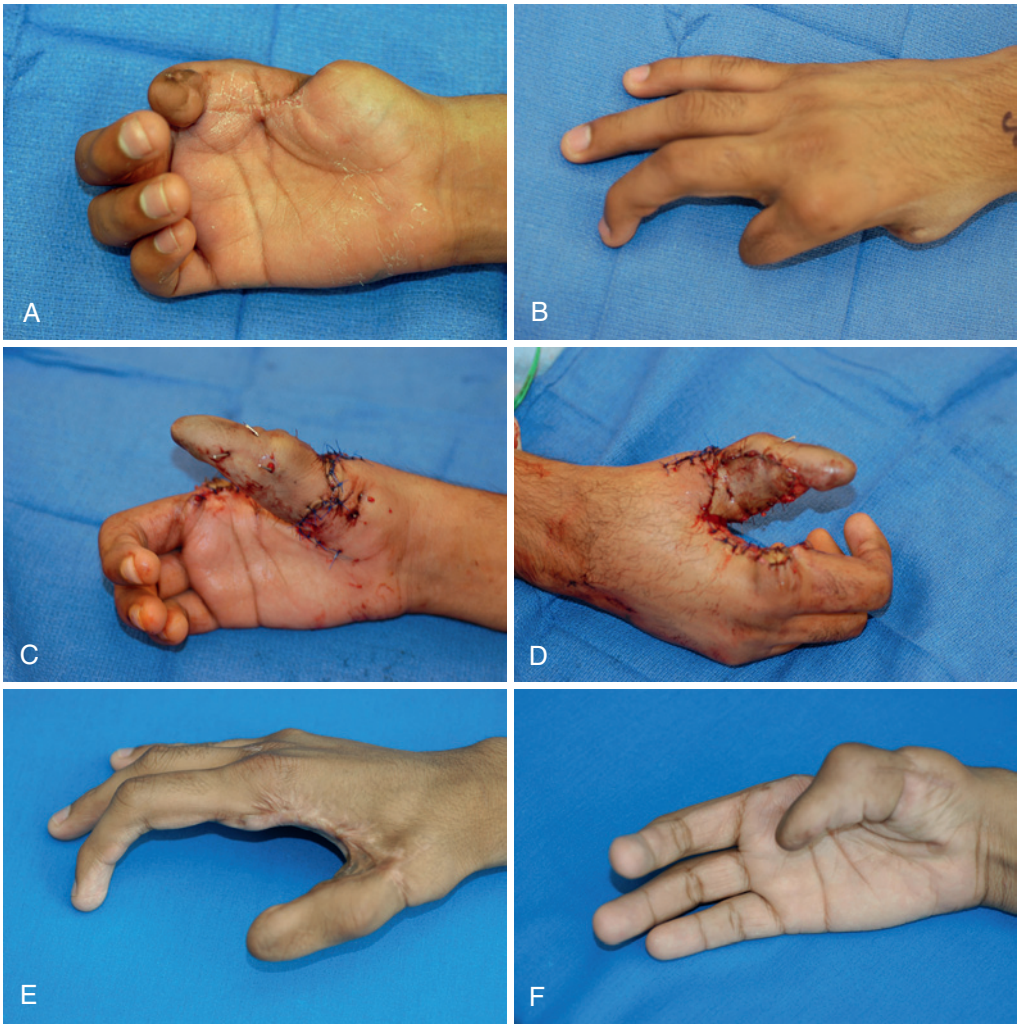

FIGURE 48.21 Pollicization of a second metacarpal stump. **A,** Old amputations of the thumb and index finger through the metacarpophalangeal joints. **B,** Incisions outlined for pollicization of the index stump to the first metacarpal. **C,** Appearance of the transferred index metacarpal at 6 months. **D,** Restoration of pinch and grasp after transfer.

the bone ends is required to ensure proper positioning of the pollicized stump. At this point, it may be possible to identify the stump of the extensor pollicis longus, free it from its scar tissue, and trim it to good tendon tissue. Tendon repair to the extensor tendon of the transferred long finger stump can be completed under appropriate tension. Closure of the donor defect is accomplished by approximating the index and ring fingers by suturing their opposing deep transverse metacarpal (intervolar plate) ligaments, and closure of the palmar wound and web space is carried out (see Figure 48.22, *E*).

These techniques that entail transferring stumps of injured index or long fingers to create additional thumb length are perhaps the most practical and efficient of all the thumb reconstructive techniques. They use functionless and sometimes obstructing parts that, by virtue of their excellent sensibility, can substantially improve function in their new position. Potential complications include partial or complete necrosis of the transferred part, nonunion of the bony juncture, and flap or graft necrosis. With careful planning, precise surgical technique, and appropriate postoperative care, these procedures should have a high degree of predictability and patient acceptance, despite the fact that the cosmetic appearance of the reconstructed thumb may be somewhat bulbous.

Total Loss With Destruction of the Basal Joint

Amputations up to, but not including, the basal joint of the thumb can be successfully reconstructed with either free toe transfer or pollicization as described in the previous section. Loss of the basal joint of the thumb, however, leaves the surgeon with the unattractive option of a thumb arthrodesed in opposition (such as might be achieved through an osteoplastic technique), pollicization, or free transfer of an injured digit from the opposite hand.[4] The chief advantage of pollicization and free digit transfers is that the hyperextended MP joint can substitute for the lost basal joint of the thumb.

Pollicization of either a normal index or ring finger has emerged as the most popular technique, and each has its advocates. Littler[74] has championed index pollicization on the grounds that it is technically simpler, provides restoration of excellent thumb function and sensation, and is cosmetically pleasing. Others have suggested that the index finger is too long and that its deletion deprives the hand of the most important

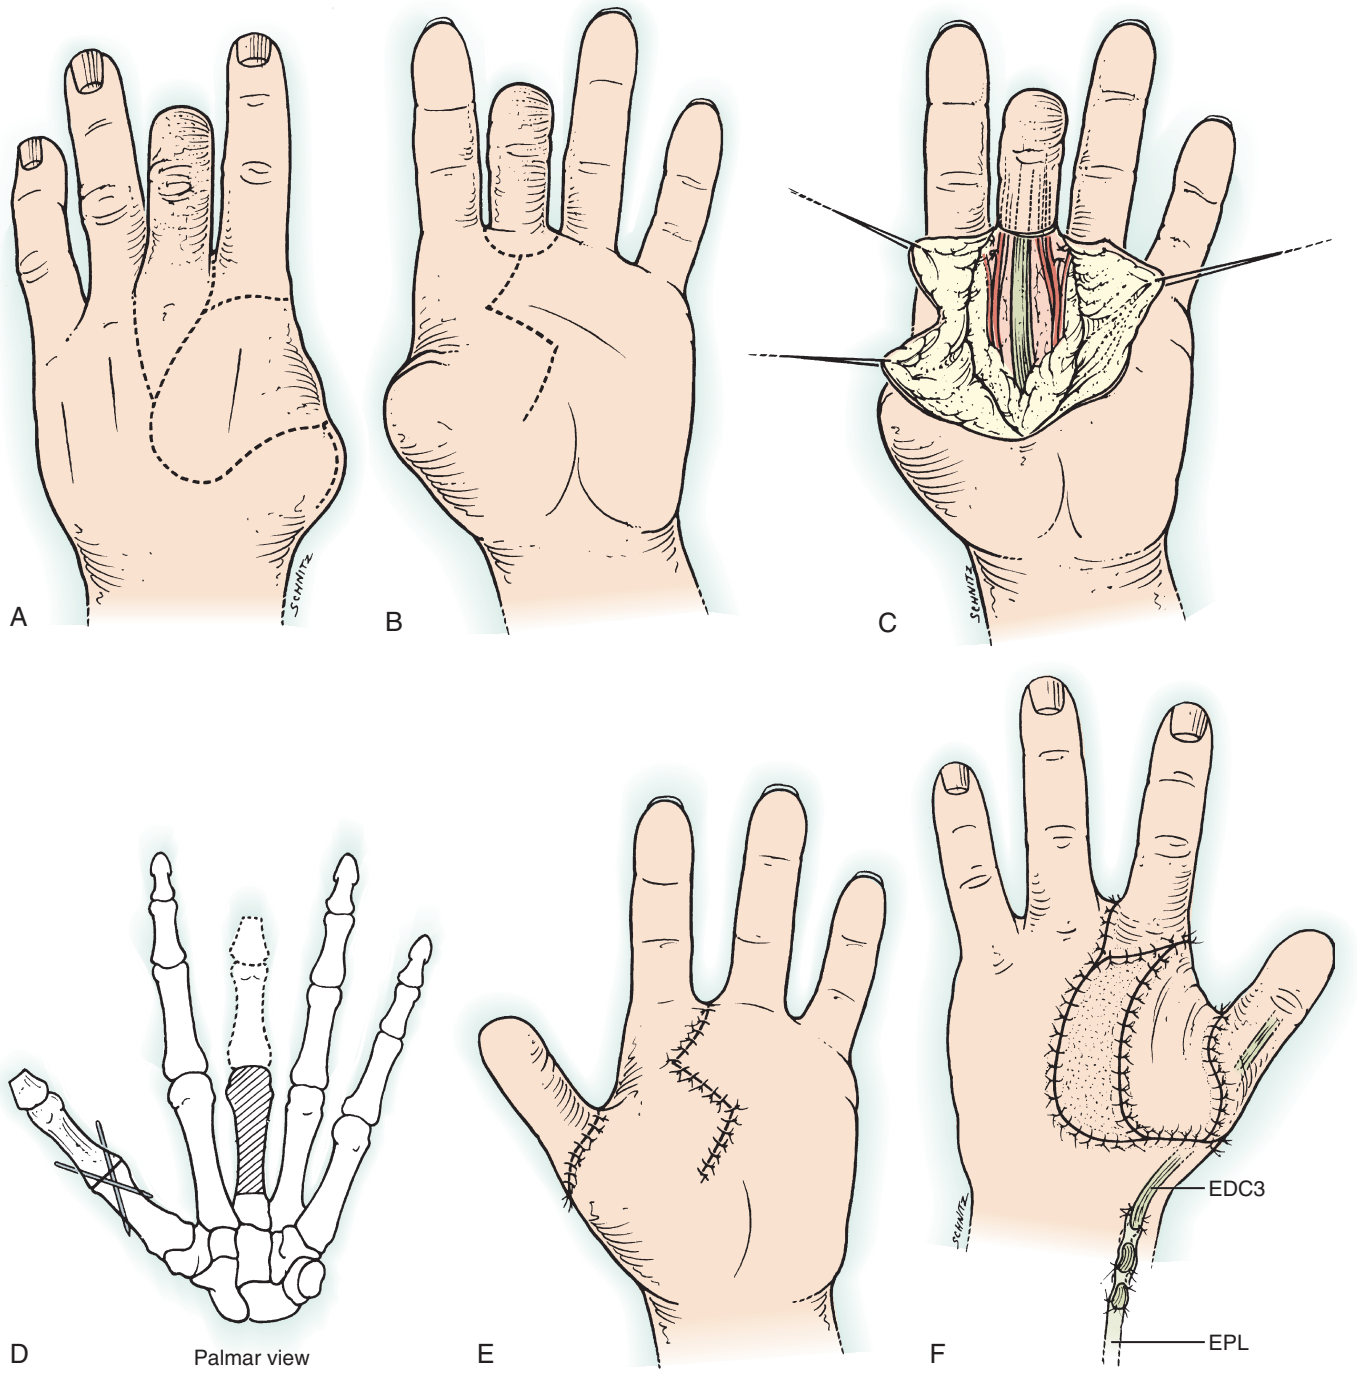

FIGURE 48.22 Pollicization of the stump of the long finger. **A,** Dorsal incision creating a dorsal lateral flap for thumb web coverage. **B,** Palmar incisions. **C,** Palmar dissection showing isolation and ligation of the ulnar digital artery to the index finger and the radial digital artery to the ring finger. **D,** Diagram of bone transfer using phalangeal bone from the long finger stump and ray excision of the third metacarpal (*stripes*). **E,** Closure of the palmar wound after completion of pollicization. **F,** Dorsal wounds after completion of web space reconstruction using the dorsal flap with free skin graft coverage of the donor defect proximal to the index finger. Suture of the extensor pollicis longus (EPL) to the extensor digitorum communis of the long finger (EDC3) is shown. (Modified from Reid DAC: Reconstruction of the mutilated hand. In Rob C, Smith R, Pulvertaft RG, editors: *Operative surgery: the hand*, ed 3, London, 1977, Butterworth.)

prehensile digit.[16,36] They prefer ring finger transfer to the thumb position because there is a minimal sacrifice of normal hand function, and excellent cosmetic and functional recovery can be achieved. Regardless of the digit transposed, pollicization as described for congenital thumb deformities (see Chapter 44) may allow restoration of not only the basal joint but also the motors lost due to injury to the thumb intrinsics.

CONCLUSION

Restoration of a functional thumb after injury remains one of the chief responsibilities of the hand surgeon. Restoration attempts should begin at the time of injury with adequate débridement and coverage of small injuries and, in the case of more significant amputations, attempts at replantation. When

CRITICAL POINTS *Pollicization of an Index Finger Stump*

Indications

- Loss of the thumb at or near the MP level
- Partial amputation of the index finger

Technical Points

- Incise circumferentially around the palmar base of the index finger near the MP joint.
- Extend this incision dorsally as a "V" proximal to the midportion of the second metacarpal.
- Incise from the tip of this dorsal "V" transversely toward the ulnar aspect of the thumb metacarpal and distally along the ulnar aspect of the thumb metacarpal.
- Raise the dorsal flaps to the level of the MP, taking care to leave at least one dorsal vein to the stump intact.
- Identify the radial digital nerve and artery and flexor tendons to the index finger.
- Identify the radial digital artery to the long finger, and ligate it well away from the bifurcation of the common digital artery.
- Tease apart the digital nerves to the ulnar index finger and radial long finger into the palm.
- Alternate between palmar and dorsal dissection to separate the second intermetacarpal space; sharply divide the transverse intermetacarpal ligament, and bluntly separate the interossei.
- Expose the second metacarpal subperiosteally.
- Obliquely osteotomize the second metacarpal at its base.
- Resect an appropriate amount of metacarpal, based on the required thumb length (amputations at the MP level typically require metacarpal just proximal to the neck).
- Remove scarred bone and cartilage from the thumb stump.
- Transfer and fix the index stump to the residual thumb metacarpal; before performing osteosynthesis with a compression plate or crossed Kirschner wires, pronate the transferred index finger to align its palmar surface with the palmar surface of the residual thumb.
- Release the tourniquet, and achieve hemostasis.
- Transfer the lateral flap into the new web defect.
- Inset flaps with fine, nonabsorbable sutures.
- Dress the area with nonadherent gauze, a compressive dressing, and a splint.

Postoperative Care

- Inspect the wound at 10 to 14 days.
- Apply a short-arm thumb spica–style cast; maintain the cast until bony union occurs.
- After cessation of casting, a thermoplastic web spacer splint should be worn and then weaned over several months.
- Begin active and passive range-of-motion exercises immediately after removal of the cast.

Expected Outcomes

- Improved function in the hand
- Deepening of the first web space with ray resection of the second metacarpal, and better span of the hand
- Minimal morbidity from loss of the index finger

loss is limited to the soft tissue of the tip, a multitude of local flaps have been used successfully to reconstruct the defect. We have detailed the most commonly used and reliable techniques, although many others have been reported. Intermediate levels of loss may be treated with phalangization, but as more surgeons become facile with microsurgical procedures, free toe transfer will become the most attractive option. With destruction including the basal joint, pollicization of another digit remains the best method of restoring thumb function. Although the procedure offered to the patient may be governed by these guidelines, a successful reconstruction is one that provides adequate function for the patient with an acceptable loss from the chosen donor site.

CASE STUDY 48.1

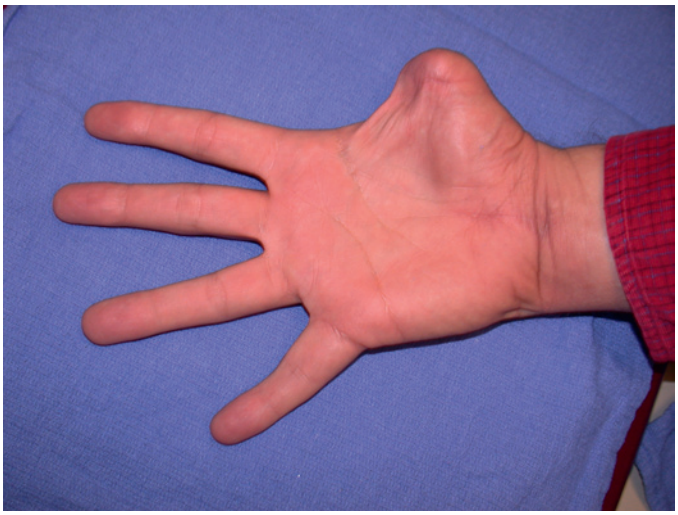
A 36-year-old migrant farm worker had a thumb amputation at the interphalangeal joint (eFigure 48.8).

Question: What procedure would improve hand function with the least amount of "down time"?

Answer: Four-flap "Z"-plasty first web space deepening increases the thumb index span with minimal down time.

Question: Which procedure will provide the best reconstructive option for this patient?

Answer: Toe-to-hand microvascular transfer is the gold standard reconstructive procedure for this injury because it will afford the best cosmesis, sensation, and functionality.



eFIGURE 48.8

CASE STUDY 48.2

A 26-year-old graduate student suffered a bicycle chain injury resulting in a 3.5-cm volar thumb open wound with exposed tendon and distal phalanx (eFigure 48.9).

Question: The patient does not want scars on any other part of his hand. Is the Moberg palmar advancement flap an option for this patient?

Answer: No, the defect is too large to be reconstructed by the palmar advancement flaps. The indications for the Moberg palmar advancement flaps are defects of 1 to 2 cm for the standard flap and 2 to 2.5 cm for the palmar advancement flap with proximal releasing incisions.

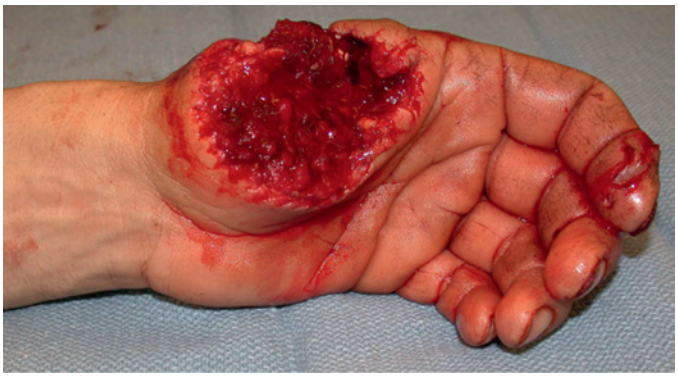
eFIGURE 48.9

CASE STUDY 48.3

A 42-year-old carpenter with an amputation his dominant thumb at the metacarpal level presents to your emergency department (eFigure 48.10). The amputated segment is mutilated and not replantable. You discuss reconstructive options with the patient, and he prefers microvascular toe transfer.

Question: What procedure will be helpful prior to toe transfer in this patient?

Answer: This patient has a large soft tissue defect that must be reconstructed prior to toe transfer. The best reconstructive option for this defect is a reversed radial forearm flap; it will bring a robust artery and veins (radial artery and venae comitantes) into the region and greatly simplify the toe transfer.



eFIGURE 48.10

CASE STUDY 48.4

A 40-year-old mechanic has suffered a nonreplantable thumb avulsion injury at the level of the proximal phalanx (eFigure 48.11). You discuss reconstructive options, and he is not amenable to sacrificing a toe.

Question: What are some of the options for thumb reconstruction?

Answer: Any of the osteoplastic thumb reconstruction methods can be used as long as they can provide sufficient soft tissue to cover the exposed tissues. Therefore, the Gilles "cocked-hat" flap is not an option. In this instance, a composite reversed radial forearm island flap was used (eFigure 48.12).

49.1 Flexor digitorum superficialis tenodesis for proximal phalangeal amputation. View at 4 weeks following revision amputation through the proximal phalanges of the index, long, and ring fingers. To increase metacarpophalangeal flexion, the flexor digitorum superficialis tendon was tenodesed to the proximal phalanx.

The most common cause of an amputated finger or thumb is accidental traumatic injury. In other cases, digital amputation may be necessary because of congenital deformity or acquired pathologic conditions (e.g., malignant tumors or chronic infection). Other indications may arise as sequelae of trauma, such as stiffness or debilitating pain, or revision surgery may be needed to improve the fit of a prosthesis. Amputations may occasionally be self-inflicted because of a psychological disturbance or in an attempt to defraud an insurance company.[20] Return of function is the primary consideration after an amputation; for this reason, the surgeon should be aware of the patient's occupation and vocations. The surgeon should express empathy and gauge the patient's emotional response following the amputation. Failure to appreciate the patient's attitude and ability to adjust to the injury may compromise an otherwise successful operative procedure.

As surgeons, we tend to be much influenced by the experience of mentors early in our careers, and later, our own expanding experience is helpful. We hold fast to methods that prove satisfactory in our hands and quickly seek alternatives to procedures that yield unsatisfactory outcomes. The numerous articles referenced in this chapter attest to the reasoned contributions of many authors who treat seemingly similar amputation situations by widely disparate methods. For some surgeons, the more technically demanding procedures have great appeal. Others prefer the simplest yet most effective procedure, such as shortening of bone followed by primary closure, or healing by secondary intention. There is clearly no gold standard technique for every clinical scenario.

The *goals* of amputation surgery in the upper extremity should be (1) preservation of functional length, (2) provision of durable skin coverage, (3) preservation of useful sensibility, (4) avoidance of symptomatic neuromas, (5) prevention of adjacent joint contractures, (6) prevention of morbidity, so that the patient has the fewest complications possible, (7) allowance of early prosthetic fitting when applicable, and (8) allowance of early return to work, play, and activities of daily living.

Any amputation in a child, whose ultimate role in life is yet undefined, should be approached with a conservative attitude. Late reconstruction is generally preferable to any early radical ablative procedure. Adults with well-defined functional roles may be better served by a more definitive approach that will accelerate their functional rehabilitation.

At times, deciding whether to perform limb salvage or amputation may be difficult. Consultation with an experienced and knowledgeable colleague is helpful and should always be documented in the patient's medical record. It will reassure the patient and family and will be helpful should medicolegal matters ensue. Photographs of the injured extremity before amputation are useful to document the severity of the injury. Although replantation or attempted salvage of a severely traumatized limb is an option at times, it may be more of a technical triumph than a procedure done in the patient's best interests. The enthusiasm for the successful technical accomplishment of replanting an amputated finger part versus closure and early rehabilitation has been dampened by poor patient outcomes at a greater financial cost, including lost wages and the cost of hospitalization and therapy. Cold intolerance can be a substantial problem for patients following an amputation, but the symptoms tend to improve over time.[28]

CRITICAL POINTS *Principles of Amputation Surgery*

- Maintain length
- Restore sensation
- Provide stable soft tissue coverage
- Prevent symptomatic neuromas
- Prevent adjacent joint contractures
- Allow early prosthetic fitting when applicable
- Allow early return to activities of daily living

DIGITAL TIP AMPUTATIONS

An amputation of the fingertip is the most common type of amputation seen in the upper extremity and at the same time provokes the greatest controversy because of the multitude of treatment options. Multiple techniques have been developed to advance local skin or transfer soft tissue to ensure coverage of an area where bone is exposed. The surgeon, in consultation with each patient, must choose the type of coverage that appears to be most appropriate for that individual's needs and within the technical abilities of the surgeon. Regardless of choice of treatment, the goals of preserving functional length and restoring adequate sensibility remain constant. When one is comparing the various treatment options available or looking for guidance, the injury zone classification systems of Hirase,[69] Allen,[3] and Tamai[139] provide a useful frame of reference (Figure 49.1).

Digital Tip Amputations With Skin or Pulp Loss Only

When the digital tip is amputated, the geometry of the defect dictates the various treatment possibilities. The loss may be transverse or oblique, with more volar skin loss than dorsal skin loss, or the reverse may be true. Some slicing amputations may result in skin loss primarily from the ulnar or radial side of the digit and may spare the distal tip.

Nonmicrosurgical Reattachment or Composite Graft

If the amputated part is available and not highly contaminated, it may be cleansed and reattached as a "biologic cover." This is an effective approach in children with injuries distal to the distal interphalangeal (DIP) joint in which the tip is defatted and repaired to the stump without microsurgery. If there is bony involvement, stability may be afforded by repair of the amputated tip with absorbable sutures, Kirschner wires, or an 18-gauge needle. The nail plate is removed and the nail plate repaired.[92] Timing of repair is crucial. Moiemen and Elliot noted that those repaired within 5 hours after injury had a 61% survival rate compared with none after this time point.[109] The tip may become necrotic but should be left in situ as long as there is no developing infection because the tissue acts as a biologic dressing. Similar success has not been noted within adults.[93] Heistein and Cook[67a] reported on 53 patients who underwent composite tissue grafting of injuries distal to the DIP joint. The success rate was 43% for injuries between the DIP joint and the eponychium and 58% for injuries distal to the eponychium. Factors linked to suboptimal results were smoking, age older than 18 years, alcohol use, presence of diabetes, and crush injury. In an effort to improve survival, Chen and colleagues[31a] reported on a technique whereby the distal amputated tip was defatted and deepithelialized and the bone excised in patients who sustained either a crush or sharp transection injury. The survival rate was higher than 93% with an average two-point discrimination of 6.3 mm after 6 months. Over 90% of patients were happy with the cosmetic appearance and 86% were able to use the finger normally at work.

Dressing Changes and Healing by Secondary Intention

Healing by secondary intention with dressing changes is one of the best options for a tip amputation without exposed bone. This technique is especially applicable when the amputated part is unavailable or cannot be used. This technique is simple, inexpensive, and effective, regardless of patient age (Figure 49.2).[3,21,38,41,45,71,74,95] Healing by secondary intention is most

applicable for wounds with skin loss of 1.5 cm or less; healing will occur by reepithelialization over 3 to 4 weeks with return of normal sensation and two-point discrimination. Indeed, recovery of sensation tends to be better than with other forms of surgical reconstruction. Dressing changes can also be used to treat wounds where there is additional loss of subcutaneous tissue of similar size, but it may take 1 to 2 months to heal by secondary intention. The patient performs daily dressing changes and local wound care. Protective splinting may be used to protect the healing wound. Patients can be referred to hand therapists within the first few days after injury to use modalities such as MIST ultrasound therapy (Celleration, Inc., Eden Prairie, MN) to encourage granulation tissue formation. Ultrasound works by reducing the bacterial load and promoting tissue regeneration by increasing angiogenesis, release of growth factors, and collagen deposition.[81] Patients are encouraged to work on the range of motion to avoid joint stiffness and/or contractures.

Bojsen-Moller and colleagues reviewed a series of 134 digital tip injuries in 110 patients who were treated by dressing changes, shortening of the digit, or skin grafting.[19] They observed that nonoperative treatment was almost always uncomplicated, whereas in some of the surgical cases, there were complications such as infection or graft failure that actually prolonged treatment. In addition, there was no significant difference in time off work between the treatment groups. The authors concluded that management of an amputation by shortening and primary closure was inferior to skin grafting or dressing changes. Allen[3] reported on 46 patients with 49 fingertip injuries from the lunula and distal phalanx. If the distal phalanx was exposed it was trimmed back to allow soft tissue to cover it. Forty-five patients thought their results were very good or good, 3 thought they were acceptable, and 1 deemed the result as poor. Four of the 49 injuries required secondary surgery, 3 for nail growth problems and 1 because of lack of soft tissue coverage. The average two-point discrimination was 6 mm, and the average time off work ranged from 18 to 26 days. None of the patients had any joint stiffness, although 50% did experience cold intolerance, which was marked in 10%. Weichman and colleagues[149] compared the outcomes of patients with fingertip injuries treated nonoperatively with those treated operatively (nail removal, revision amputation, or grafting with full-thickness grafts or local flaps, such as the "V-Y" advancement, cross-finger, thenar, or first dorsal metacarpal flap). Those who had surgery had larger wounds (3.3 cm versus 1.75 cm), volar oblique lacerations (50% versus 9%), exposed bone (81% versus 35%), and a distal phalanx fracture (81% versus 47%). The authors found that patients requiring operative treatments had

more time off work (4.3 weeks compared with 2.9 weeks), which is likely related to the extent of injury.

Primary Closure

Primary closure may be performed if the repair is without tension at the wound edges. Often this can be difficult because there tends to be a lack of sufficient mobile dermis for a tension-free primary repair. Primary closure, when possible, was shown in the series by Holm and Zachariae to give results equivalent to conservative healing by secondary intention.[71] However, in the series reported by Sturman and Duran,[136] 51% of the patients complained of tenderness and had some disability. Shortening of the bone may allow primary closure; however, the surgeon needs to perform traction neurectomies to prevent a symptomatic neuroma. A nail bed ablation is performed if the injury is at or through the lunula. The entire germinal and sterile matrix is excised, which requires scraping the dorsal cortex of the distal phalanx with a curette and excising the tissue on the undersurface of the proximal nail fold and in the paronychial folds. The patient needs to be informed of the potential risk of a neuroma and a nail horn at the time of closure because these entities can become symptomatic several months after the procedure.

Split-Thickness Grafting

Split-thickness skin grafting has been a popular method for coverage of the exposed pulp when there is a well-vascularized recipient bed.[59,111] Split-thickness grafts contract more than full-thickness grafts and are limited by the fact they cannot be placed directly onto bone or tendon devoid of its paratenon.[92] In a study by Holm and Zachariae, only 56% of the patients who had undergone skin grafting considered their results to be good after 5 years of follow-up, compared with 90% of patients treated conservatively with a wound that was permitted to heal by secondary intention.[71] The most important complaints after skin grafting were induration and fissuring of the skin and reduced sensibility in the area of the graft, as well as complaints about the donor site. Cold sensitivity was present in 39% of the patients treated conservatively and in 33% of those who received a split-thickness skin graft. Hypoesthesia was present in 26% of those treated conservatively and in 67% of those who were treated with a skin graft. The authors concluded that split-thickness skin grafting offered no advantages for fingertip coverage.

Sturman and Duran monitored 235 patients with a fingertip amputation for a minimum of 1 year and reported their late outcomes.[136] Of the patients who had split-thickness skin grafts, 70% reported tenderness in the area of the graft, and in 41%, the tenderness was considered to be marked. Cold sensitivity was present in 49% of the patients who had split-thickness skin grafts, including 27 of the 53 who had thumb or index tip amputations. Fifty-nine percent of the latter group avoided the injured digit when the pickup test was administered. Thirty-two percent of them noted diminished touch sensibility. The average two-point discrimination measured was 5 mm, considerably greater than the normal 2 mm.

Digital Tip Amputations With Exposed Bone

When bone is exposed, the question becomes whether length should be preserved (necessitating coverage of the site) or whether sacrifice of length is justifiable. An important variable is the extent of nail matrix injury. The development of a hooked nail is avoided by careful attention to wound closure and avoidance of the loss of bony support for the nail bed. Closure of a fingertip amputation by pulling the nail bed over the distal phalanx should be avoided. If a satisfactory amount of distal phalanx is absent, the nail bed must be trimmed back to the same level at the end of the bone so that it does not curve over the end of the bone and subsequently lead to the development of a hooked nail. A nail bed ablation is performed if the injury is at or through the lunula. Given that the primary aim is to restore function to the injured individual, some wounds with minimal exposed bone may be converted to wounds with no bone exposed by rongeuring followed by closure. My preference for closure is to use absorbable 3-0 suture to avoid the need for suture removal because often sutures may be covered with thick eschar and painful to remove. Alternatively, the wound may be left to heal by secondary intention, ensuring that the nail bed is supported by underlying bone. Antibiotics are not routinely prescribed if there has been adequate wound débridement without gross contamination. Patients are seen after 1 to 2 weeks and are sent to occupational therapy to work on edema control and range of motion. Tip desensitization is started once the wound is healed and stable. Many of these injuries are work related, and most manual workers are able to return to duty without restrictions by 6 to 8 weeks after injury.

If there is no possibility of direct closure of the wound, bony coverage may be accomplished by one of several described techniques, each with its own merits and limitations.

Semiocclusive Dressings

Studies have demonstrated successful treatment with the use of an occlusive dressing.[43,70] The dressing should be applied within a few days of the injury. Self-adhesive OpSite or Flexifix film (Smith and Nephew, London, UK) is used. The dressing is changed weekly until epithelialization has been completed. Hoigne and associates reported on a series of 17 patients with an exposed distal phalanx; patient satisfaction was good with regeneration of approximately 90% of the original soft tissue volume with an average two-point discrimination of 4 mm.[70] The average duration of dressing use was 6.5 weeks. There were no cases of bone regeneration or infection. Complications included a single case of a nail horn and posttraumatic neuroma.

Bilayer Matrix Wound Dressing

The Integra Bilayer Matrix Wound Dressing (BMWD) (Integra Life Sciences, Plainsboro, NJ) is an acceptable alternative to flap coverage. The graft consists of an acellular dermal matrix composed of bovine collagen covered by a silicone layer. It is designed to act as a skin regeneration scaffold that allows the host's cells to grow into the dermal template. They can be placed directly onto bone or tendon once the wound bed is clean and devoid of contamination. It can be sutured in place and its "take" encouraged with bolster or negative pressure dressings. The graft is normally applied as part of a two-stage procedure in which autologous skin graft is applied 3 to 4 weeks after matrix application. Taras and coworkers used two-stage grafting in digital injuries with exposed bone, joint, tendon, or hardware in 21 digits.[142] The area of Integra application ranged from 1 to 12 cm^2. Twenty of 21 digits demonstrated complete

FIGURE 49.3 Treatment of a patient with a ring avulsion injury with Integra and skin grafting. **A,** Ring avulsion injury, palmar view. **B,** Ring avulsion injury, dorsal view. **C,** Application of Integra. **D,** Granulating wound after Integra placement. **E,** Granulating bed for skin graft. incorporation of the dermal matrix, and following skin grafting, 16 of 20 digits demonstrated complete incorporation. Single-stage use avoids the morbidity of skin grafting and is the same as healing by secondary intention because the healing process relies on both wound contraction and reepithelialization. In a series of nine patients with an average defect of 2.3 cm^2 (range, 1 to 3.2 cm^2), Jacoby and colleagues[75a] demonstrated high patient satisfaction, with a mean static two-point discrimination of 9.6 mm (4.6 mm for the opposite unaffected finger). One patient developed an early infection, followed by a hook nail deformity 18 months after treatment. There were no other complications. The Integra BMWD is more expensive than a semiocclusive dressing or healing by secondary intention. However, the graft may be placed directly on bone, preserving critical length and obviating the need for flap coverage with the associated inconvenience and morbidity (Figure 49.3).

Atasoy-Kleinert Volar "V-Y" Flap

In 1970, Atasoy and associates described a triangular volar "V-Y" advancement flap (Figure 49.4) for reconstruction of the distal pad with preservation of length when bone is exposed.[6] It is indicated for dorsal oblique or transverse distal fingertip amputations beyond the midpart of the nail. The flap is contraindicated in injuries in which there is an oblique amputation with more palmar skin loss than dorsal skin loss and in situations in which there is extensive skin loss as a result of the injury.

Digital anesthesia is administered before preparation of the wound. After surgical preparation of the hand, a Tourni-Cot

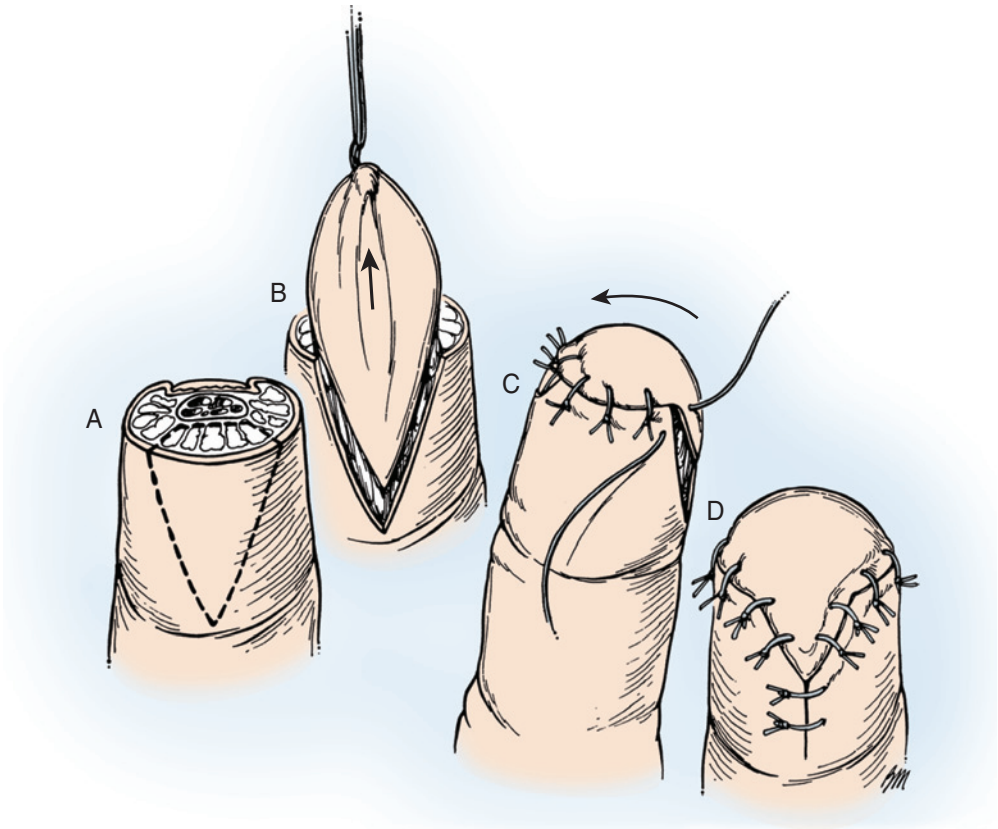

FIGURE 49.4 The Atasoy-Kleinert volar "V-Y" technique is applicable to distal tip injuries with bone exposed and when the distal injury is either transverse or oblique and sloping in a dorsal proximal–to–volar distal direction. In injuries with more volar pad loss, there is usually insufficient skin for this technique to be used. **A,** Marking of the flap. Note that the apex is at the DIPJ crease. **B,** Raising and advancement of the skin flap distally. **C,** Closure of the flap from distal to proximal. Take care to ensure the flap is not overly tight. **D,** Closure of V-Y. (Copyright Elizabeth Martin.)

(Mar-Med, Grand Rapids, MI) is used to exsanguinate the digit and simultaneously provide tourniquet ischemia. Alternatively, the finger is elevated and a Penrose drain tied at the base of the digit. A pattern may be made to cover the dimensions of the defect and then transposed proximally to the cut edge of the skin that is to be advanced. The base of the triangle will be the distal cut edge, and an appropriate triangle of skin is made according to the pattern, with the apex of the triangle being at the DIP flexion crease. The two sides of the triangle should be at least 1.5 times the length of the desired advancement. Only the full thickness of the skin is cut. The digital nerves and blood vessels of the flap are preserved. Its blood supply is from the small arterial branches of the digital arteries distal to the trifurcation of the digital nerves. Separation between the flexor sheath and subcutaneous tissue is performed by dividing the fibrous septae that anchor the subcutaneous tissue to the bone, which facilitates advancement of the flap distally. The skin of the flap must be connected to the subcutaneous tissue to maintain its viability. The base of the triangle is carefully contoured and sutured to the nail bed or remaining nail, and the resulting "V" incision on the palmar aspect of the digit is closed, thus converting it to a "Y" (see Figure 49.4). The Tourni-Cot or Penrose drain is removed prior to flap insetting to ensure its viability. The flap can be adequately mobilized up to 1 cm and if necessary defatted to facilitate tension-free skin closure. Postoperative management consists of sterile dressings over the surgical sites that allow early motion of all adjacent joints. Active motion and digital usage are advanced as healing ensues over the next few weeks.

In their initial report, Atasoy and associates stated that 56 of 61 patients available for follow-up had normal sensation and motion.[6] However, a follow-up study conducted by Frandsen found hypoesthesia or dysesthesia in 7 of 10 patients with triangular volar flaps.[51] Four of the 10 patients had subjective complaints of cold intolerance, and 5 of the patients also had difficulty grasping objects. Conolly and Goulston had unsatisfying results in 4 of 7 patients treated by this technique.[38] The results were deemed unsatisfactory because of persistent paresthesias or impaired sensibility. Tupper and Miller reported diminished sensibility in all 16 of their patients.[144] Eight of their patients reported hypersensitivity, particularly cold intolerance.

Kutler Lateral "V-Y" Flaps

Kutler described the use of "V-Y" advancement flaps for digital tip injuries (Figure 49.5).[87] The technique involves advancing two triangular flaps from lateral positions to cover the tip of the digit.

Preparation of the digit is similar to that used in the Atasoy technique. The tip of the digit is débrided as necessary. Two triangular flaps are developed from the midlateral aspect of each side of the digit, and the incisions are made just down through the dermis. The subcutaneous tissue is similarly mobilized from the phalanx on a deep plane by dividing the fibrous

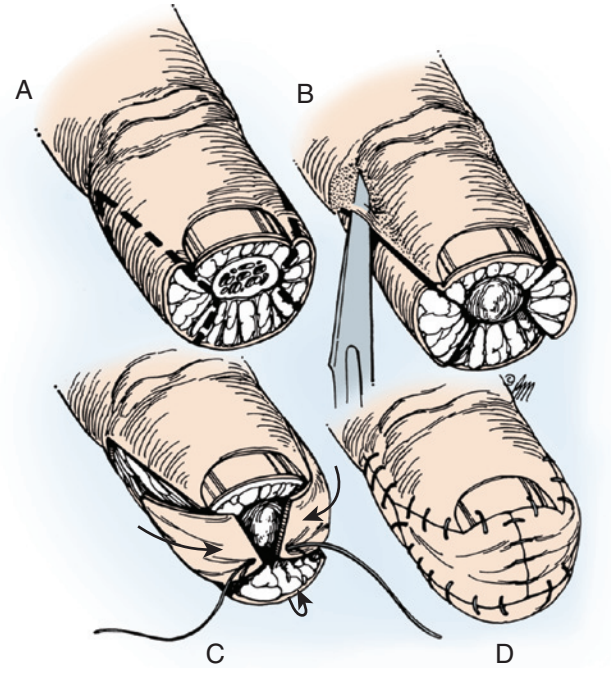

FIGURE 49.5 **A,** Triangular flaps are marked, centered over the midlateral aspect of the finger. **B,** The skin is incised and fibrous septa divided, allowing mobilization of the flaps distally. **C,** Distal advancement of the flaps. **D,** The wounds are closed from distal to proximal.

septae. Both triangles are advanced to the midline distally and sutured together. The "V" apex of the triangle is closed in a "Y" fashion, and the surrounding edges and nail bed, or nail, are carefully sutured to the distal edges of the advanced flaps (see Figure 49.5). This flap can only be advanced up to 3 to 4 mm. Haddad reported on a series of 20 patients treated with this technique and stated that slight skin necrosis occurred at the edges if the flaps were too large.[64] Subjective evaluation in a series of 22 patients was reported by Freiberg and Manktelow, who noted mild hypersensitivity and numbness in 7 of 22 patients.[52] Frandsen reported a follow-up study of 14 patients who underwent Kutler's technique and found subjective complaints of coldness in 8 patients (57%), tenderness on percussion in 10 (71%), difficulty in grasping small objects in 6 (43%), and slight hypoesthesia or dysesthesia in 10 (71%) when objectively measured.[51] Patients also reported an average time off work of 61 days.

Shepard reported excellent results with a modification of Kutler's technique in 28 traumatic amputations and 9 reconstructive procedures by dividing the dorsal pedicle and advancing the flap 10 to 14 mm. The nerves, vessels, and subcutaneous tissues are preserved under the palmar skin incision.[129] The dorsal incision is made down to bone and the fibrous septa divided. On the palmar side, the skin is incised only and the flap advanced distally. He suggested that the Kutler technique is most applicable to oblique palmar and transversely oriented amputations.[129]

Given the limited advancement of the Kutler lateral "V-Y" flaps, others have described modifications by either raising the triangular flap on its neurovascular pedicle[18] or extending the flap to the proximal interphalangeal (PIP) joint crease to increase its size and ability to advance distally.[88,131] The flap could be advanced up to 2 cm, although patients were at risk of cold intolerance (49%), numbness (78%), PIP joint flexion contractures (17%), and DIP joint flexion contractures (22%).[131] These "V-Y" advancement flaps are at risk of necrosis if tension-free closure is not achieved. The tension placed on them at closure could cause a hook nail deformity because it pulls the nail bed palmarly and could also cause diminished sensation due to tension on the digital nerves and its branches.[140] This may be overcome by allowing the proximal wounds to heal by secondary intention or treating them with bilayer matrix wound dressings, thereby avoiding tension of the wounds distally.

Volar Flap Advancement

Moberg is credited with the technique of volar flap advancement for coverage of thumb tip amputations.[82] The flap is a bipedicled, axial-pattern, cutaneous advancement flap. Snow advocated the technique for fingertip amputations when length is to be maintained.[134] Advancing volar skin on its neurovascular pedicle provides the dermis with sensibility without losing length. Arons has modified this with the addition of a terminal dermal graft for padding, and sometimes a skin graft may be added at the base of the digit to gain length.[5]

Regional anesthesia is obtained, the limb is exsanguinated with an Esmarch bandage, and a pneumatic tourniquet is inflated. The distal tip is appropriately débrided, and midaxial incisions just dorsal to the flexion crease at each of the interphalangeal (IP) joints are made on both sides of the digit. The flap is completely separated from the underlying flexor tendon sheath, advanced to the distal tip, and sutured to the nail bed and the adjacent sides of the digit. The tip of the flap may need to be shaped to fit the distal defect. The lateral portions of the skin are sutured in place.

This method is more appropriate for the thumb (Figure 49.6) than for the fingers because of the more mobile skin of the thumb and the decreased likelihood of subsequent flexion contracture. However, in both the thumb and fingers, flap advancement is limited to 1 cm. Reported complications are fixed flexion deformity of the IP joints and skin necrosis on the dorsum of the finger. The studies of Caplan and coworkers,[26] Leffert and associates,[94] and Armenta and Lehrman[4] suggest that the blood supply to the flexor tendon apparatus must be compromised for this flap to be used. Although I do not know of any reports of tendon nutritional complications after the use of this technique, such complications could theoretically be a disadvantage of this method.

Cross-Finger Pedicle Flap

The cross-finger pedicle flap technique, first described by Gurdin and Pangman in 1950, has found acceptance when other techniques for local flap coverage are not possible and in those situations in which it is deemed important to maintain length.[63] Examples of such circumstances are distal amputations of the index finger or thumb and situations in which multiple digits are injured and maintenance of length in the remaining injured tips is critical.[22] The flap, however, is associated with stiffness postoperatively and is considered contraindicated in patients with preexisting arthritis or in patients over the age of 50 years. Paterson noted an increased incidence of stiffness in patients older than 41 years.[117]

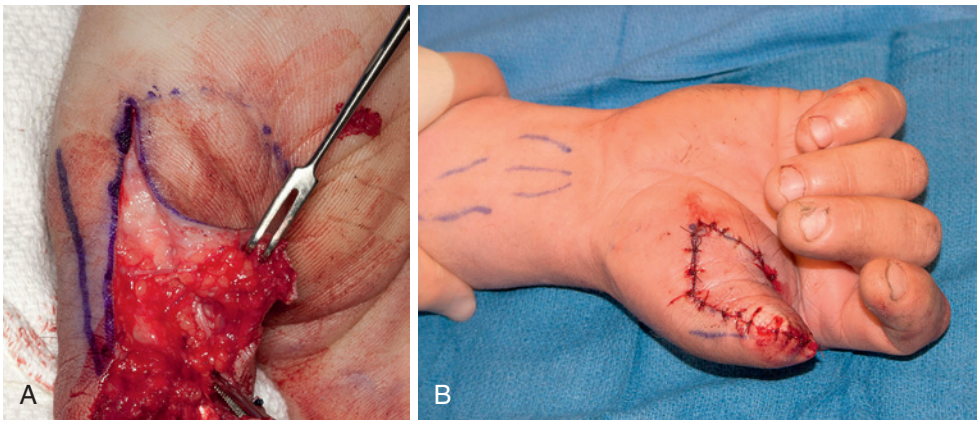

FIGURE 49.6 Patient with traumatic amputation of thumb with advancement flap to preserve as much length as possible. **A,** Raising flap from distal to proximal with neurovascular bundle within volar flap to maintain viability. **B,** Bony coverage by volar lap advancement.

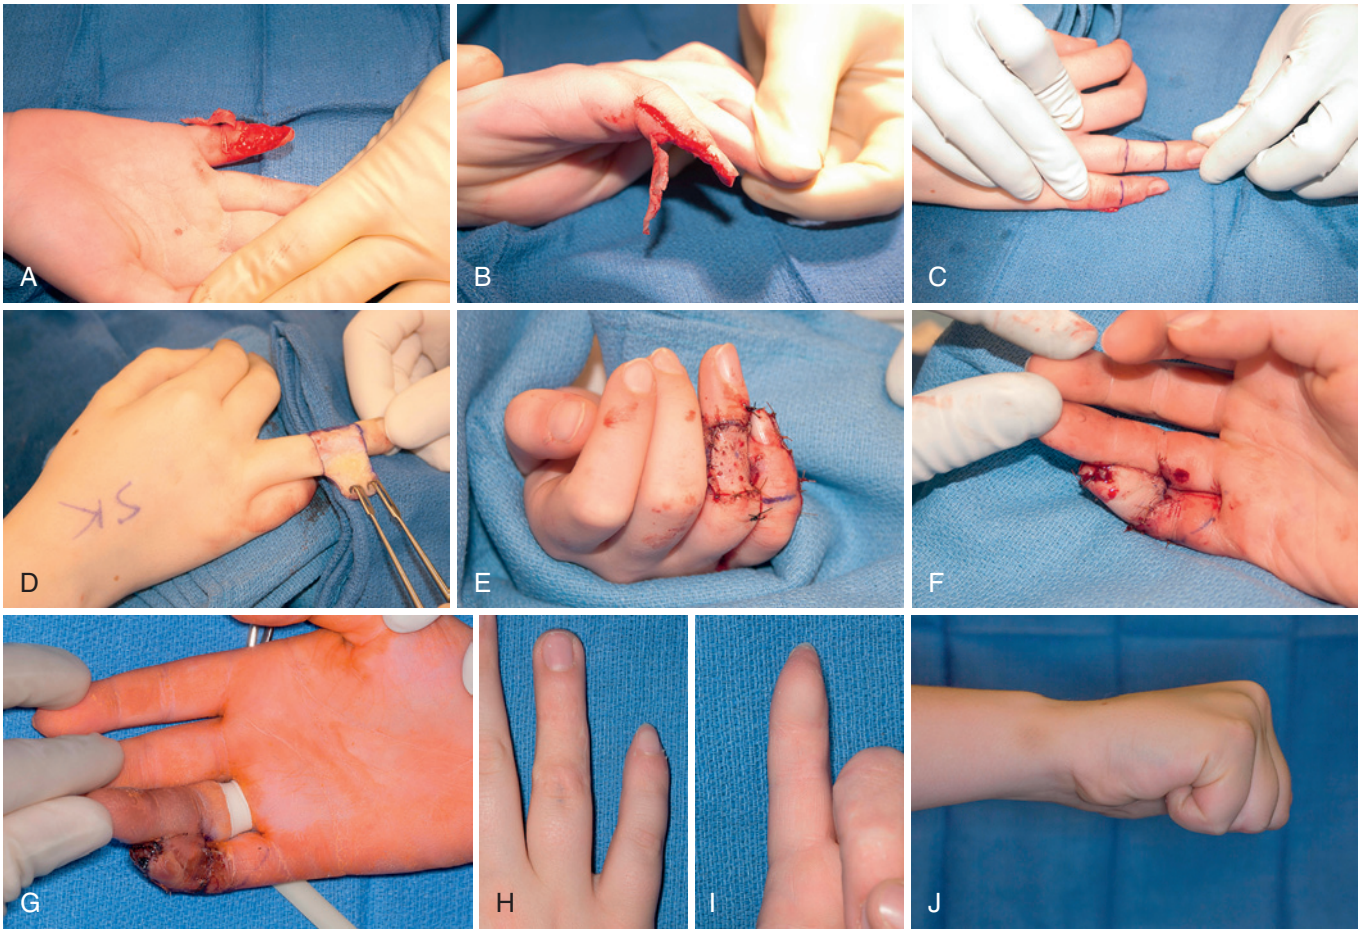

FIGURE 49.7 Cross-finger flap for loss of palmar skin to small finger. **A,** Tip degloving injury. **B,** Lateral view of degloving injury. **C,** Marking out flap on dorsum of ring finger. **D,** Raising cross-finger flap, staying above the paratenon. **E,** Full-thickness skin graft to donor site ring finger. **F,** Insetting of cross-finger flap palmarly. **G,** Penrose drain occluding blood supply from ring finger to flap demonstrating that flap has developed its own blood supply from small finger and is ready for division. **H,** Note aesthetic appearance of donor from ring finger. **I,** Aesthetic appearance of cross-finger flap. **J,** Full range of motion.

The flap provides coverage for an oblique volar defect of the pulp region or for extensive soft tissue loss on the volar fingertip with exposed bone and tendon. The example shown in Figure 49.7 in which the adjacent digit is used as a donor and the flap is laterally based is a common application of this technique. A piece of an Esmarch bandage is used to template the defect and to design the flap. It is important to make a template rather than estimate the flap size. I prefer to cut the template 2 mm larger around its three sides to ensure tension-free insetting of the flap.

Once the template has been made, the donor site is outlined with a marking pen. With careful tissue handling, the flap is reflected with preservation of its venous drainage at the base of the flap. The dissection is carried down to the plane between the paratenon of the extensor mechanism and the subcutaneous fat. Three of the four available margins of the flap are sutured in place on the recipient site. The fourth margin is sewn down at the time of flap detachment and closure. A full-thickness skin graft from the ipsilateral antecubital region or medial forearm is used to cover the defect on the extensor surface of the donor digit. Skin without hair is used because this can be a cosmetic concern, especially if the digits are hairless. To avoid undue tension on the vascular pedicle of the flap, the two fingers may be sewn together or a transdigital Kirschner wire placed. A bulky soft dressing may be reinforced with a plaster splint. At 3 weeks postoperatively, a Penrose drain is placed around the base of the donor digit to assess whether the flap is being perfused from the recipient finger. If so, the flap is detached and inset into the recipient site. Cohen and Cronin modified the technique to include a dorsal sensory branch of the digital nerve that is coapted to the recipient digital nerve at the time of flap division.[36] They reported an average two-point discrimination of 4.8 mm in 88% of the patients in their series.

After detachment of the flap, motion of the digits is encouraged to mobilize all the adjacent joints. Follow-up studies by Sturman and Duran,[136] Kleinert and associates,[84] and Johnson and Iverson[77] have indicated that the return of sensibility to cross-finger flaps as measured by two-point discrimination tests shows excellent reinnervation in the majority of these flaps with progressive improvement occurring with time. Lassner and colleagues[89] reported an average sensibility of 3.6 mm and cold intolerance in 6 of their 15 patients with a bilaterally innervated sensory flap.

Thenar Flap

In 1926, Gatewood described the technique of a thenar flap for coverage of digital tip injuries with exposed bone.[54] This was subsequently expanded on by Flatt[49] in 1957 and modified by Smith and Albin[132] with a technique that they describe as a thenar "H"-flap.

The indications for the random-pattern thenar flap are similar to those for a cross-finger flap, namely, when preservation of length is important and other techniques are not applicable. The flap has been advocated for use only in the index and long fingers and in younger patients without any preexisting arthritis or joint injury. The proposed advantages are (1) better skin color and texture match, (2) abundance of subcutaneous tissues, and (3) return of some sensibility. To avoid permanent joint stiffness or unsightly scarring in the donor area, one must keep in mind the three cardinal technical principles outlined by Melone and colleagues[103]: (1) Design the flap near the metacarpophalangeal (MP) crease of the thumb and avoid the midpalmar area; (2) fully flex the MP joint with whatever amount of flexion is required in the IP joints of the recipient finger; and (3) detach the pedicle 10 to 14 days postoperatively and begin immediate active range-of-motion exercises.

Thenar "H"-Flap. Figure 49.8 shows the thenar "H"-flap as described by Smith and Albin.[132] The area of contact of the injured digital tip with the thenar eminence is outlined. An "H" is drawn on the skin approximately 20% wider than the defect.

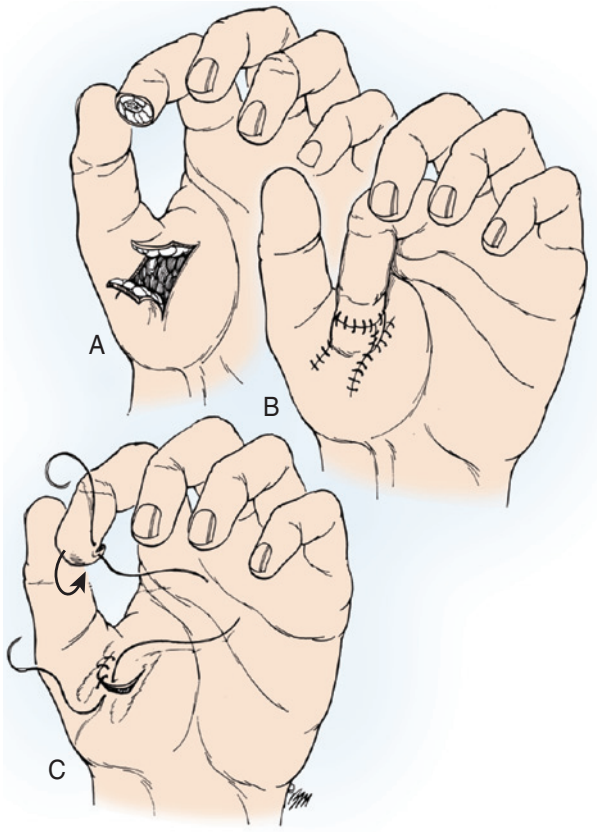

FIGURE 49.8 **A** to **C,** The thenar "H"-flap as described by Smith and Albin. (Copyright Elizabeth Martin. See also Smith RJ, Albin R: Thenar "H-flap" for fingertip injuries. *J Trauma* 16:778–781, 1976.)

The transverse limb of the incision is made at the most distal contact point of the fingertip with the thenar eminence (see Figure 49.8, *A*). Square proximal and distal flaps are elevated, including the subcutaneous tissue. The proximal flap is sutured to the fingertip, and the distal flap is sutured to the proximal margin of the defect on the volar side of the injured finger (see Figure 49.8, *B*). The proximal flap is advanced distally and the distal flap advanced proximally to close the donor defect. A soft dressing is applied, and 2 weeks later the flap is detached. The fingertip is closed with the proximal flap, and the distal flap is advanced into the thenar defect (see Figure 49.8, *C*). This closes the donor site primarily and avoids the potential problem of an unsightly scar in the thenar eminence.

An alternative technique is to elevate a proximally based flap and suture it to the injured tip in a fashion similar to that just described but to use a full-thickness or split-thickness skin graft or Limberg-type flap for the thenar defect when the flap is divided and inset.[49,54]

Satisfactory outcomes with the thenar flap have been reported in several clinical series.[11,48,103] Porter compared the results of 56 pedicle flaps with 44 free grafts.[120] He found sensibility was better in cross-finger and thenar flaps and that these flaps resulted in excellent cosmesis. Porter also concluded that full-thickness grafts were superior to split-thickness skin grafts. In terms of subjective and objective sensibility evaluation, of the five methods evaluated in his study, the results were superior with the thenar and cross-finger flaps.

Island Flaps

A number of elegant and ingeniously conceived island flaps have been described for coverage of fingertip amputations.[1,2,50,68,85,154] These consist of flaps raised on their neurovascular pedicle, and advantages include the avoidance of prolonged digital immobilization in an awkward position, single-stage reconstruction permitting early rehabilitation, introduction of an independent blood supply to provide a good soft tissue bed for nerve grafting or repair, satisfactory restoration of a well-padded sensate digital pulp, the potential for a composite tissue transfer, a wide selection of donor sites, and a greater arc of rotation for mobilization of the flap over longer distances. These include homodigital and heterodigital island flaps and can be anterogradely or retrogradely based.[72,80] However, island flaps are more technically demanding and are associated with complications such as flap failure, joint contracture, and cold intolerance.[155] In addition, they have not proved to be more advantageous than simpler methods of achieving coverage of a fingertip amputation. The use of an island flap may be beneficial in select cases, and the reader is referred to comprehensive review articles to become familiar with the indications and surgical techniques.[50,140]

Free Flaps

With advances in microsurgery, free tissue transfer has been used to treat complex digital defects, including medial arm free flaps, anterolateral thigh flaps, wraparound toe flaps, and arterialized venous flaps.[32,34,76,83] These can be complicated by their bulky appearance, necessitating revision surgery, donor site morbidity, and unpredictable survival rates. A fasciocutaneous free flap based on the superficial palmar branch of the radial artery has been reported for medium-to-large volar soft tissue defects, including the fingertip region.[75] The use of a free thenar flap has also been reported by Kamei and Sassu and associates.[79,126] Coverage of complex digital defects using a proximal first dorsal metacarpal artery free flap was recently described in 10 patients.[73] The proximal first dorsal metacarpal artery flap is particularly applicable when the defect is large or when scars or injuries prevent the use of a pedicled homodigital or heterodigital flap. Ulnar artery free flaps have been described for managing complex digital defects because they are thin, have aesthetic and textural characteristics similar to those of the finger, and tend to be free of hair. Given that they require harvesting of a major artery, ulnar artery perforator free flaps have been developed to treat such defects. These can be either proximally or distally based.[100,138] Zheng and colleagues[156] described the use of a distal ulnar artery perforator bilobed free flap in the treatment of 15 patients with complex digital defects. Citing the advantages of having a cosmetic appearance similar to that of digital skin, the presence of the donor and recipient sites within the same surgical field, preservation of the main trunk of the ulnar artery, having a size similar to that of the proper digital artery, containing both the accompanying and superficial veins, and allowing sensation via the medial cutaneous nerve of the forearm or dorsal sensory branch of the ulnar nerve, the authors reported satisfactory outcomes in 14 of 15 patients (1 patient had partial flap necrosis) with good digit range of motion and two-point discrimination ranging from 6 to 11 mm.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Digital Tip Amputation

I prefer to treat all digital tip injuries without exposed bone nonoperatively, with dressing changes or ultrasonic MIST therapy to allow healing by secondary intention. Educating the patient and the family with photographs from previous cases has proven to be invaluable. The analogy that the injury looks "like a dog's dinner" and that it will heal, with pictures from similar case examples, allows one to gain the trust of the patient and help the patient engage with therapy.

In single-digit injuries with a small protruding portion of the distal phalanx, I will trim the bone back and allow healing by secondary intention. For larger defects with more exposed bone, I prefer the "V-Y" advancement flap for dorsal oblique or transversely oriented fingertip amputations. For volar oblique wounds, I use bilayer matrix wound dressings followed by a skin graft when appropriate. I tend not to favor the thenar flap for concern of developing IP joint stiffness but may consider it in young patients with index or long fingertip amputations. If the defect is large, I use a cross-finger flap. If the defect also involves a large portion of the volar tissues, I use a neurovascular island flap, although I have become more and more impressed with the results obtained with bilayer matrix wound dressings and have been increasing their indications in my practice.

AMPUTATIONS FROM THE DISTAL INTERPHALANGEAL TO THE METACARPOPHALANGEAL JOINT (EXCLUDING THE THUMB)

Distal Interphalangeal Joint Disarticulation

My preferred method of management for an amputation through the DIP joint or just distal with loss of flexor digitorum profundus (FDP) function is skeletal shortening and primary closure. I preserve the FDP attachment when possible to maintain some length, IP joint flexion, and pinch stability (Figure 49.9). If the insertion of the FDP is not salvageable, I pull the tendon as far distal as possible and transect it under tension. Whitaker and colleagues presented experimental and clinical data suggesting that there was less inflammation if the articular surface of the middle phalanx was preserved.[150] However, I believe that the shape and contour of the amputation stump should be fashioned to resemble the normal distal phalangeal tuft. This is accomplished by rongeuring off the volar and lateral condylar prominences. The digital nerves should be dissected and cut under tension to allow them to retract away from the cutaneous scar into an area where the inevitable neuromas will not become symptomatic. The flexor and extensor tendons should be inspected and their cleanliness established; they should not be sutured to each other. This inevitably limits the excursion of both and compromise function of the remaining digits. Wang and associates[147a] reported on the outcomes of revision amputation at or distal to the DIP joint and noted that the average arc of motion of the PIP joint was 94 degrees; 24% of patients experienced cold intolerance; most patients had normal sensibility with a mean two-point discrimination of 5.6 mm; and the return to work averaged 7 weeks after surgery.

Complications of Digital Amputation: The Lumbrical-Plus Finger

Distal release of the FDP tendon to the index finger may lead to a "lumbrical-plus" deformity. As the independent FDP and its lumbrical move proximally, tension increases in the lumbrical tendon and its contribution to the intrinsic extensor of the PIP joint. As active flexion of the digit is attempted, further proximal migration of the lumbrical may put sufficient tension on this lateral band to cause paradoxic extension of the PIP joint. Sectioning the lumbrical tendon allows the superficialis to regain control of the PIP joint and may alleviate the problem. In my experience, this rarely occurs, and sectioning of the lumbrical is unnecessary at the time of the amputation.

Amputation Through the Middle Phalanx

If amputation has occurred proximal to the DIP joint of the index finger, most patients will transfer pinching and picking up of small objects to the tip of the long finger (Figure 49.10). Therefore, efforts to preserve index finger length by flap coverage may be necessary. Preserving length in other digits may also be important in certain occupations such as a professional musician or one who uses a computer keyboard and mouse. For injuries in which preserving length is not feasible, the bone should be shortened sufficiently to allow primary coverage with available skin without tension (Figure 49.11). The flexor digitorum superficialis (FDS) insertion should be preserved because the middle phalangeal segment will be able to participate effectively in grasping activities; PIP flexion is always limited, however, if the middle phalanx stump is short. If amputation has occurred proximal to the insertion of the superficialis or if the tendon has been transected, there will be no active flexion of the remaining middle phalanx; therefore, preservation of the middle phalanx is more of a cosmetic issue and less of a functional consideration (Figure 49.12).

The amputation is designed as a "fish-mouth" incision with equal palmar and dorsal skin flaps (Figure 49.13). Alternatively, the incision can be fashioned with a larger palmar skin flap to ensure that the thicker palmar skin covers the tip surface. Regional or digital anesthesia can be used for this procedure. Limb exsanguination is performed by arm elevation and compression of the brachial artery for cases of infection or tumor. Otherwise, the arm is elevated and exsanguinated using an Esmarch bandage. The skin is incised and the extensor tendon cut. On the palmar surface, the neurovascular bundles are identified and the digital vessels isolated and cauterized. The digital nerves are dissected proximally and cut under tension so they retract proximally. The FDP tendon is cut under tension. The insertion of the FDS tendon is protected as much as possible and the osteotomy of the middle phalanx planned a few millimeters proximal to the level of the skin incision to ensure tension-free closure. The phalanx is cut using a reciprocating saw and the ends are smoothed with a rasp. If a disarticulation is to be performed, the articular cartilage is left intact but the volar and lateral condyles are trimmed with a rongeur to decrease stump protuberance. The tourniquet is deflated, hemostasis is obtained, and the wounds are closed with a 4-0 nonabsorbable suture. A soft dressing is applied and range-of-motion exercises are encouraged. Sutures are removed at 2 weeks or once the wounds have healed. Edema control and desensitization exercises are initiated.

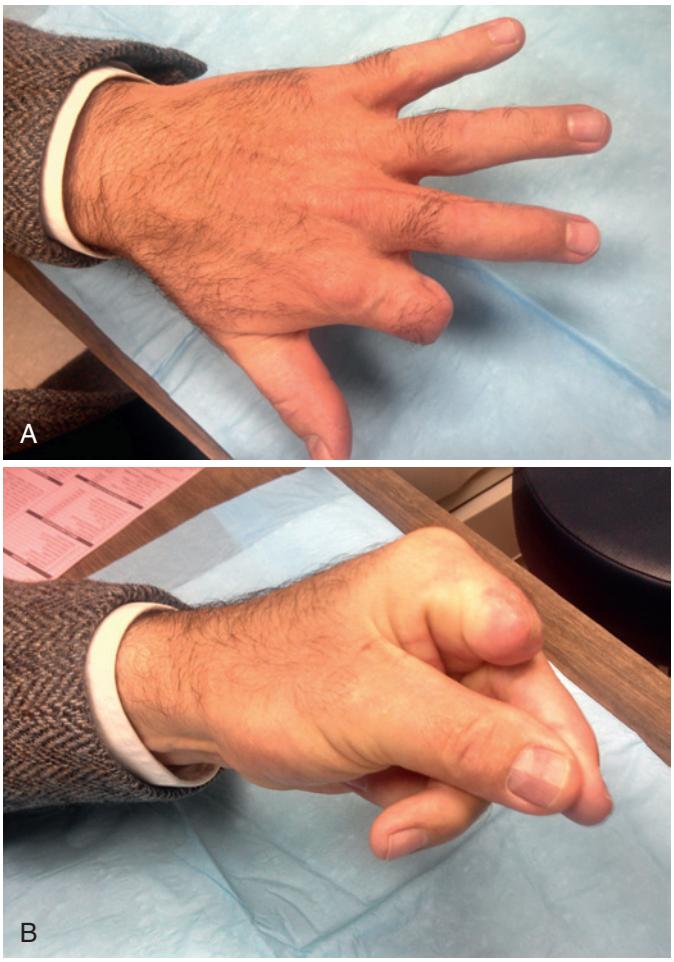

FIGURE 49.10 In a patient with an amputation proximal to the distal interphalangeal joint of the index finger, pinch will virtually always be transferred to the long fingertip. **A,** Dorsal view showing amputation through proximal phalanx. **B,** Lateral view highlighting patient transferring pinch to the long finger. FIGURE 49.11 Use of volar and dorsal skin flaps for coverage when a distal amputation in the finger, that is, distal to the metacarpophalangeal joint, is indicated. Volar flap coverage is considered preferable because of its greater sensibility. This technique is also applicable when primary closure is desired by means of bone shortening. The digital nerve is sectioned after distal traction to allow the inevitable neuroma to form at a location proximal to the cutaneous scar. **A,** Fish-mouth incision. **B,** Traction neurectomy. **C,** Closure of incision. Amputations Through the Proximal Interphalangeal Joint

Amputations through the PIP joint should be carried out in a manner similar to those through the DIP joint, with denuding of articular cartilage, shaping of the condyles of the proximal phalanx, and coverage with local skin.

FIGURE 49.12 Note the amputation proximal to the insertion of the superficialis through the base of the middle phalanx. Although no flexion control of the middle phalangeal remnant is possible, the length preserved with such an amputation may be helpful in preventing small objects from falling through the hand.

Amputation Through the Proximal Phalanx

If an amputation has occurred proximal to the PIP joint, the remaining proximal segment is under motor control of the intrinsic muscles and the extensor digitorum communis. This provides active MP joint flexion of approximately 45 degrees. The remaining segment will participate in gripping and help keep small objects in the palm. To improve flexion at the MP joint, tenodesis of the FDS tendon to the end of the proximal phalanx can be performed. Kirschner wire holes are made through the distal end of the proximal phalanx and the FDS tendon is sutured at its resting length to the phalanx, which provides almost 90 degrees of flexion with grasp (Figures 49.14 and 49.15).

If the amputation has occurred near or at the MP joint level, particularly in the long and ring fingers, functional problems such as dropping small objects through the defect will result, and further consideration of prosthetic replacement or a proximal ray amputation should be contemplated. If the amputation involves the index finger, immediate ray amputation should be considered.

RAY AMPUTATIONS

A ray amputation involves excision of a digit from its metacarpal base. Indications include trauma, tumor resection, infection, failed replantation, debilitating Dupuytren disease, and macrodactyly.[30] When considering a ray amputation, it is important to think about its effects on overall hand function because the amputation will affect the three functional units—namely, (1) an opposable thumb, (2) the index and long fingers

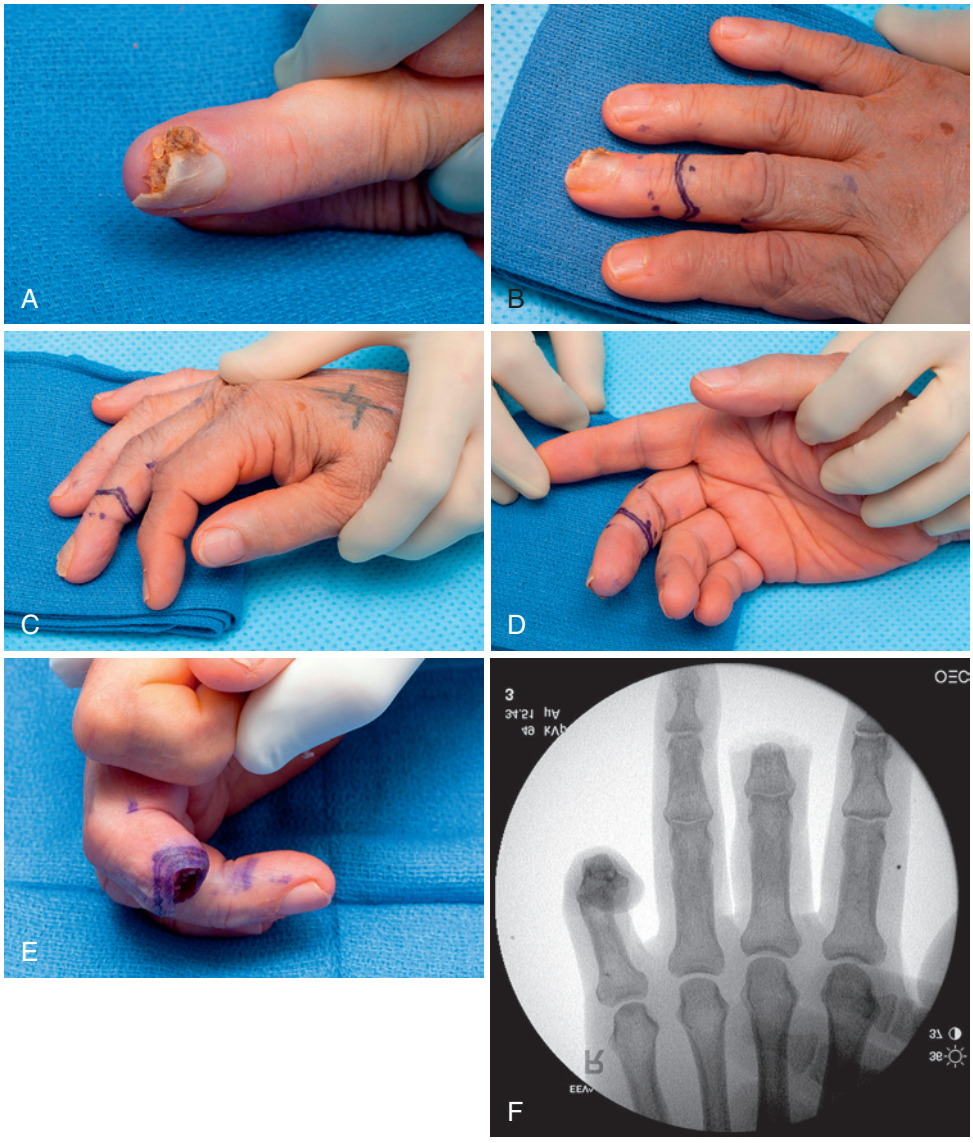

FIGURE 49.13 **A,** A 75-year-old woman with squamous cell carcinoma of the fingertip. Magnetic resonance imaging of the finger demonstrated increased edema within the distal phalanx, and therefore an amputation through the middle phalanx with clean margins was performed. **B** to **D,** Fish-mouth insertion. **E** and **F,** View following amputation through the middle phalanx.

CRITICAL POINTS *Digital Amputation Levels*

- Amputations through the DIP joint are managed by skeletal shortening and primary closure.
- If the FDP attachment and, thus, DIP joint flexion are intact, length should be maintained with flap coverage to preserve joint motion and stability.
- In amputations through the middle phalanx, bone should be shortened to allow primary coverage by available skin without tension. If possible, the amputation level should be distal to the FDS insertion.
- Amputations through the PIP joint are managed like those through the DIP joint.
- If amputation through the proximal phalanx is near the PIP joint, some useful gripping function is preserved and can be enhanced with FDS tenodesis.
- If amputation is near or at the MP joint, ray amputation should be considered.

for pinch, and (3) the ring and small fingers for grip.[110] It can narrow the palm span by 10%, with a resultant decrease in grip strength.[102] However, the narrower palm must be weighed against other impairments related to the space created by the missing digit, especially for the central digits, because small objects may fall through this area. Ray amputation may be indicated at the time of initial trauma, but in most instances, it is performed as an elective procedure secondary to functional impairment or unremitting pain. In most injuries, the principle of saving all viable tissue should be followed. Tissue that may appear at first glance to be of little functional benefit may serve as a good source of material for subsequent reconstruction (e.g., bone graft).[31]

Peimer and colleagues[117a] conducted a retrospective review of 12 patients who underwent primary ray amputations (within 2 weeks) and 13 patients who had secondary ray amputations for either traumatic or oncologic reasons. They noted that patients who underwent primary ray resection had better

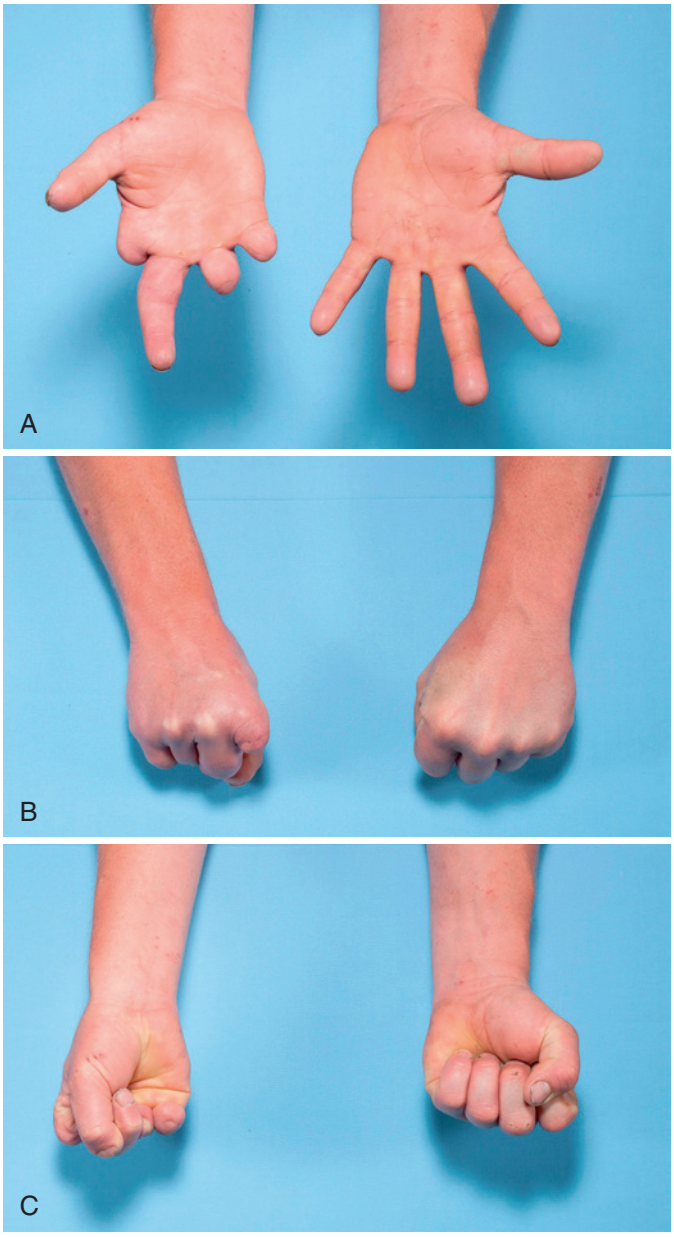

FIGURE 49.14 Twenty-six-year-old male following replantation of right long finger and FDS tenodesis to ring and small finger proximal phalanges. **A,** Palmar view of hand with full extension of ring and small fingers at metacarpophalangeal joint. Dorsal **(B)** and palmar **(C)** views of hand showing good flexion at the metacarpophalangeal joint of the ring and small fingers, which provided the patient with the ability to grasp and function as a manual laborer.

strength and dexterity and had to take less time off work. On average, patients lost 28% of grip strength, 26% of opposition, and 13% of key pinch strength. The vast majority of patients, excluding those involved in workers compensation or litigation cases, were satisfied with the functional outcome, with most returning to the preinjury occupation. Melikyan and colleagues[102] reported on 20 patients at an average of 32 months following surgery. Grip strength decreased by 27% and three-point pinch by 22%. Patients who had an amputation of border digits recovered better than those who had amputation of the central digits, with the latter group having impaired manual dexterity.

Index Finger Ray Amputation

Murray and colleagues reviewed 41 patients who underwent index finger transmetacarpal amputation (13 patients at the level of and 28 patients proximal to the metacarpal head). They reported a 20% reduction in power grip, key pinch, and supination strength.[113] Pronation strength, which is a measure of grasp stability, decreased by 50% owing to the narrowing of the palm. With loss of the index finger, the pronosupination fulcrum is decreased by 25%, resulting in a loss of stability and a mechanical disadvantage for forearm rotation (Figure 49.16).[110] There was no significant difference in strength between those who had proximal or distal amputations. Patients noted that the overall hand function had improved, despite the loss in strength, because of the ability to maintain thumb prehension. Cold intolerance was the most common persistent symptom (35 of 41 patients). Fifty-nine percent of patients had suboptimal results owing to hyperesthesia in the thumb/long finger web space. This was secondary to excessive mobilization of the index finger radial digital nerve during the amputation process and interfered with hand function in 37% of patients.[113] Fisher and Goldner[46] reported a similar complication in five patients; it appeared 6 to 8 weeks after surgery. Although this problem may resolve with secondary surgery, the symptoms may recur over time. In the series of Murray and associates, 34 patients underwent elective ray amputations. Twenty-one complained of pain in the stump before the transmetacarpal amputation, and only 3 experienced complete relief after the procedure. This information is important when advising a patient preoperatively about the possibility of *persistent postoperative neuroma-like symptoms*. Ay and Akinci[9] described a technique of primary transposition of the index finger digital nerves into the interossei to decrease neuroma formation. After amputation of the digit, the radial and ulnar digital nerves are mobilized in a proximal direction and inserted within the interossei of the long finger.

In an effort to restore strength to the long finger, several tendon transfers have been described, including transfer of the first dorsal interosseous muscle to the second dorsal interosseous tendon or extensor hood, the extensor indicis proprius to the long finger extensor, or the FDS to the proximal phalanx of the long finger. Of the more commonly performed transfers, Murray and associates[113] found no differences in key pinch strength in patients who had or had not undergone transfer of the first to the second dorsal interosseous tendon. In 11 of 28 cases in which the second dorsal interosseous tendon was augmented by transfer of either the first dorsal interosseous tendon or one of the long flexor tendons of the index finger, there was an intrinsic-plus deformity evident on clinical examination. From these data it would appear that procedures designed to augment the second dorsal interosseous tendon are unnecessary and may lead to additional complications.

Germann and colleagues[55] reported on 120 patients with ray amputations (42 of the index finger). The majority of patients noted minimal functional deficits in performing activities of daily living. There was no significant loss of strength compared with patients who had undergone an amputation through the middle phalanx with respect to tip, key, and palmar pinch and sustained grip. Unlike those who had undergone digital amputation, 90% of patients with a ray amputation were happy

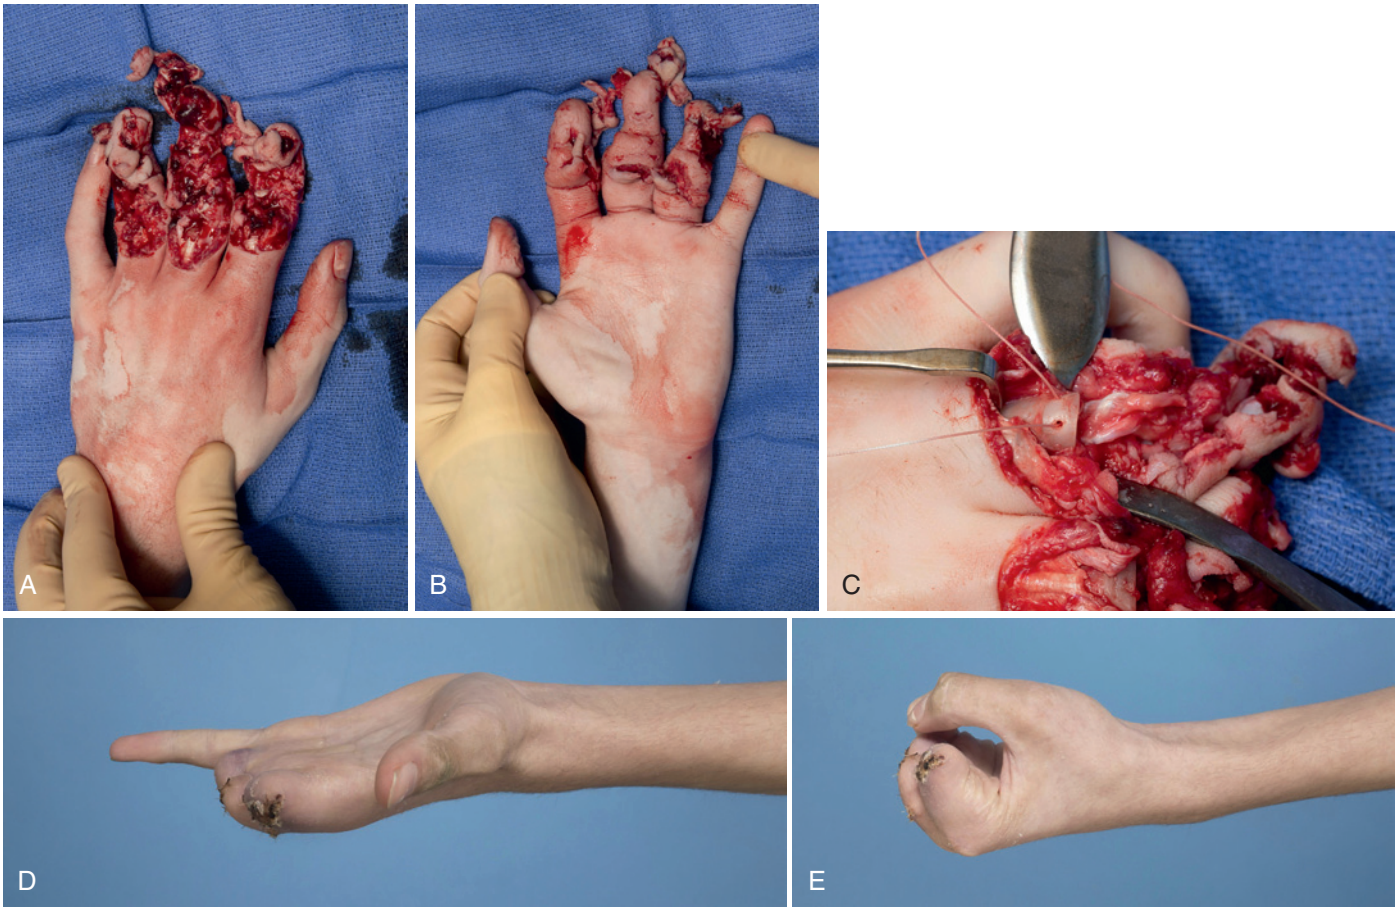

FIGURE 49.15 This patient sustained a punch press injury with proximal phalangeal amputations of his index, long, and ring fingers. Flexor digitorum superficialis tenodesis was performed to improve flexion of the proximal phalanges, and fillet flaps were used from the palmar skin for wound coverage. **A,** Dorsal view. **B,** Palmar view. **C,** Flexor digitorum superficialis tenodesis to proximal phalanx through drill holes at the end of the bone. The underlying flexor digitorum superficialis tendon will be sutured to the end of the distal phalanx. **D,** Full extension of metacarpophalangeal joint. **E,** Note that with the flexor digitorum superficialis tenodesis, patient was able to achieve nearly 90 degrees of flexion at the metacarpophalangeal joint. Patient will be fitted with a body-powered M-finger (see hand prosthetics section).

with the cosmetic appearance. Similar results were reported by Melikyan and associates[102] in an evaluation of ray amputations. Eight of the 20 patients underwent index finger ray amputation. Grip strength was decreased by a mean of 19% compared with the contralateral hand. Interestingly, 6 of 8 patients learned to transfer manual dexterity precision skills (commonly performed between the thumb and index finger) to the long finger without difficulty, presumably because of the unrestricted first web space. Many cases of ray amputation are performed following trauma. Puhaindran and coworkers[122] reported on the outcomes of single-ray amputation (7 of the index finger, 5 of the long finger, 6 of the ring finger, and 7 of the small finger) for tumors of the hand that included soft tissue malignant tumors, metastases, giant cell tumors of bone, and primary bone sarcomas. Ten patients underwent postoperative radiation treatment (2 for positive margins and 8 for close margins). None of the patients had local recurrences. Patients who received preoperative radiotherapy had a decrease in functional outcomes and grip strength that averaged 66% compared with the contralateral hand.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Index Finger Ray Amputation

For trauma cases, transmetacarpal amputation is not performed in the acute setting unless there is injury proximal to the MP joint. In cases of multiple-digit injuries, it is especially important to preserve as much finger length as possible. For ray amputation, regional anesthesia is preferred. For cases of infection or tumor, limb exsanguination is performed by arm elevation and compression of the brachial artery. Otherwise, the arm is elevated and exsanguinated using an Esmarch bandage. A proximally based "V" incision is fashioned on the volar surface at the midproximal phalangeal level of the index finger. Dorsally, this is joined by a "Y"-shaped incision with proximal extension over the index metacarpal (Figure 49.17, *A*). The longitudinal dorsal incision is made through the subcutaneous tissue, and the veins are ligated as necessary. If indicated, dorsal sensory branches of the superficial radial nerve should be divided under tension to allow proximal retraction. The extensor digitorum communis and extensor indicis proprius tendons

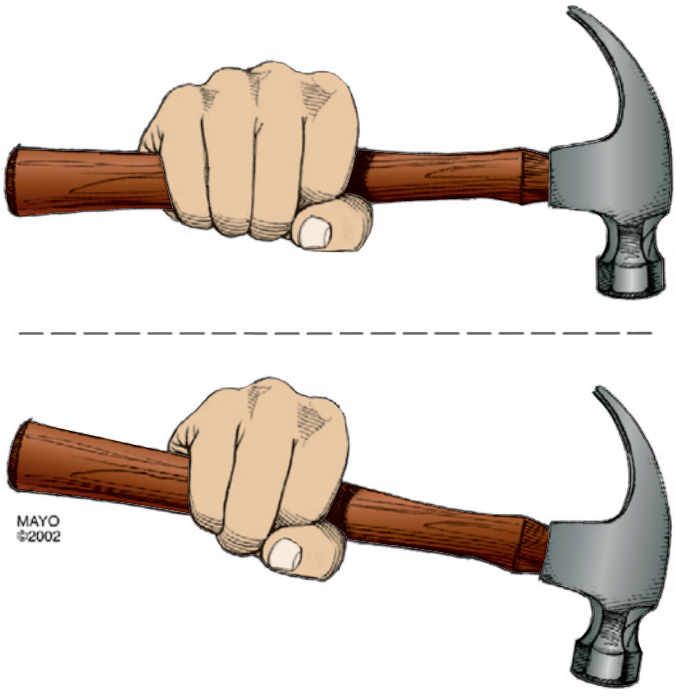

FIGURE 49.16 Loss of a ray decreases the span of the palm and has a negative effect on pronosupination strength. (Modified from Moran SL, Berger RA: Biomechanics and hand trauma: what you need. *Hand Clin* 19:17–31, 2003, Figure 11, p 23. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

are divided at the level of the second metacarpal base and reflected distally to expose the underlying periosteum. The dorsal periosteum is sharply incised, and a subperiosteal sleeve is raised. The index finger metacarpal is transected via a reciprocating saw distal to the insertion of the extensor carpi radialis longus tendon (maintaining wrist strength), with care taken to protect the underlying radial artery as it passes beneath the base of the metacarpal (see Figure 49.17, *B*). A rasp is used to address any rough edges of the transected metacarpal base. Dissection is carried around the distal circular portion of the incision. The first dorsal interosseous tendon and lumbrical muscle to the radial side of the index finger are divided. One next proceeds around the palmar aspect of the finger, and the neurovascular bundles to the index finger are identified. Care must be taken to identify and protect the radial digital nerve to the long finger and its accompanying digital artery. The vessels to the index finger are ligated and the digital nerves dissected distally into the middle phalangeal segment and divided. The flexor tendons are transected under tension to promote retraction into the palm. The tendon of the first palmar interosseous tendon is also divided.

The volar plate, deep transverse intermetacarpal ligament (DTIL), and proximal portion of the flexor tendon sheath are sharply incised, permitting delivery of the amputated digit. The distal end of the digital nerves that have intentionally been transected in the finger are now carefully dissected proximally, with their connections with the palmar skin left undisturbed (see Figure 49.17, *C*). The distal ends are transposed proximally into the interosseous space between the first and second dorsal interossei to provide protection from external compression (see Figure 49.17, *D*). Alternatively, the nerves may be coapted. The tourniquet is deflated, hemostasis is obtained, and the periosteal sleeve is closed. The skin flaps are trimmed, inset, and closed with interrupted sutures. A well-padded soft dressing is applied, and early motion is encouraged. Strengthening is started at 6 weeks following operation. Patients should be followed to ensure an uneventful recovery because complications such as neuroma formation and carpal tunnel syndrome may occur. The latter may occur as a result of proximal migration of the transected flexor tendons into the carpal canal.

Long Finger Ray Amputation

Given its central location, the long finger plays an important role in hand function, especially in lateral pinch, chuck pinch, and power grip.[110,135] Any loss of length distal to the PIP joint can lead to small objects falling between the gap of the index finger and ring finger[53] (Figure 49.18) and a loss of three-point chuck pinch. Angular deformity of the index finger can occur when the amputation is at the level of the MP joint.[29] Key pinch strength is diminished because the origin of the adductor pollicis muscle is removed from the long finger metacarpal. One of the main complications following central ray deletion is scissoring of the adjacent index and ring fingers due to instability of the DTIL and altered intrinsic muscle function. Given this, two techniques of long finger ray amputation have been popularized, namely, repair or reconstruction of the DTIL and ray transposition.

Long Finger Ray Amputation Without Transposition

Melikyan and colleagues reported on the outcomes of patients who underwent central ray amputation compared with those who underwent border digit ray amputation.[102] Amputations were performed through the base of the metacarpal, and the DTIL was closed for central deletion cases. Compared with patients who underwent border digit deletion, those who underwent long finger ray amputation had weaker three-point pinch, decreased manual dexterity, and weakness in torque power and work output of up to 38% compared with the contralateral hand. The authors did not find any cases of gapping or scissoring by primarily repairing the DTIL (Figure 49.19). One of the concerns with imbrication of the DTIL when the metacarpal base of the long finger is left in situ is the scissoring that may develop as the metacarpal heads of the index finger and ring finger are drawn together. This was highlighted by Steichen and Idler,[135] who stated that the procedure may be better suited for ring finger ray amputation because in the ring finger, the metacarpal is thinner and gap closure is more readily achieved due to the mobility of the fifth carpometacarpal (CMC) joint; in the long finger, the metacarpal is wider and the index finger CMC joint stiffer. Nonetheless, in their report of 13 patients (4 of whom had long finger surgery and 9 of whom had ring finger surgery), satisfactory functional and cosmetic results were noted in all but 1 patient, who complained of continued palmar tenderness and narrowing of the palm. For cases in which the DTIL is absent or deficient, Gong and coworkers[56] described a technique of reconstructing the dorsal transverse intermetacarpal ligament using a free tendon graft. Following metacarpal base osteotomy, a free tendon graft (either a graft from the amputated digit or an autograft) is looped around the index and ring finger metacarpal necks and sutured to itself and

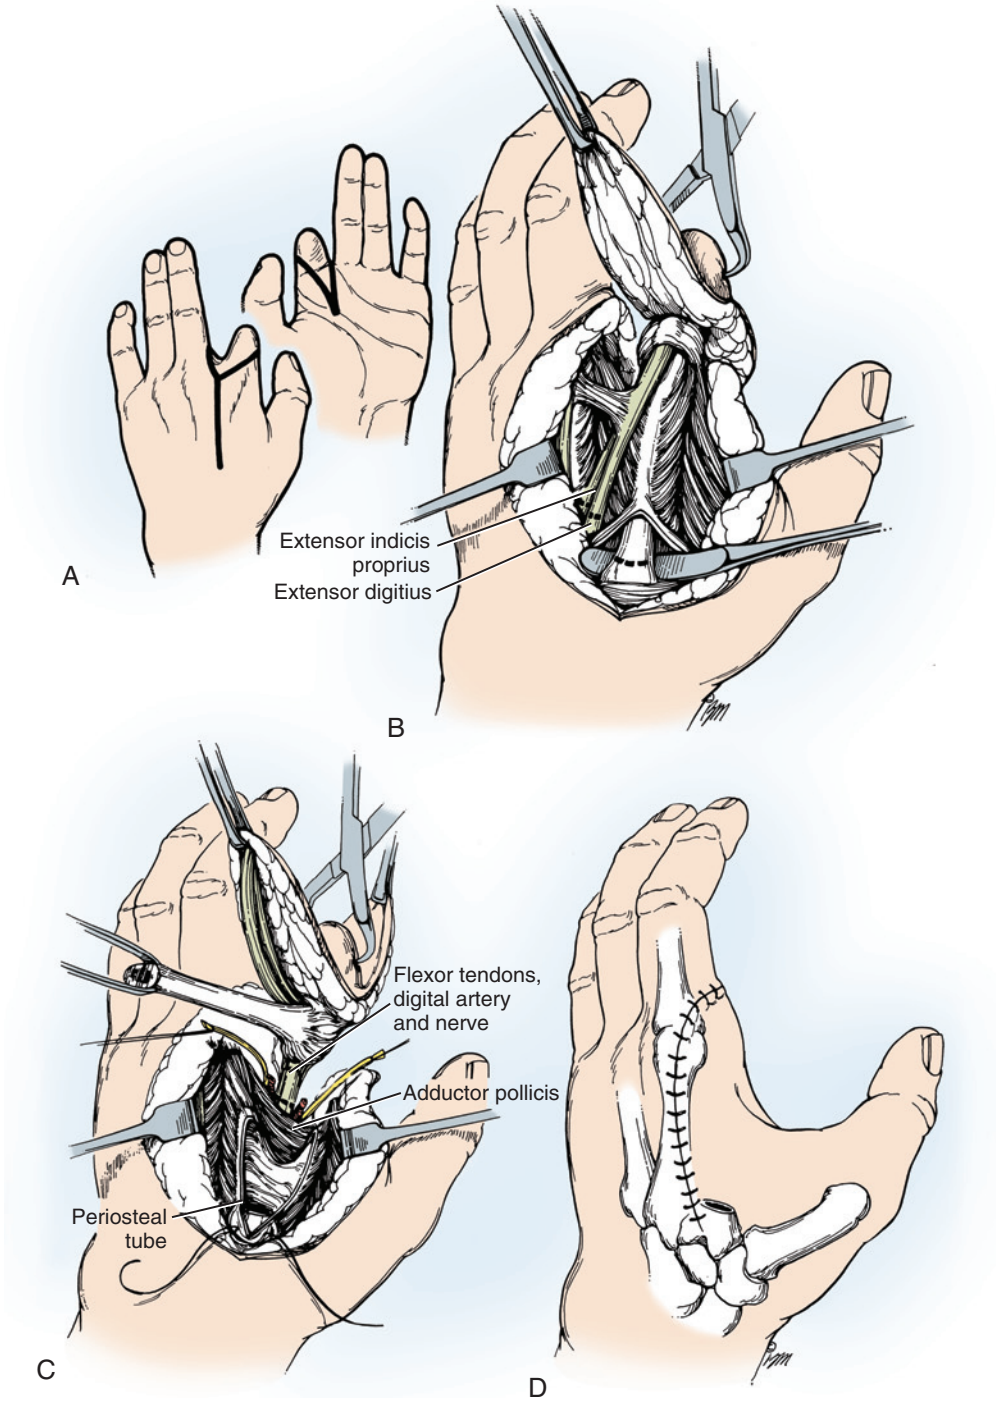

FIGURE 49.17 **A** to **D,** Technique of index finger ray amputation. After the appropriate skin flaps are raised, dissection proceeds from dorsal to volar. After division of the extensor digitorum communis and extensor indicis proprius, the index finger metacarpal is transected at its flare, distal to the extensor carpi radialis longus insertion. Following division of the lumbrical, dissection proceeds volarly where the neurovascular bundles are identified. The digital nerves are transposed into the interosseous space to prevent the formation of a symptomatic neuroma.

to the adjacent periosteum (Figure 49.20). An alternative method of fixation would be to use biotenodesis screws within the index finger and ring finger metacarpal necks.

To draw the index and ring fingers closer together, Iselin and Peze[73a] described a technique whereby a closing wedge osteotomy of the capitate (distally based wedge with apex proximal) is performed after long finger ray amputation. The operation was performed in 12 patients, and the authors reported satisfactory closure of the gap between the index finger and ring finger with soft tissue repair; patients were satisfied with the functional and aesthetic results. Alternatively, Lyall and Elliot[97a] described a technique whereby the entire middle finger ray is amputated at the CMC joint. Care must be taken to protect the underlying motor branch of the ulnar nerve. Subperiosteal

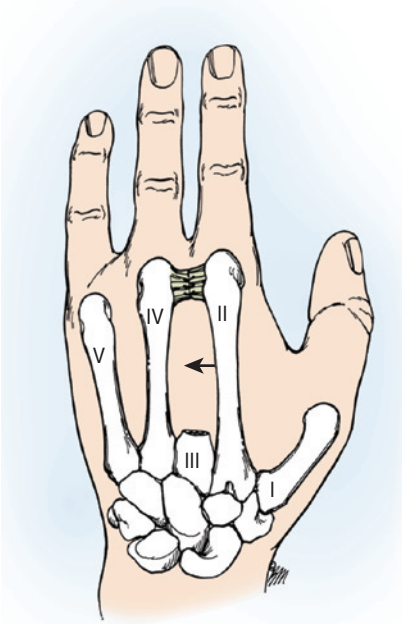

FIGURE 49.19 Long finger ray amputation with repair of the deep transverse intermetacarpal ligament. This may be provisionally stabilized by a transverse intermetacarpal Kirschner wire during the healing process. The *arrow* indicates how the index and ring finger metacarpals are drawn together, obliterating the space left after long finger deletion.

dissection of the extensor carpi radialis brevis from the dorsal aspect of the long finger metacarpal base is necessary to preserve its function. Reconstruction of the hand involves closing the gap between the index finger and ring finger metacarpals while avoiding angulation and malrotation. From proximal to distal, sutures are placed between the periosteum/muscles of the index finger and ring finger metacarpals, followed by their respective sagittal bands and DTIL (having excised the palmar plate of the long finger MP joint, which can act as a barrier to preventing closure of the dead space). Dorsal skin excision or dermadesis helps to further support the reconstruction. A palmar "V" flap of excess skin is excised.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Long Finger Ray Amputation Without Ray Transposition

After satisfactory regional or general anesthesia, the limb is exsanguinated and a tourniquet is applied. A dorsal incision is made and extended along the shaft of the long finger ray (Figure 49.21). The distal ends of the incision are carried over the proximal phalangeal skin to preserve sufficient skin for closure of the commissure between the index and ring fingers. This technical point is important when performing ray amputations of the middle two rays to preserve skin and prevent iatrogenic web contracture. Alternatively, a web-saving incision that

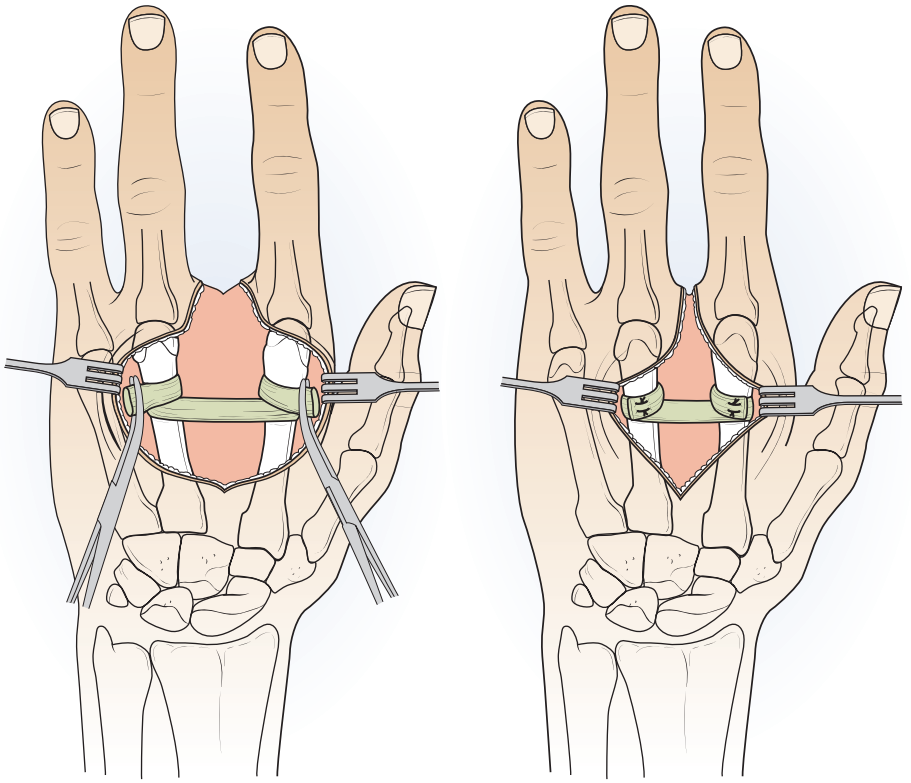

FIGURE 49.20 Reconstruction of dorsal transverse intermetacarpal ligament between index and ring finger metacarpals after central ray deletion. (From Gong HS, Shin SI, Baek GH: Creation of a "dorsal transverse intermetacarpal ligament" to prevent scissoring deformity in central ray amputation. *J Hand Surg Eur Vol* 33:163–165, 2008.)

avoids placing the scar in the new web space can be used (Figure 49.22).

The extensor digitorum communis tendon to the long finger is divided proximally. The long finger metacarpal is osteotomized at its base distal to the extensor carpi radialis brevis insertion after subperiosteal dissection has been carried out and the intrinsic muscles reflected. The second dorsal interosseous, lumbrical, and third dorsal interosseous tendons are divided. The DTIL is identified as it lies between the palmar lumbrical and dorsal interossei. A continuous band is created by leaving the volar plate in situ as the metacarpal is released from its volar capsule and adjacent interossei. Palmar dissection is carried out in a fashion similar to the procedure for the index finger, and the blood vessels are ligated and the digital nerves transected as far proximally as possible. The flexor tendons are divided and allowed to retract proximally. The digital nerves of the long finger are buried deep in the muscles of the second and third intermetacarpal spaces or can be sutured together in an end-to-end manner.[58] Wound closure is critically important in order to try to prevent malrotation and scissoring of the index and ring fingers. The ring finger and index finger metacarpals are compressed together to close the space created by central ray deletion. The DTIL is imbricated in a pants-over-vest configuration with 3-0 nonabsorbable sutures. This should be performed tightly because the repair will stretch. In cases where the intermetacarpal ligaments are absent or insufficient, free tendon grafts may be used to prevent scissoring.[56] The palmar skin is closed and scissoring of the digits checked via wrist tenodesis. The dorsal structures are next closed, including the periosteum/muscles of the index and ring finger metacarpals, followed by their sagittal bands and the dorsal skin. Attention should be paid to dorsal skin closure because dorsal skin dermadesis can exacerbate any malrotation caused by gap closure after central ray deletion. The hand is inspected by passive range of motion of the fingers and wrist tenodesis to check for rotational deformity. The commissure is fashioned to reflect a dorsal-volar slope of the web skin between the index and ring fingers. Temporary Kirschner wires can be placed from the index to ring finger metacarpals. A splint is applied, and early digit range of motion is encouraged. The Kirschner wires are removed after 4 to 6 weeks, and active and active-assisted range-of-motion exercises are begun. Strengthening is delayed until palmar tenderness has resolved.

Long Finger Ray Amputation With Transposition

Despite technical advancements, acute long finger ray resection with repair of the DTIL may still cause malrotation and scissoring of neighboring digits. To avoid the subsequent loss of three-point chuck pinch and the functional impairment that may ensue, transposition of the index finger to the long finger has been advocated.[29,65] The advantage of index finger ray transposition is that it gives immediate closure of the intervening space when the long finger ray is removed and allows the surgeon to control rotation at the osteotomy site.

Colen and coworkers[37] reported on the functional outcomes after ray transposition for central digital loss. Eleven patients had an index finger transfer for long finger deletion and 8 had a small finger transposition for ring finger amputation. Total grip was 80% compared with the contralateral hand, with greater digit range of motion, pinch, and grip strength in those

who underwent small finger to ring finger transfer than in those who underwent index finger to long finger transfer. Posner[120a] reported on a series of 14 patients who underwent 9 index finger and 5 small finger transpositions. In 13 of 14 patients, the step-cut osteotomy had healed by 9.5 weeks. There were no instances of malrotation, and all patients were happy with the prehension function and cosmetic result. Hanel and Lederman[65] treated 10 patients with index finger to long finger ray transposition. Rigid internal fixation was used, and patients were mobilized immediately. The authors reported a union rate

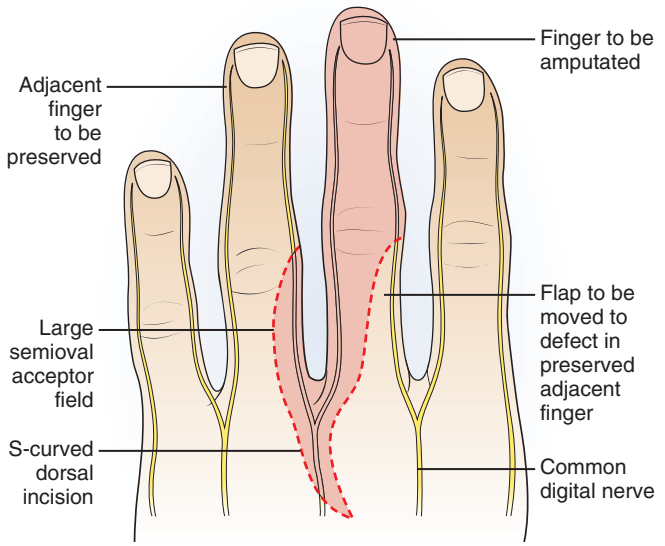

FIGURE 49.22 An incision is made to preserve the web space with amputation of the long or ring finger ray with its digital nerves (*shaded*), with preservation of the adjacent digital nerves of the transposed ray (*unshaded*).

FIGURE 49.23 This radiograph demonstrates a nonunion of index finger to long finger ray transposition. The osteotomy site in the long finger metacarpal was made too far distally. If ray transposition of the index finger is done, it is important to perform the osteotomy at the metacarpal base; this leads to a lower nonunion rate.

of 100%, no loss of range of motion, and no cases of malrotation. The average strength of grip and pinch was 65 and 78%, respectively, compared with the contralateral hand. The size of the web space in the reconstructed hand was within 2 mm of the uninjured hand. Six patients involved in workers' compensation cases returned to the same occupation. Patients were uniformly pleased with the hand function and aesthetic results. Carroll[29] also reported his results in 20 cases in which the entire index metacarpal was transposed to the base of the capitate and an arthrodesis was performed between the base of the index metacarpal and the capitate after the transposition. He noted no difference between this procedure and transposition to the base of the long finger metacarpal but preferred osteotomy at the base of the index metacarpal and osteosynthesis of the transposed metacarpal shaft to the base of the third metacarpal.

Complications of ray transposition include malunion, nonunion (Figure 49.23), and stiffness of the transposed digit related to extensor tendon adherence at the osteotomy site. In addition, the transfer results in a large first web space and removes the necessary relationship between the thumb and the index finger for precision pinch.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Long Finger Ray Amputation With Ray Transposition

After satisfactory regional or general anesthesia, the limb is exsanguinated and the tourniquet inflated. A dorsal incision is made extending along the shaft of the long finger ray (Figure 49.24, *A*). The distal ends of the incision are carried out over the proximal phalangeal skin to preserve sufficient skin for closure of the commissure between the index and ring fingers. Alternatively, a web-saving incision that avoids placing the scar in the new web space can be used (see Figure 49.22).

After the dorsal skin is incised, the extensor digitorum communis tendon to the long finger is divided proximally and reflected distally. Subperiosteal dissection is performed to expose the long finger metacarpal and maintain the origin of the adductor pollicis muscle. Many methods of osteosynthesis have been described, including Kirschner wires and rigid internal fixation. With the advent of locking technology, my preference is the use of rigid fixation with plates and screws. The plate is placed onto the proximal aspect of the metacarpal and aligned along its shaft. A mark is placed on the metacarpal at a point that ensures a minimum of three screw holes proximally. The plate is removed and a transverse osteotomy made at the marked area, which tends to lie at the metadiaphyseal junction and is distal to the extensor carpi radialis brevis insertion (see Figure 49.24, *B*). Attention focuses palmarly, whereby the flexor tendons of the long finger are sharply divided under tension and retracted proximally. The digital arteries are ligated and the radial and ulnar digital nerves are sutured in an end-to-end manner.[58] As the long finger is excised, care is taken to identify and preserve the DTIL (see Figure 49.24, *C*).

Through the same incision, the index finger metacarpal is exposed and a transverse osteotomy performed at the proximal metadiaphyseal flare (see Figure 49.24, *D*). To aid in the mobilization of the index finger metacarpal, the first palmar and second dorsal interossei are resected. The "T"-plate is applied to the long finger metacarpal base and secured proximally. The index finger metacarpal shaft is transposed onto the recipient site of the long finger metacarpal base. The overall alignment of the digit as well as its height in relation to the ring finger metacarpal is checked and adjusted before rigid osteosynthesis is performed. Bone graft from the excised long finger metacarpal can be used at the osteotomy site. After fixation, the periosteal sleeve containing the origin of the adductor pollicis is

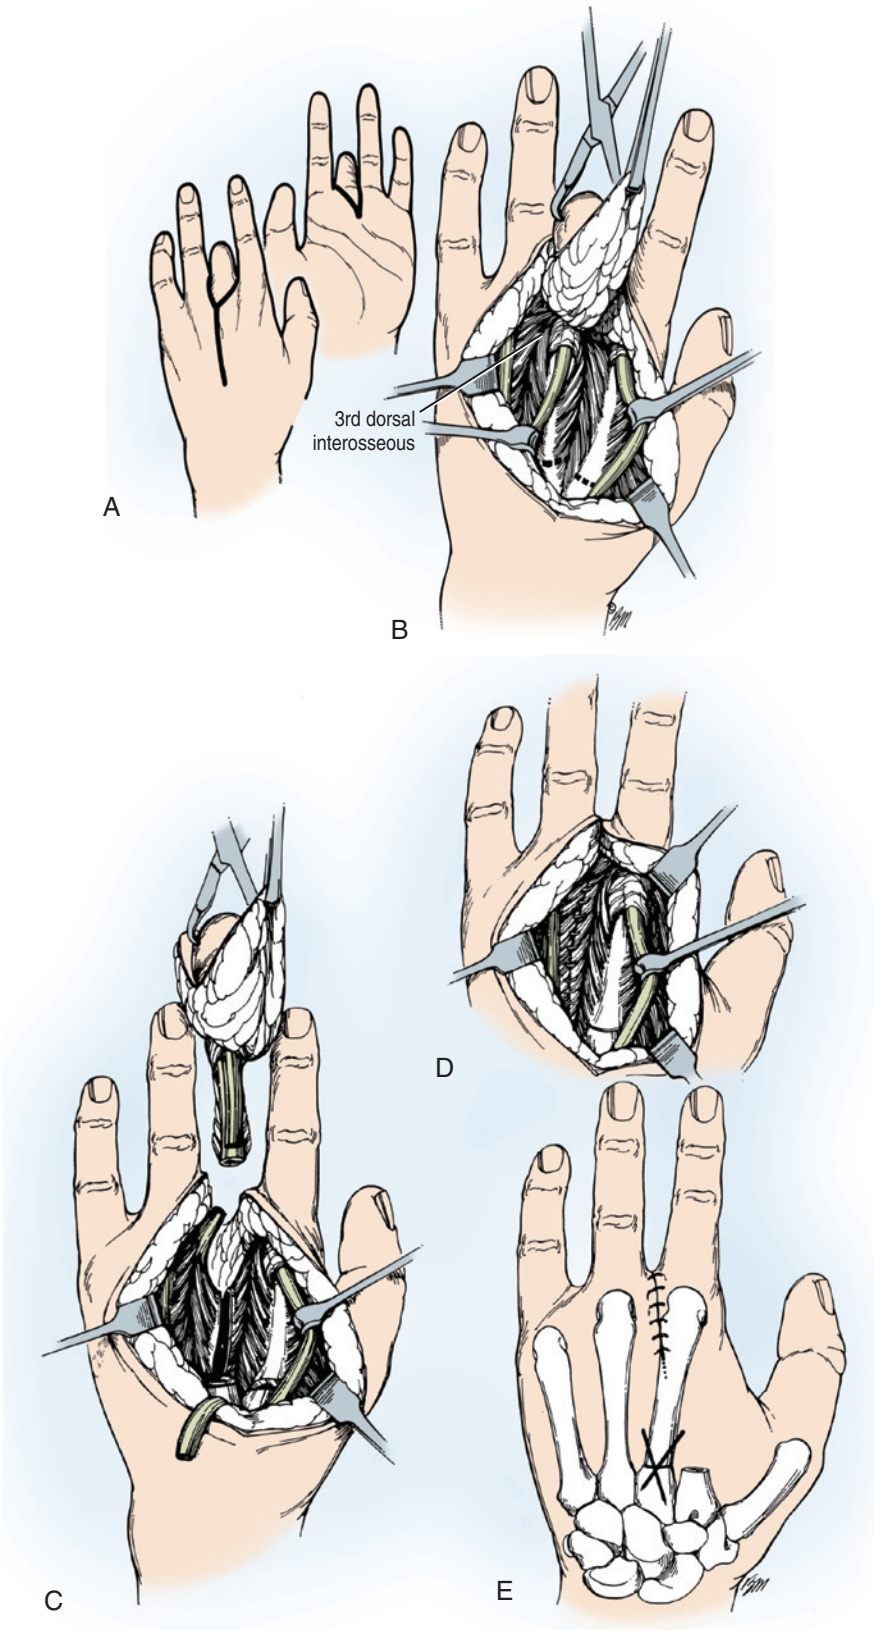

FIGURE 49.24 **A** to **E,** Diagram detailing index finger ray transposition to the base of the long finger metacarpal.

reattached to the index finger metacarpal in its newly transposed position. The DTIL between the index finger and ring finger is securely repaired in a pants-over-vest configuration with 3-0 nonabsorbable sutures. The alignment of the digits is rechecked through both passive range of motion and wrist tenodesis. To aid with abduction of the transposed digit, the third dorsal interosseous tendon is sutured to the distal end of the first palmar interosseous tendon. After hemostasis is obtained, the dorsal fascia and skin are closed. The commissure is fashioned to reflect a dorsal-volar slope of the web skin between the index and ring fingers. Patients are immobilized in an intrinsic-plus splint for up to 4 to 6 to weeks (depending on the method of fixation) to ensure healing of the osteotomy. The PIP joints are left free for active motion (Figure 49.25). If an extensor lag develops at the long finger MP joint, a dynamic extension splint is used.[65]

RING FINGER RAY AMPUTATION

Along with the long finger, the ring finger plays an important role in forming the keystone of the palmar arch, and, together with the small finger, it plays an important role in power grip. On its own, it plays a minimal role in precision pinch and grip and is considered by some to be the least important digit with respect to hand function.[143] Despite this, ring finger ray resection can have negative effects on hand function. Nuzumlali and colleagues[115a] compared patients who underwent amputation (through the proximal phalanx) with those who underwent ray resection for ring finger avulsion injuries at the PIP joint. Compared with the amputation cohort, key and chuck pinch strengths were substantially decreased in the ray resection patients; this finding suggests that ray resection be avoided in patients requiring key and chuck pinch in their occupations. In addition, central ray deletion can have a negative impact on manual dexterity.[102]

As with the long finger, two techniques of ring finger ray amputation have been described, namely, performing the procedure with bony transposition or without it.

Ring Finger Ray Amputation Without Transposition

In the ring finger, unlike in the index finger and long finger, there is 15 to 30 degrees of mobility between the ring and small finger metacarpal bases and the hamate at the carpometacarpal joint. The ring finger and small metacarpal bases also share a common articulation with the hamate. It is therefore possible for the base of the fifth metacarpal to slide radially if the entire

metacarpal shaft of the fourth metacarpal is excised. This possibility is enhanced by the anatomic lack of tendinous attachments to the base of the fourth metacarpal, unlike in the remaining metacarpals in the hand. This concept was borne out by the results of Steichen and Idler,[135] who reported on patients who underwent central ray resection without transposition. Given the mobility of the fifth CMC joint and the narrower diameter of the fourth metacarpal, they noted that it was relatively easy to close the intermetacarpal space between the long finger and small finger compared with the space between the index finger and ring finger after long finger deletion. Cosmetic and functional results were satisfactory in 12 of 13 patients.

Transmetacarpal ray resection of the ring finger can leave an open space between the long finger and small finger because the remaining metacarpal base prevents convergence of the two digits. This can be avoided by complete ray deletion, but complete deletion can lead to a loss of small finger abduction and possible scissoring due to forced convergence of fifth toward the center.[91]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Ring Finger Ray Amputation Without Transposition

A racket-shaped incision is created distally over the proximal phalanx or its remnant (Figure 49.26). A proximal longitudinal incision is made over the fourth metacarpal, continuous with the racket incision. Alternatively, a web-saving incision that avoids placing the scar in the new web space can be designed (see Figure 49.22). The incision is carried down through the subcutaneous tissue, beginning dorsally. The dorsal veins are preserved when possible. The extensor digitorum communis tendon to the ring finger ray is transected proximally and the tendon is reflected distally. An incision is made through the periosteum down to the metacarpal shaft. Subperiosteal dissection is carried out, and the base of the metacarpal is identified at its articulation with the hamate. The dorsal CMC ligaments are incised; subsequently, by detaching the articulation and performing palmar flexion of the metacarpal, the volar CMC ligaments may be divided. Care must be taken to avoid damage to

FIGURE 49.26 Diagram showing racket-based incision for performing a ring finger ray resection. (Copyright Elizabeth Martin.)

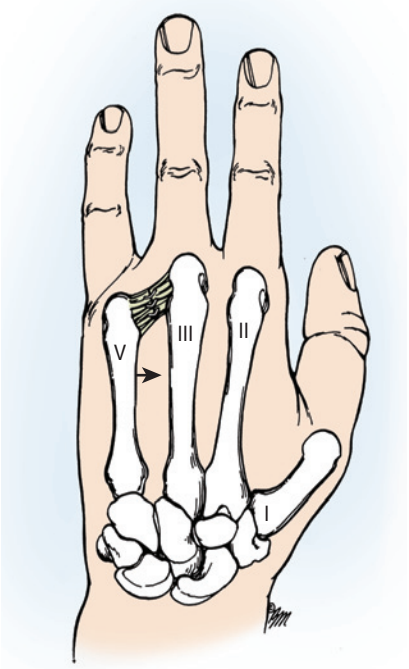

FIGURE 49.27 Suture of the deep intervolar plate ligaments with subsequent migration of the fifth metacarpal base radially across the hamate during complete ring finger ray amputation. The *arrow* indicates how the small finger metacarpal can slide on its hamate articulation toward the long finger metacarpal.

the underlying ulnar nerve and artery. The metacarpal base is elevated, and further dissection frees the metacarpal from its underlying bed. The lumbrical, second volar, and fourth dorsal interosseous tendons are divided. Dissection is carried out around the volar aspect of the amputation site, the digital vessels are identified and ligated, and the digital nerves are transected under tension at their most proximal portion. The flexor tendons are sharply divided under traction after incision of the palmar fascia. The DTIL is identified and appropriately transected close to the volar plate with careful preservation of the digital nerves. The palmar fascial attachments are incised, and the ray is removed.

As with the long finger, attention must be paid to wound closure to prevent malrotation and scissoring of the long and small fingers. The small finger is compressed to the long finger along its articulation with the hamate. The DTIL is imbricated in a pants-over-vest configuration with 3-0 nonabsorbable sutures (Figure 49.27). This should be done tightly because the repair will stretch. The digital nerves are either transposed dorsally into the interosseous space or sutured together in an end-to-end manner.[58] The palmar skin is closed and scissoring of the digits checked via wrist tenodesis. The dorsal structures are next closed. Skin dermadesis can exacerbate any malrotation caused by gap closure after ring finger ray deletion. The hand is inspected by passive range of motion of the fingers and wrist tenodesis to check for rotational deformity. Temporary transverse Kirschner wires can be placed between the long finger and small finger metacarpals. A splint is applied, and early digit range of motion is initiated. The Kirschner wires are removed after 4 to 6 weeks. Patients work on regaining active range of motion before strengthening is initiated (Figure 49.28).

FIGURE 49.28 Radial migration of the base of the small finger along the hamate after ring finger deletion.

Ring Finger Ray Amputation With Transposition of the Fifth Metacarpal

Given the risk of possible convergence of the long finger and small finger after ring finger ray resection,[37] as well as the risk of impaired mobility and the possibility of objects falling

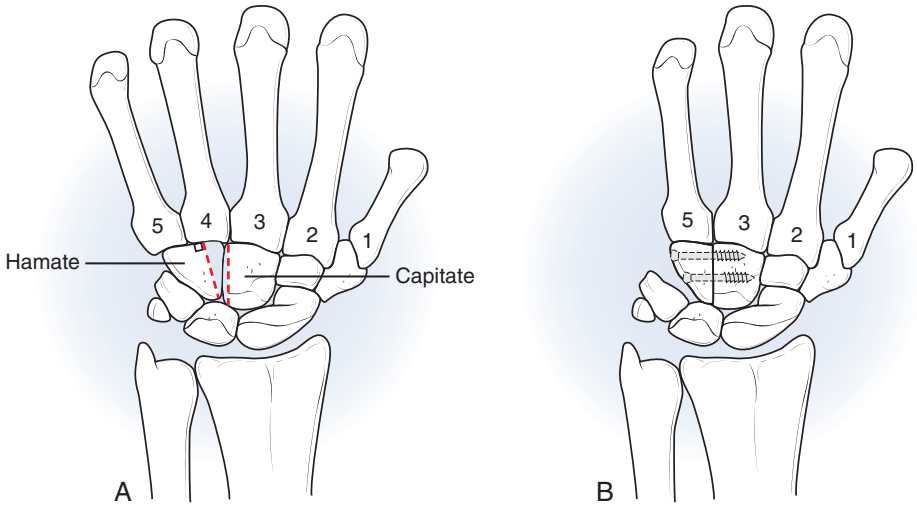

FIGURE 49.29 **A,** Osteotomy of the ulnar aspect of the capitate and radial side of the hamate. **B,** Capitohamate arthrodesis. The *red dotted line* indicates the margins of the osteotomy. (**B,** Redrawn from Le Viet D, Dailiana ZH: Third and fourth finger ray amputations by intracarpal osteotomy. *Tech Hand Up Extrem Surg* 3:110–115, 1999.)

through the space between the third and fifth rays, there are advocates for transposition of the small finger to the ring finger. Le Viet[90] described a technique that involved complete ring finger ray resection, an intracarpal wedge-shaped osteotomy, and a capitohamate arthrodesis for small finger translocation[90,91] (Figure 49.29). He proposed four main advantages: (1) convergence between the small finger and long finger is avoided, (2) the integrity of the ulnar side of the hand is maintained, (3) the fifth CMC joint is preserved, and (4) the action of the interossei is unchanged. In a series of 17 patients, 14 were satisfied with preservation of motion at the CMC joint. Complications included transient wrist pain that subsided after 6 weeks, 1 pseudoarthrosis, 1 transient case of carpal tunnel syndrome, and 7 cases of malrotation. The author acknowledged that there is a learning curve with this technique. Others have reported more favorable results and state that the technique is easier than metacarpal osteotomy.[42,97] Another concern of small finger transposition is that the finger will be shorter than the ring finger. To mitigate this issue, Posner[120a] described a step-cut osteotomy to add height to the small finger as it is transposed to the base of the ring finger metacarpal. The small finger metacarpal is cut at a more proximal level than the ring finger metacarpal and as such, can lengthen the small finger by 1.5 cm at the time of transposition (Figure 49.30). This lessened the discrepancy in length between the long finger and transposed small finger and resulted in satisfactory hand function and cosmesis.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Ring Finger Ray Amputation With Small Finger Ray Transposition

The technique is similar to that for index transposition to the long finger as previously described. A racket incision is made around the proximal phalangeal remnant of the ring finger (see Figure 49.26). The incision is extended dorsally between the ring finger and small finger metacarpals. Care is taken to identify and protect the dorsal sensory branches of the ulnar nerve as well as the extensor digitorum communis to the small finger, which may be small and mistaken for a junctura tendinum. The extensor digitorum communis tendon to the ring finger is transected proximally and reflected distally. After subperiosteal dissection, a transverse osteotomy is made through the metaphyseal flare with an oscillating saw. The metacarpal is freed distally, and the lumbrical and second volar and fourth dorsal interosseous tendons are divided. The volar extent of the dissection is carried out by identifying the neurovascular bundles, ligating the digital vessels, and transecting the digital nerves at the most proximal level possible under tension. The palmar fascia, flexor sheath, and flexor tendons are divided. The DTILs are identified and transected and the ray is excised. Dissection is carried out in subperiosteal fashion to allow an osteotomy through the base of the fifth metacarpal just distal to its metaphyseal flare. To enable transposition of the small finger, the origin of the fourth dorsal interosseous tendon is released from the fifth metacarpal.

The small finger metacarpal shaft is transposed onto the recipient site of the ring finger metacarpal base. The overall alignment of the digit in relation to the long finger metacarpal is checked and adjusted as needed before osteosynthesis is performed. Bone stabilization can be performed with a "T"-plate (the preferred technique, as discussed earlier) or two crossed Kirschner wires (Figure 49.31). Bone graft from the excised ring finger metacarpal can be used at the osteotomy site. The DTIL is imbricated in a pants-over-vest configuration with 3-0 nonabsorbable sutures (see Figure 49.27). This should be performed tightly because the repair will stretch. The digital nerves are either transposed dorsally into the interosseous space or sutured together in an end-to-end manner.[58] The wounds are closed in routine fashion, with care taken to fashion the interdigital commissure appropriately. Dry sterile dressings are applied after the tourniquet has been deflated. Postoperative management is similar to that described for long finger ray amputation with index finger transposition. Patients are immobilized in an intrinsic-plus splint for up to 4 to 6 weeks (depending on the method of fixation) to ensure healing of the osteotomy. The PIP joints are left free for active motion.

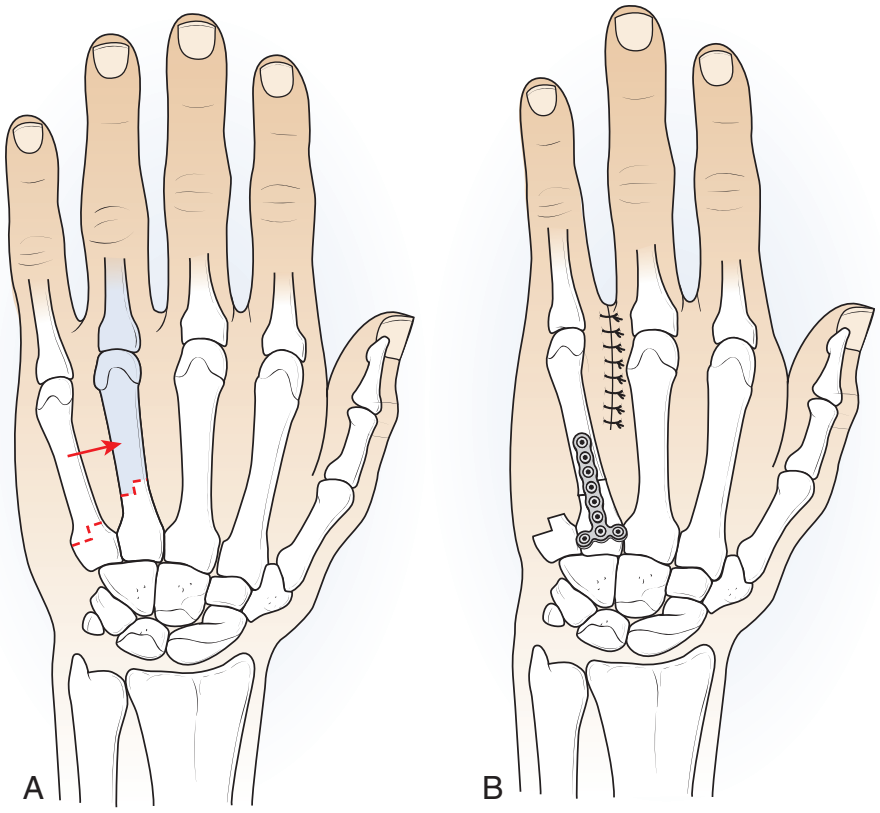

FIGURE 49.30 **A** and **B,** Step-cut osteotomy through the base ring finger metacarpal followed by transposition of the small finger. Note the approximation of the transposed small finger to the length of the amputated ring finger. The *red arrow* indicates the digit to be amputated, and the *red dotted line* indicates the level of the step-cut osteotomies within the ring and small finger metacarpals to ensure satisfactory length of the transposed digit.

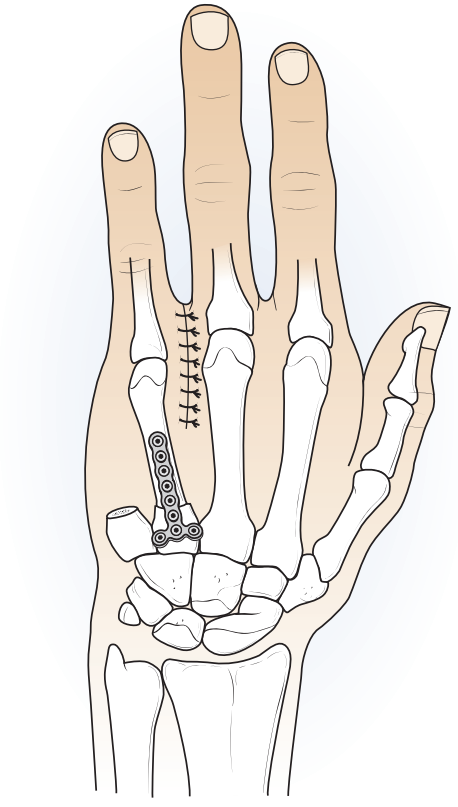

FIGURE 49.31 Small to ring finger transposition. Note osteosynthesis with two crossed Kirschner wires.

SMALL FINGER RAY AMPUTATION

The small finger plays an important role in digitopalmar grip because of the mobility of its CMC joint and the action of the hypothenar muscles.[110] It also increases the span of the hand for grasp owing to its abduction moment. These two facts have led some to believe that the small finger has the most functional value after the thumb.[143]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Small Finger Ray Amputation

For small finger ray amputation (Figure 49.32), a dorsal incision is fashioned over the small finger metacarpal and curved around the base of the proximal phalanx. Care is taken to ensure that the incision is not placed directly over the ulnar border of the hand to prevent scar sensitivity. After the dorsal skin is incised, care is taken to identify and protect the dorsal sensory branches of the ulnar nerve, which lie within the subcutaneous tissue. The extensor digitorum communis and extensor digiti minimi tendons to the small finger are transected proximally and reflected distally. Subperiosteal dissection is carried out around the base of the metacarpal, and an osteotomy is performed with a reciprocating saw at its metaphyseal flare, with care taken to protect the insertions of the extensor carpi ulnaris and flexor carpi ulnaris tendons (Figure 49.33). The metacarpal is reflected distally, and the conjoined tendon of the abductor digiti minimi and flexor digiti minimi is divided distally, as well as the third volar interosseous and lumbrical tendons. Attention is next diverted to the palmar side. The digital vessels are ligated and

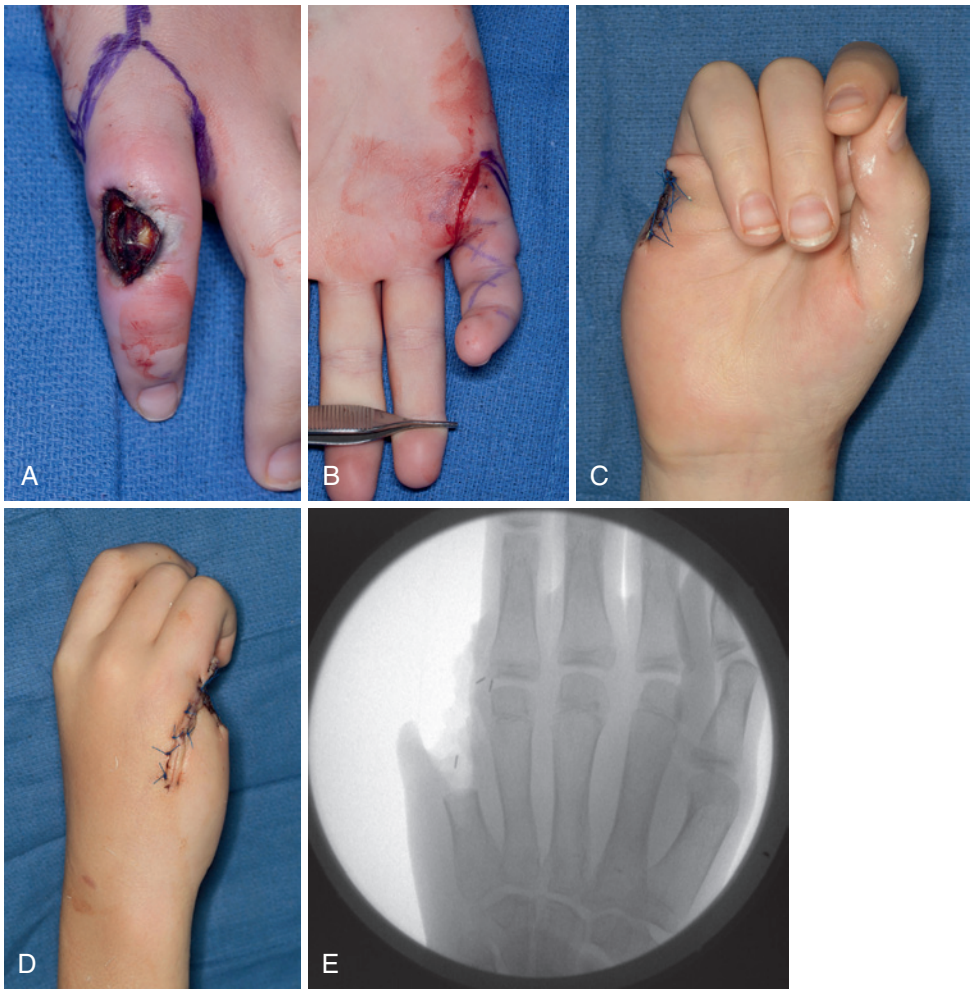

FIGURE 49.32 A 13-year-old boy with acute lymphocytic leukemia who underwent small finger ray amputation for rapidly disseminating mucormycosis infection from the small finger. **A,** Necrotic mucormycosis infection. **B,** Palmar incision. **C,** Postoperative volar view. **D,** Postoperative dorsal view. **E,** Postoperative fluoroscopic view.

the digital nerves divided proximally in the wound. They can either be transposed later into the interosseous space to protect them from direct trauma or sutured directly to each other in an end-to-end manner. The extrinsic flexor tendons are transected under tension, and the DTIL is transected between the ring and small fingers. The hypothenar muscles are not sutured to the fourth interossei and are used to fill the remaining defect, providing satisfactory cushioning to the digital nerves and ulnar side of the hand. It is not advisable to reattach the hypothenar muscles to the tendon of the fourth dorsal interosseous, because this is unnecessary and the results are unpredictable. The tourniquet is deflated, hemostasis is obtained, and the skin incision is closed. The hand is placed into a bulky dressing, and the patient is encouraged to begin early active range-of-motion exercises for all remaining digits.

CRITICAL POINTS *Ray Amputations*

- Although single-ray amputation of the index, long, ring, or small finger affects the biomechanics of the hand, it does not result in substantial loss of hand function.
- An acute ray amputation following trauma should be performed sparingly because most ray amputations are performed as secondary procedures.
- Ray amputations can improve the appearance of the hand.
- Skin incisions should be planned to prevent a web space contracture.
- Ray resections without transposition are preferred to avoid complications such as nonunion and to minimize postoperative immobilization.
- Vigilance during soft tissue closure is necessary to avoid scissoring of the neighboring.
- Amputation of the small finger ray requires preservation of the metacarpal base to protect the insertion of the flexor and extensor carpi ulnaris tendons.

MULTIPLE-DIGIT AMPUTATIONS

Amputations that involved multiple digits may be needed following mechanical trauma, infection, hypothermia, or vascular disturbances. The incidence is about 3 to 6 times greater in men than in women and is 4.9 times greater in left-handed than in right-handed individuals.[8,35,141] The basic principle in such situations is to save all viable tissue by whatever means appropriate and to preserve the tissue for possible reconstruction at a later date.[31] Amputation of the thumb is associated with substantial disability because the thumb provides over 40% of the function in the hand. Thus, all attempts are made to replant or salvage the thumb. If the thumb is deemed nonreplantable, Soucacos

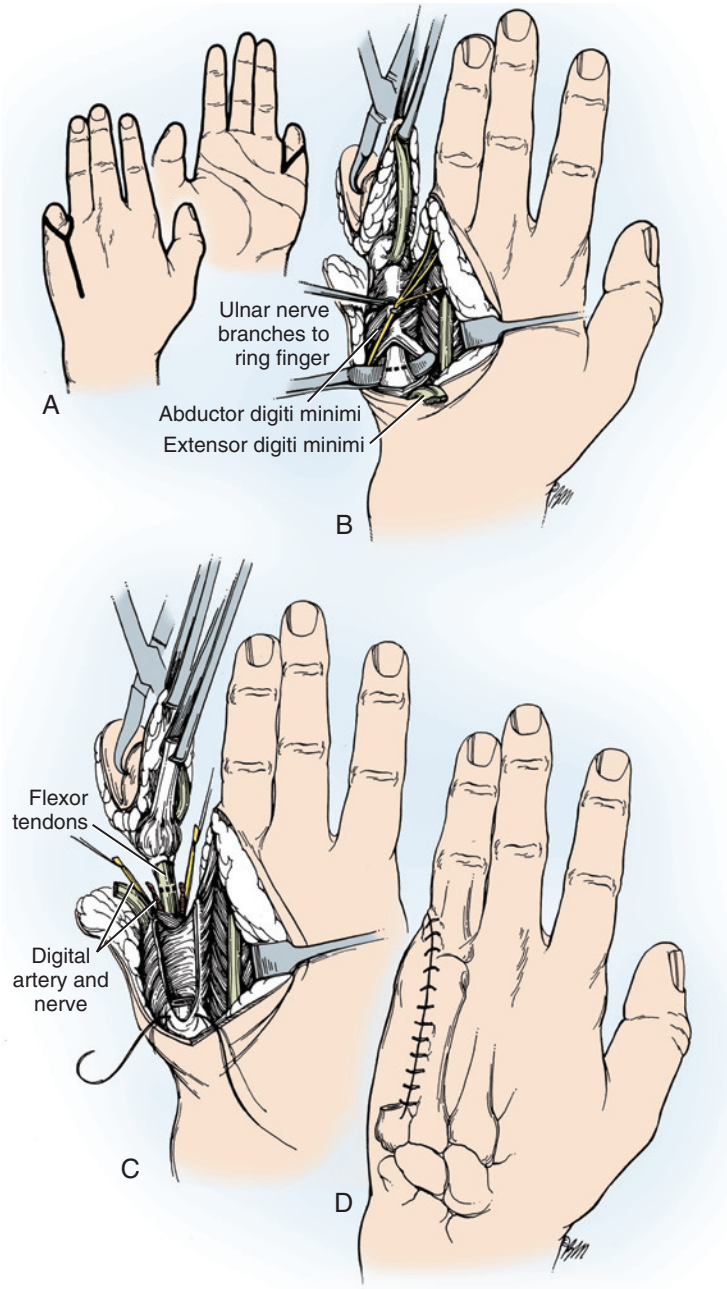

FIGURE 49.33 Ray amputation of the small finger is accomplished by transection of the metacarpal at its base, with the hypothenar muscles preserved to serve as an ulnar pad for the hand. **A,** Preoperative skin markings. **B,** Planned osteotomy site of the small finger metacarpal base, distal to the flexor carpi ulnaris and the extensor carpi ulnaris insertions. **C,** Removal of small finger metacarpal. **D,** Wound closure. FIGURE 49.34 Long and ring finger ray amputation in a 59-year-old patient with soft tissue sarcoma of the hand. **A,** Palmar view of long and ring finger ray amputation with maintenance of the superficial palmar arch. **B,** Radialization of the small finger metacarpal on its articulation with the hamate.

and colleagues[134a] advocated transpositional digital microsurgery, in which the least damaged digit is replanted to the injured thumb. Preservation of a sensate thumb and another digit allows basic opposition pinch, and the addition of a third digit further improves chuck pinch, hook grip, and power grasp.[33,110,125] This concept was emphasized by Rose and Buncke[125] when they performed selective replantation in four patients with multiple-digit amputations. The least traumatized digits were replanted to the more ulnar metacarpal rays, and this resulted in a wider hand span for grasp, improved precision handling, and better chuck pinch. Additional digits may be added by microvascular toe transfer.[57,148] Gordon and coworkers[57] reported on double microsurgical toe transfers for reconstruction of the thumb and an ulnar ray or, when the thumb was present, two-finger reconstructions with bilateral second toe transfers. Patients reported improvement in hand function, with an average of more than 9 pounds of pinch using the transplanted toes. None of the patients reported difficulties with activities of daily living, although the majority did experience symptoms of cold intolerance.

Partial hand amputations may be necessary for the treatment of malignant tumors[106] (Figure 49.34). The tumor surgeon must balance the importance of obtaining negative surgical margins, which is associated with improved survival rates, and the preservation of critical structures that are important for hand function. Puhaindran and Athanasian and colleagues[121-123] reported on eight patients with soft tissue sarcomas of the hand who underwent partial hand resection followed by postoperative radiotherapy. Six of the eight patients were disease-free and had

a mean Musculoskeletal Tumor Society score of 26 (range, 19 to 29). (The score is based on a functional outcome scoring system of 0 to 5 points for six domains: pain, function, emotion, hand positioning, dexterity, and lifting ability. The higher the score, the better the function.) Patients who had undergone double-ray amputations (index finger and long finger or ring finger and small finger) had lower functional outcome scores. In their series of double-ray amputations, four of five patients with high-grade soft tissue sarcomas of the hand were disease-free and the mean grip strength was 24% of the contralateral hand. Notwithstanding this weakness, patients maintained good key, tip, and tripod pinch when the deep motor branch of the ulnar nerve was preserved.

CRITICAL POINTS *Multiple-Digit Amputations*

- Early surgical management in the mutilated hand involves sharp débridement of contaminated tissue, maintenance of as much digit length as possible, and preservation of all viable tissue for later reconstruction.
- All attempts should be made to preserve thumb function.
- Preservation of an additional digit will result in basic opposition pinch, and the addition of a third digit will improve chuck pinch, hook grip, and power grasp.

AMPUTATIONS THROUGH THE CARPUS

Amputations through the carpus require special consideration. Coverage may be possible with local or distant skin, but the intrinsic musculature is absent (Figure 49.35) and the patient is incapable of pinching and grasping. Preservation of the distal radioulnar joint (DRUJ) and the triangular fibrocartilage complex (TFCC) maintains forearm rotation. One of the concerns about keeping the carpus is the added length to the arm following prosthetic fitting. This may initially create a dilemma for both the patient and surgeon. More proximal amputation and fitting with a conventional prosthesis are alternative considerations, especially in terms of early functional rehabilitation. However, at the time of the initial traumatic event, the injured patient is incapable of making a decision such as this. Therefore, it is preferable to save what is salvageable and allow time for the patient to make a decision after having an opportunity to evaluate the alternatives. In addition, the preservation of some wrist movement is beneficial as the patient hooks objects between the forearm and carpus.

WRIST DISARTICULATION

As with a transcarpal amputation, one of the main advantages of a wrist disarticulation is preservation of the DRUJ and forearm rotation. Preserving the length of the forearm and the metaphyseal flare of the distal radius aids in prosthetic suspension. Despite these advantages, prosthetists argue that fitting may be more challenging than for transradial amputees because conventional prostheses may be too long, the prominence of the radial and ulnar styloids can lead to pressure necrosis, and myoelectric fitting is more difficult. This was highlighted by Wright and colleagues[153] in their review of prosthetic usage in patients with upper extremity amputations. The authors found a 94% utilization rate in patients with a below-elbow amputation compared with only 54% in those with a wrist disarticulation. One of the main reasons for the lower utilization rate could be the added length of the forearm in patients with a wrist disarticulation who can use the stump for object manipulation. In addition, by maintaining its sensibility, the stump may be more useful than an insensate prosthesis. Other factors linked to poor utilization of prosthetics include the type of device, late fitting, the cost of repairs, and the perceived limited functionality of the device.[7,16,40]

With improvements in prosthetic technology, preoperative consultation with the local prosthetist regarding the preferred level may be worthwhile. Hand transplantation is an option in the future and should be a part of the decision as to whether to shorten the residual limb to accommodate a prosthesis. Whenever possible, the patient, after weighing all of the medical information, should have the final decision about choosing a long transradial amputation or a wrist disarticulation.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Wrist Disarticulation

After satisfactory regional or general anesthesia, the limb is exsanguinated using an Esmarch wrap and the tourniquet inflated. If the surgical indication is infection or tumor, the arm is elevated and drained using gravity exsanguination and digital occlusion of the brachial artery. If possible, skin flaps are marked and raised at a level distal to the DRUJ such that the palmar flap is longer and the dorsal flap shorter for closure over the amputation stump (Figure 49.36). Once the skin has been incised, flaps are raised in a proximal direction and all veins ligated (Figure 49.37). My preference is to start on the dorsal surface and identify all the appropriate nerves, vessels, and tendons. The superficial branch of the radial nerve and the dorsal sensory branch of the ulnar nerve are dissected and divided under traction. Care is taken to ensure that they adequately retract in a proximal direction away from the amputation stump to minimize the chance of symptomatic neuroma. The posterior interosseous neurovascular bundle is identified and divided using electrocautery. The extensor tendons are divided at their resting physiologic tension and fixed to the distal radius. This has two main purposes: (1) Contraction of the extensor muscles can be used to drive a myoelectric prosthesis, and (2) the tendons are readily accessible if the patient becomes a candidate for hand transplantation. Attention then focuses on the palmar surface, where the medial antebrachial cutaneous, median, and ulnar nerves and the anterior interosseous neurovascular bundles are divided in a similar manner. An alternative method was described by Louis and colleagues,[95] whereby a separate longitudinal incision was made between the pronator teres and brachioradialis just distal to the elbow flexion crease to doubly ligate the median, ulnar, and superficial radial nerves at this region. This causes a neuroma-in-continuity to form at this site, and these neuromas are buried beneath the proximal muscles, where they are less likely to be symptomatic. The authors noted they did not find it necessary to ligate the antebrachial cutaneous nerves in the proximal forearm. The radial, ulnar, and median arteries (when present) are doubly ligated proximal to the wrist. After transection of the vessels, flexor tendons are secured to the distal radius in a fashion similar to that for the extensor tendons. Wrist disarticulation is performed through a transverse dorsal incision of the radiocarpal joint that gives visual access to the radiocarpal joint. By identifying and

CASE STUDY 49.1

A 15-year-old right-hand-dominant boy sustains a table saw injury to his left hand at school. Examination demonstrates dorsal degloving injuries to the index, long, and ring fingers through the proximal phalanges, with bone loss (eFigures 49.1 to 49.4).

Given the extent of the injury and the fact that the digits are not replantable, the patient is taken to the operating room emergently for revision amputation of the injured digits and wound closure using the palmar skin to maintain proximal phalangeal length. To improve flexion of the preserved metacarpophalangeal joints, the flexor digitorum superficialis tendons of the injured digits are tenodesed to the proximal phalanx (eFigures 49.5 to 49.8).

The patient's wounds heal without complications (eFigure 49.9 and Video 49.1). The treatment options now are observation (the thumb and small finger and span of the hand have been retained), prosthetic fitting, or toe-to-hand transfer.

The patient elects to use a prosthesis, and he meets with the prosthetist within 4 weeks of amputation for early fitting. He is fitted with iLimb digits (eFigure 49.10) to enable a full hand grasp around power tools and prevent toggling.

In addition, he receives a passive mechanical device for heavy-duty use (eFigure 49.11) and a passive silicone partial hand device to use in social settings (eFigure 49.12).

protecting the distal radioulnar ligaments as well as the TFCC, the radiocarpal and ulnocarpal ligaments are divided, allowing amputation of the hand with the carpus. The prominent ulnar and radial styloid processes must be rounded off with a rasp to ensure they do not cause pressure necrosis at the wound edges. The skin flaps are fashioned to eliminate redundancy. The tourniquet is deflated, hemostasis is obtained, and the subcutaneous tissue and skin are closed in layers. A suction drain is used as necessary. A soft dressing is applied with compression in a distal-to-proximal direction to prevent edema. The patient is seen at 2 weeks following operation for suture removal and referral to the amputation team for prosthetic fitting.

HAND PROSTHETICS

Improvement of hand function after multiple-digital amputation can be provided by modern-day prosthetics. Early prosthetic fitting of the upper extremity amputee has many advocates. Biddiss and Chau[17] noted that when fitted within 6 months of an amputation, patients were 16 times more likely

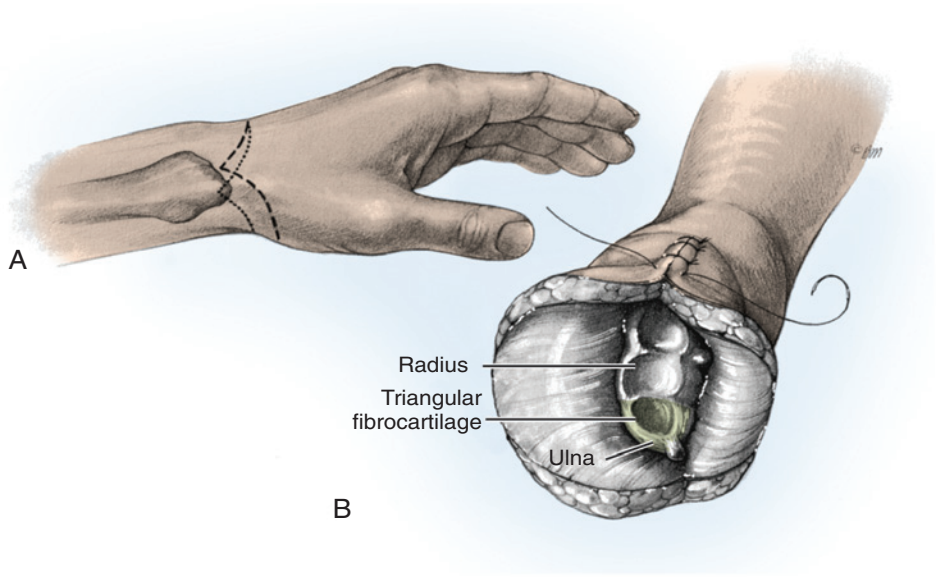

FIGURE 49.36 Wrist disarticulation. With modern prosthetic techniques, this is a very functional level of amputation. Care must be taken in the course of the operation to preserve the distal radioulnar joint ligaments and the triangular fibrocartilage complex to maintain distal radioulnar joint stability. **A,** Skin markings demonstrating fishmouth incision. **B,** Wrist disarticulation.

to continue using the prosthesis. In contrast to patients with lower extremity amputations, in whom vascular insufficiency and problems with wound healing are major concerns, most upper extremity amputees have excellent vascularity in the amputation stumps and are much less prone to wound breakdown and other wound-healing complications. The major advantage of the application of modified upper extremity prostheses in the early postsurgical period is the early performance of bimanual activities. In addition, early prosthetic fitting allows for patient education in prosthetic use during the wound-healing phase and thus shortens the period of morbidity and hastens functional rehabilitation. Prosthetic fitting improves patients' ability to perform many activities of daily living, such as hygiene and dressing, and enhances their self-esteem.

When deciding on the type of prosthesis, the use of a trial device can help determine whether it will meet the needs and expectations of the patient. Factored into the decision are variables such as age, gender, profession, patient motivation, and unilateral versus bilateral involvement. The level of amputation plays an important role in prosthetic fitting. The thumb, for example, affects 40% of hand function, and any type of device should afford length, stability, and opposition.[145] Preserved sensation is an important determinant of thumb function because a partially amputated thumb with preserved sensory function may be more useful than one that is insensate but of normal length. A custom-made thumb prosthesis may restore length but can impede function due to a lack of sensation, especially when the other digits have been treated with a prosthesis. In these cases, procedures such as distraction osteogenesis, web space deepening, pollicization, or microsurgical toe transfer may be more beneficial in providing a functional thumb.[114,118]

Types of Prostheses

There are four main types of partial hand prostheses: *passive devices, opposition posts, body-powered designs,* and *externally powered designs*. Passive devices are high-definition silicone prostheses that provide the most aesthetically pleasing appearance of the hand and thereby have an important psychological benefit for the patient's body image. The color tone and skin creases are matched with those of the recipient's hand (Figure 49.38). A nail is applied to the digital prosthesis. The prosthesis can be designed to fit all levels of injury from the fingertip to a complete hand. In addition to improving the overall appearance of the hand, this passive prosthesis can protect areas of hypersensitivity and also serve as a post for stability with other functioning digits.

Opposition posts are used in patients who are missing a thumb but have all the other digits. They add length and can help hold objects with the remaining functioning digits. Most are rigid, but advancements in the development of articulating hinges have allowed the joints to be manually positioned for task-specific activities.

Body-powered prostheses use movement from a more proximal joint to drive distal function by means of a harness and cables. They claim improved sensory feedback from the cable system and tend to be relatively durable, yet are limited with respect to their range of motion and prehensile strength. Traditional body-powered prostheses had a terminal hook voluntary opening or closing device (Figure 49.39); newer examples include the X-finger (Didrick Medical, Naples, FL) and M-finger

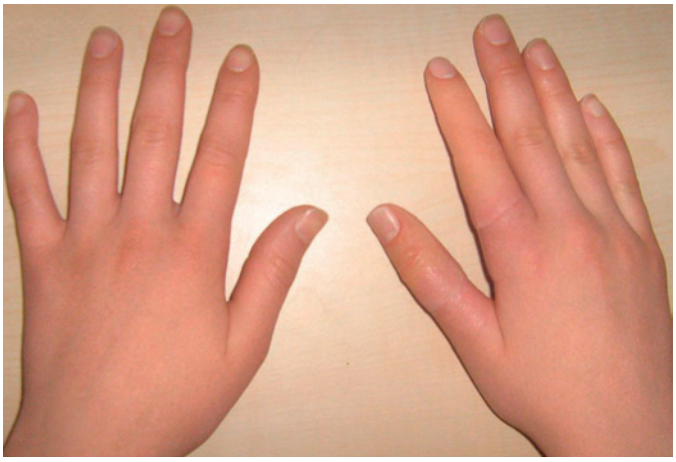

FIGURE 49.38 Silicone prosthetic replacement of amputated right thumb and index finger. Note the aesthetic appearance compared with the other digits. (Liberating Technologies, Holliston, MA) (Figure 49.40, *A* and *B*). The latter uses a cable system where wrist flexion causes prosthetic finger flexion at the MP and PIP joints (the DIP joint is fixed). For patients with partial digital amputation, power from the native MP joint can drive prosthetic PIP joint flexion by means of a cable from the dorsal side of the MP joint to the volar side of the prosthetic PIP joint. As such, this prosthesis allows for independent finger motion to improve the dexterity of the hand.

With advancements in modern-day biomaterials and engineering, there have been considerable improvements in *externally powered prostheses* for the hand.[157] The devices are now lighter, more functional, and more durable than ever before. The prosthetic hands have mobile joints and individually powered fingers that can perform power gripping, tip and key pinching, and three-point chuck gripping. They currently fall into two main categories: *single-grasp, three-digit hands* and

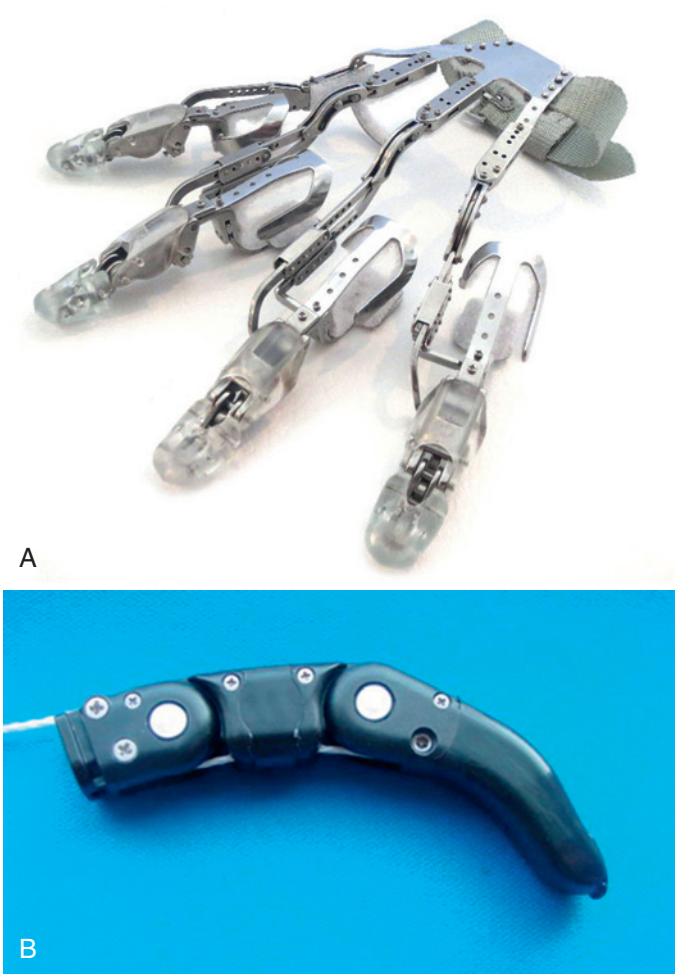

FIGURE 49.40 **A,** Use of the X-finger for partial digital amputations. **B,** The M-finger uses a cable device system where wrist motion causes flexion of the prosthetic finger. multigrasp anthropomorphic hands (Figure 49.41 and Tables 49.1 and 49.2).[15] Although the former are often easier to control, lighter in weight, and more affordable than their more advanced counterparts, they are also more limited in function because they are able to form only a single, rigid grasp. Examples of the multigrasp anthropomorphic hands include the iLIMB (Touch Bionics, Mansfield, MA) and the Michelangelo hand (Ottobock, Minneapolis, MN). The iLIMB has a thumb and independently powered fingers. The thumb must be positioned manually to the required position. The Michelangelo hand is similar to the iLIMB prosthetic hand, except that it has its own independently powered thumb, obviating the need for manual positioning. The Contineo MultiGrasp hand (Orthocare Innovations, Oklahoma City, OK) was developed in the Revolutionizing Prosthetics program of the Defense Advanced Research Projects Agency and offers powered thumb abduction and adduction. More recently, a research team at the Mayo Clinic in Rochester, MN, has been working with collaborators in Italy and Arizona to transform a robotic Softhand from a heavy, wall-powered, tethered device to a lighter, battery-powered device that weighs about as much as commercially available prosthetic arms. The SoftHand prosthetic component (SoftHand Pro) (Figure 49.42) is portable, compatible, and patient friendly. The long-term objectives of this study are to design and build a low-cost, high-performance prosthetic hand that will allow patients who have undergone amputation to perform a wider range of daily tasks than they currently are able to with commercially available prostheses. Early evaluation of the SoftHand Pro shows that it holds great promise. Current multifunctional prosthetic hands are not robust enough to withstand the functional demands of many users and are often prohibitively expensive. The SoftHand Pro attempts to address some of these issues with innovative solutions. Stein and Walley compared patients who had undergone amputation of one upper extremity limb and were using a body-powered cable hook device, a myoelectric hand, and a normal remaining hand. Patients with the hook device tended to wear the prosthesis longer (14 hours versus 9.6 hours) and could complete functional tasks twice as fast as patients with a myoelectric hand. Despite this, patients with myoelectric devices preferred the function, range of motion, and aesthetic appearance to those of conventional body-powered prostheses.

Myoelectric fingers, such as the ProDigits (Optimus Prosthetics, Columbus, OH), Vincent fingers (Vincent Systems, Karlsruhe, Germany), and iLIMB (Figure 49.43), have a power supply and a series of linked motors and struts that drive finger motion. For cosmesis, the myoelectric fingers can be covered with a material that resembles natural skin (Livingskin, Touch Bionics, Hilliard, OH). They can be driven by myoelectric activity via surface electrodes placed on the remaining musculature. These myoelectric control sites can be within the hand or forearm. Commonly used muscles of the hand include the thenar, hypothenar, and dorsal interossei; there is the advantage of allowing individual finger function independent of wrist motion.[145] In the absence of a myoelectric signal, small switches can be incorporated within the device to activate the digit. Because each finger is self-contained, a variety of digital amputations can be accommodated, and the device can provide up to 30 pounds of grip strength, as compared with 8 pounds with the body-powered devices. Despite these advantages, the motors and batteries add weight and cost to the device. To improve the ability of the prosthesis to perform the ever-increasing complexity of hand movements, the number of myoelectric sensor points needs to increase.[157] To accomplish this goal, one can reroute selected transected nerves (that may go on to form neuromas) to provide signals to nonfunctional muscles. This targeted reinnervation causes the muscle to act as a biologic amplifier of residual nerve signals and, therefore, to develop proprioception from the transferred nerve with the overlying skin acquiring its sensory territory. These areas can produce surface myoelectric impulses used to control prosthetic devices. For example, a muscle signal using the ulnar nerve transfer site can be used to control finger motion within the prosthetic hand.[112,128,157] Targeted reinnervation for motor control is called *targeted muscle reinnervation* and tends to be used in patients with more proximal amputations, such as for shoulder disarticulation and at the transhumeral level.[27]

Another area of research for prosthetic control has focused on the use of direct brain wave control.[39] Cerebral control of a prosthetic device has the major advantage of being independent of the peripheral nervous system within the residual limb, which may be damaged or nonfunctioning. Da Paz and Braga[39]

FIGURE 49.41 Types of myoelectric hands. **A,** Vincent hand (Vincent Systems, Karlsruhe, Germany). **B,** iLimb hand by Touch Bionics (Hilliard, OH). **C,** iLimb Pulse (Touch Bionics). **D,** Bebionic hand (RSL Steeper, Leeds, UK). **E,** Bebionic hand version 2 (RSL Steeper). **F,** Michelangelo hand (Ottobock, Minneapolis, MN). (Used with permission from Belter JT, Segil JL, Dollar AM, et al: Mechanical design and performance specifications of anthropomorphic prosthetic hands: a review. *J Rehabil Res Dev* 50(5):599–618, 2013, Figure 1.)

used functional magnetic resonance images of the brain to study the relationship between cerebral activation and control of a myoelectric prosthetic hand. They noted similar activation in the areas of the brain that controlled prosthetic and contralateral hand function, suggesting that it may be possible to control myoelectric devices through cortical regulation.

Hopper and colleagues[71a] studied the use of digital prostheses in workers' compensation cases and noted that 28% of patients did not use or seldom used the prosthesis (low use) and only 24% used it for more than 4 hours a day (high use). Those in the former group included male patients, patients with stump complications such as cold intolerance, patients with hypersensitivity and pain, and patients with amputations at the more distal digital level. Those with a ring finger or thumb prosthesis reported the least use. Patients who tended to wear the prosthesis were workers who did not do manual labor and had either an index finger or a small finger injury. Women were more likely to continue wearing the prosthesis than men over the long term. Lifchez and coworkers[94b] noticed an improvement in hand function in patients with multiple-digit amputations who used their prostheses. Ten patients who had undergone amputation of two or more fingers proximal to the DIP joint were given a series of hand function tests. Patients reported using their prostheses on an average of 4.3 days a week for over 7 hours a day. Five of the nine employed patients returned to their preinjury occupations. When patients used the device, they had increased tip pinch, lateral pinch, and grip strength and better function in activities of daily living. Burger and colleagues[24] investigated whether patients with a partial hand amputation were able to return to their previous occupations and whether they used their silicone prostheses. The index finger was most commonly affected, and most fingers were amputated through the middle phalanx or PIP joint. Less than 50% of patients were able to return to the same job. Those involved in nonmanual labor and those who had undergone amputation of only one finger had a better chance of keeping the same job. None of the patients with amputation of three or more fingers were able to keep their previous jobs. The greatest loss and functional impairment were caused by partial or complete thumb amputation. Less than a third of patients used the prosthesis at work, and, on average, they wore it 5.3 hours a day (women tended to wear it longer than men, for 7 hours versus 3.5 hours). Loss of tip sensibility while using the prosthesis was the main cause for lack of usage at work.

TABLE 49.1 Published General Characteristics of Commercial Prosthetic Hands

Hand	Developer	Weight (g)	Overall Size	Number of Joints	Degrees of Freedom	Number of Actuators	Actuation Method	Joint Coupling Method	Adaptive Grip

FIGURE 49.43 A 28-year-old patient who underwent revision amputations of his digits for frostbite. On the left hand **(A** to **D)**, he has been fitted with the iLIMB myoelectrically controlled prosthetic device, which allows complete grasp, precision pinch, and up to 12 different grip patterns. The ideal level for use of this partial hand prosthesis is at the metacarpophalangeal joint or more proximally through the palm to allow for room for the iLIMB digits to be mounted at the amputation site and provide function and an acceptable aesthetic appearance. The device is controlled by two surface-mounted electrodes next to the skin, inside the prosthetic socket. The patient is retaught to activate the muscles with proportional control, to make the hand open and close at the desired speed and with the intended force. On the right side **(E** to **G)**, the amputated digits had greater residual length; if an iLIMB prosthesis had fit, it would have made the fingers excessively long, so that it would have been difficult for the patient to touch his digits to the thumb and have good grasp function. As a result, he was fitted with a passive prosthetic device. The passive digits are positioned manually to help enable full passive grasp or thumb-to-forefinger prehension. The patient opens and closes the device using the proximal phalanges inside it. The wrist strap holds the prosthesis in place and allows the user to lift heavy objects. (Courtesy of Brandon Sampson.)

One of the main problems with modern-day prosthetics is that they do not provide sensory feedback to the user. In addition, the socket can lead to skin breakdown, excessive sweating, and restriction of movement.[78] In an effort to mitigate this problem, *osseointegrated prostheses* have been devised with varied success.[78,96,99] This involves a two-stage procedure in which an implant is placed into a bony stump, followed by attachment of a prosthesis (Figure 49.44). Advocates argue that tactile perception is improved and socket problems are fewer. Lundborg and colleagues[96] reported on three patients who underwent placement of a titanium-based osseointegrated prosthesis for traumatic amputation at the thumb MP joint. After 3 months, they noted that the fixture was stable enough within the proximal phalanx to allow attachment of the thumb prosthesis. They noted no signs of implant loosening and postulated that the improvement in tactile discrimination was secondary to transfer of pressure to the endosteal nerves within the bone. Similar results were reported by Manurangsee and colleagues[99] in the treatment of index and long finger amputations at the base of the proximal phalanges but with bone of at least 1.5 cm in length remaining to accommodate the implant. All patients reported improvements in grip strength, hand function, and deep sensation, with minimal wound complications. In trying to decide which patients may benefit from this treatment modality, Jönsson and associates[77] highlighted four main criteria: (1) The bone quality and length of the stump were sufficient to accommodate the implant; (2) the patient could not be fitted with a standard prosthesis or had a history of socket complications; (3) the patient did not have a history of immunosuppression; and (4) the patient was highly motivated. The authors reported on 10 thumbs and 1 partial hand reconstruction. Overall, patients reported improvements in function and quality of life. Complications included one infection that required removal of the implant and two loose implants.

FIGURE 49.44 This figure shows the concept of an osseointegrated prosthesis. (Reprinted from Manurangsee P, Isariyawut C, Chatuthong V, et al: Osseointegrated finger prosthesis: an alternative method for finger reconstruction. *J Hand Surg [Am]* 25:86–92, 2000, Figure 1C, p 88.)

CRITICAL POINTS *Hand Prostheses*

- Early prosthetic fitting (within 30 days) is recommended with the aid of a multidisciplinary team to improve acceptance and use.
- When deciding on the type of prosthesis, patient-specific variables need to be considered and more than one type of device may be necessary to meet patient needs.
- With improvements in technology, modern-day prosthetics have the potential to be as functional as the digit that was amputated.
- Development of a prosthesis with improved sensory feedback may increase rates of adoption.

REHABILITATION PROCESS OF THE HAND AMPUTEE

Successful rehabilitation of the amputee requires the input of a comprehensive multidisciplinary team. The members of the team should include the surgeon to provide surgical expertise, occupational therapist to provide rehabilitation, prosthetist to fabricate upper extremity devices, psychiatrist for psychological support, and pain management specialists to administer the appropriate analgesia; equally as important are other upper extremity amputees, who can provide camaraderie. A support network of amputees is vitally important for the recently injured patient undergoing various psychological stressors that can lead to low self-esteem, disability, denial, and a low rate of prosthetic use.[7,16,17,153] The Amputee Coalition of America provides important information and support.

The rehabilitation process has four stages that may overlap to ensure maximum recovery of the patient. These include the *postsurgical stage, preprosthetic training stage, basic prosthetic stage,* and *advanced functional training stage*. The goal is to provide the patient with the necessary physical and psychological skills to meet functional goals and requirements.[124,133] Many of these principles have come from the experiences gained through the management and rehabilitation of patients in the Veterans Affairs Agency and the Defense Advanced Research Projects Agency.

The *acute postsurgical phase* lasts from the time of surgery until all wounds have healed. During this period, emphasis is placed on achieving a stable wound, edema control, desensitization, scar management, and pain control. Depending on the nature of the wound, serial débridement may be needed if the wound has been heavily contaminated or has substantial tissue damage. Once the wound has been definitively closed, occupational therapists focus on controlling edema by using distal-to-proximal compression wrapping followed by silicone sleeves that provide continuous compression and also aid in minimizing scar formation.[124,133] These dressings also help with the desensitization process, which advances to massage and the use of texture devices as the scar matures. During this time, the therapist also works on the range of motion of adjacent joints to minimize the development of joint contractures. Training in activities of daily living such as feeding and hygiene is encouraged by means of custom adaptive aids as needed. During this period, patients can have residual or phantom limb pain. In a study by Jensen and colleagues,[76a] 57% of patients had stump pain 8 days after surgery, and it lasted for up to 2 years in 21% of patients. Involvement of a pain specialist may be necessary if symptoms do not resolve within the first few weeks after surgery. Within the immediate postoperative period, a patient-controlled analgesia pump can be used or an indwelling catheter can be placed. As medications are weaned, the patient can be given long-acting opioids and then transitioned to short-acting medications, such as short-acting opioids, nonsteroidal antiinflammatory medications, anticonvulsants, or tricyclic antidepressants. Other modalities such as transcutaneous electrical nerve stimulation (TENS) and thermal treatments can improve pain control because they have a synergistic effect with other pharmacologic and psychological interventions.[108]

The provision of psychological support, through work with trained psychologists and psychiatrists as well as family members, is started early in the rehabilitation process to ease patient fears and promote independence. These issues are gaining increasing scrutiny because early therapeutic regimens can reduce medical bills, disability payments, loss of income, and mental health costs. Psychological stress can be triggered by the sudden and unexpected nature of the injury, the alien hospital environment, fear of loss of bodily function, helplessness, and humiliation.[108] Early in the recovery process, many patients experience symptoms suggestive of posttraumatic stress disorder. Grunert and colleagues[62] showed that up to 94% of patients suffered from flashbacks, nightmares, poor concentration, cosmetic concerns, and the fear of death within 2 months of their injuries. Given that these symptoms can persist for up to 6 months after injury,[61] patients, as well as family members, require psychological support as early as 3 days after injury, and it may continue throughout the rehabilitation. The hand surgeon can play an important role in the promotion of a healthy adjustment to the injury because he or she is often the

first health care professional involved with the patient.[105] A positive preoperative and postoperative relationship with the surgeon can result in improved patient compliance, satisfaction, and recovery.[104]

Psychological adjustment during recovery from devastating hand injuries has three interlinked phases.[14,60] *Functional acceptance* is the process whereby the patient comes to terms with his or her altered form. This is dependent on several factors, such as the patient's motivation, nature of the injury, and type of functional disability. The next phase is acceptance of the *aesthetic appearance* of the hand and is affected by age, gender, underlying personality, and perception of how others see the hand. Early involvement with prosthetists can be important in improving the patient's cosmetic concerns following a mutilating hand injury. The final stage of adjustment is related to the *emotional acceptance of the injury*. This is characterized as the time necessary for the patient to accept the loss of a finger, hand, or other body part. This stage has a variable length related to numerous prognostic factors such as occupation, personal and family relationships, feeling of self-guilt as a cause of the injury, previous history of mental health issues, whether the injury is work related, severity of the injury, and whether there has been early or delayed psychological therapeutic intervention.[60]

Therapeutic modalities include pharmacotherapy such as tricyclic antidepressants, monoamine oxidase and selective serotonin reuptake inhibitors, and psychotherapy. The latter includes cognitive behavioral therapy (e.g., systematic desensitization, graded exposure) and management of life skills, such as relaxation therapy, anger control, and cognitive restructuring to address pain, anxiety, and depression.[105] Weis and colleagues[149a] investigated the efficacy of imaginal exposure, a form of cognitive behavioral therapy, when given early (within 30 to 60 days) or later (after more than 120 days) following a severe work-related injury. The authors noted that the therapy had a beneficial effect on symptom reduction in the early treatment group, so that fewer therapeutic sessions were required than in the group for whom treatment was delayed. Eighty-three percent of patients were able to return to work after 6 months. Despite receiving psychological therapy, the remaining 17% who did not return to work still cited psychological distress rather than physical disability as the main reason for not returning.

During the 2 to 3 weeks after definitive surgical management, the *preprosthetic phase* occurs, in which time is spent readying the patient to accept a prosthesis. This coincides with the "golden window" for upper limb prosthetic fitting during the first 30 days after amputation.[98a] Forty-seven patients underwent immediate, early, or late postoperative fitting after upper extremity amputation. Those fitted within 30 days of amputation had a 93% rehabilitation success rate and a 100% return to work rate within 4 months after injury compared with a successful rehabilitation rate of only 42% and a return to work rate of only 15% in those fitted with a prosthesis after 30 days from injury. During this period, changes in limb volume and sensitivity will occur, and the occupational therapist will work on range-of-motion and physical conditioning of the injured limb. Psychological support is ongoing and adapted to meet the changing demands of the patient.[133] This may include interaction with other amputee patients as well as participation in occupation-based activities. Change of hand dominance training may be introduced in patients with substantial mutilating hand trauma. Given the limitation of fine motor skills with the available prosthetics, patients learn to use the contralateral uninjured hand independently.

If a patient is to be fitted with a myoelectric prosthesis, the patient begins electrode site identification and training. The goals during this phase are to teach the patient how to effectively contract the residual limb muscles to activate a basic myoelectric device. Forearm flexors control closing and pronation of the prosthesis, and extensors control its supination and opening movements.

Patients gradually advance into the *prosthetic training stage* of rehabilitation. The goal during this phase is to ensure that the prosthesis becomes an integral part of the patient's life as the patient learns the actions required for prosthetic control and incorporates the device into activities of daily living. Each patient trains with a variety of prostheses to determine which is the best fit. A patient often chooses different prostheses to match particular tasks at hand. Patients are also taught principles of skin care to avoid breakdown.

The final stage of the rehabilitation process is the *advanced prosthetic training stage*. Patients learn efficient prosthetic use as therapy is tailored to meet specific needs. They are challenged through a series of tasks that require precise motor control, such as using a tool, musical instrument, or cooking utensil. This training enhances knowledge about the prosthetic components, limb care, and how to don and doff the prosthesis. Furthermore, postural and strengthening programs emphasizing educational awareness of altered body patterns will prevent overuse injuries.[27,133] Ultimately, the patient selects the myoelectric or body-powered prosthesis as the preferred prosthesis. Advanced training guides the patient to facilitate selection via operation and control of the prosthesis to engage in complex tasks.

CRITICAL POINTS *Rehabilitation*

- Successful rehabilitation starts from the time of injury and requires a multidisciplinary team.
- Rehabilitation extends through a four-stage process: postsurgical stage, preprosthetic training stage, basic prosthetic stage, and advanced functional training stage.
- Most patients experience signs and symptoms of psychological trauma that need to be addressed for them to return to their job, family, and society.

PAIN MANAGEMENT AFTER AMPUTATIONS

Despite the surgeon's expertise, 7 to 49% of patients will develop residual pain in the limb after an upper extremity amputation.[119] This pain can have a deleterious effect on recovery and function, including causing difficulties with prosthetic training, depression, reduced likelihood of employment, and overall disability.[66] The two types of pain commonly seen after an upper extremity amputation are phantom limb pain and residual limb pain. *Phantom limb pain* is pain felt in the amputated limb, whereas *residual limb pain* is pain felt in the remaining proximal body part.[133] After an amputation, patients may develop the non-painful phenomenon of *phantom limb sensation* because they feel that the amputated part is still present. The mechanism for this bothersome phenomenon is ill-defined, but fortunately, it resolves gradually over time.

An early approach to pain management may prevent long-term impairment of function.[151] The treating surgeon should begin pain management immediately with either postoperative patient-controlled analgesia or long-acting opioids. Involvement of a pain specialist is required to facilitate the prescribing of short-acting narcotics and anticonvulsants. Nonpharmacologic therapies such as thermal treatments, massage, or TENS are synergistic to pharmacologic measures. Psychological support is equally as important to address any developing issues such as low self-esteem, concerns about disability, and denial.

Desensitization is recognized as an effective way to decrease pain following amputation. The physiologic basis for dysesthesias and their response to desensitization techniques is not entirely understood. Sica and associates[130] demonstrated that the amplitude of the cortical-evoked response of the contralateral somatosensory cortex was diminished in patients with partial limb amputations.[130] Interestingly, they found an increase in amplitude of the evoked response in the proper area corresponding to the uninjured limb on the same side as the partial amputation. These data suggest that the cerebral cortex adapts when its peripheral afferents are interrupted. Exactly how this information relates to dysesthesias after amputation is unclear. Empirically, desensitization techniques appear effective because of this adaptability of the central nervous system to repetitive stimuli. Several techniques of desensitization have been suggested, but most are related to early return to functional activities as advocated by Fisher and Boswick[47] or intensive supervised programs of progressive resensitization to textures and objects.[12] On many occasions, patients are unable to visit regularly with a hand therapist. Given this dilemma, it is important to review a home program of desensitization. Patients and their family members are shown how to rub and tap the fingertip against various smooth and rough surfaces, such as sandpaper and cloth, for a minimum of 6 weeks. The patient is educated on the importance of participating in the home program and routine visits with a hand therapist to prevent the functional consequences and limitations of the hypersensitive part.

Optimizing the care of the patient with a major limb loss requires a comprehensive multidisciplinary approach, including the help of a pain management specialist. Residual limb pain and phantom limb pain occur in 56 to 85% of amputees and have a considerably negative impact on long-term functional outcomes.[86,152] Hanley and colleagues[66] reported on the incidence of chronic pain in 104 patients with upper limb amputations at 6 months after surgery. They noted residual limb pain in 71% and phantom limb pain in 79% of their patients. Interestingly, the patients also complained of pain in the back (52%), neck (43%), and uninjured contralateral arm (33%). Men reported a greater amount of neck, phantom limb, and residual limb pain, and those who used a prosthesis were significantly more likely to have phantom limb pain ($p < .05$). Patients who complained of pain in the nonamputated limb reported a high level of disability and days off work. Overall, 90% of patients experienced at least one type of postamputation pain. This study serves as an important reminder to the surgeon to actively address these issues, either by himself or herself or with the help of a multidisciplinary team.

Phantom limb pain remains a persistent and poorly understood problem that is extremely difficult to treat. Montoya and colleagues[109a] studied cortical regulation in healthy controls, patients with a congenital upper limb amputation, and traumatic amputees. The authors noted that traumatic amputees who had symptoms of phantom limb pain demonstrated reorganization of their sensory and motor cortical maps compared with the other patients. Li and associates[94a] noted that digital amputation caused changes with synaptic transmission within the anterior cingulate cortex, a region that relays pain within the central nervous system, as possibly contributing to phantom limb pain. Jensen and colleagues[76a] noted that the presence of preoperative limb pain plays a role in the development of phantom limb pain immediately after surgery. Fifty-eight patients who primarily underwent elective lower limb amputations for peripheral vascular disease were interviewed preoperatively and postoperatively about their stump and phantom limb pain. The incidence of residual limb stump pain was 57% at 8 days, 22% at 6 months, and 21% by 2 years following amputation. The incidence of phantom limb pain was much higher (72% at 8 days, 65% at 6 months, and 50% at 2 years) in patients who had preoperative pain. Lambert and coworkers[87a] conducted a prospective randomized trial comparing preoperative epidural medications (bupivacaine and diamorphine) with intraoperative perineural analgesia (bupivacaine) of 30 patients undergoing lower limb amputations. The authors noted that at 3 days following amputation, there was a significant reduction in stump pain in the epidural group but no real differences in phantom limb pain with either regimen. Aggressive pain management with multimodal pharmacologic management in conjunction with integrative and alternative measures such as biofeedback, hypnosis, relaxation techniques, or acupuncture may contribute to a successful outcome.[116]

Neuromas

A peripheral nerve injured during amputation will attempt to regenerate. Regeneration is initiated by axonal growth (sprouting) from the proximal nerve end. There are a host of neurotrophic factors that are released to stimulate the repair process, including substance P, calcitonin gene-related peptide, and fibroblast growth factors.[23] Because there is no end organ present, a neuroma will form (Figure 49.45). Even when repair is possible, some regenerating axons can grow outside the repair site and become symptomatic. The overall incidence of neuroma formation following amputation varies from 2.7 to 30%.[47,115,137,146] Most neuromas are asymptomatic. Only 3 to 5% become symptomatic; they can be frustrating for the patient and the surgeon, resulting in dissatisfaction and disability.

Patients tend to present with a history of trauma from a sharp, crushing, or stretch injury. Symptoms include hypersensitivity and an aching or throbbing pain. The pain may or may not localize to a single peripheral nerve distribution. The diagnosis is made clinically, with patients usually having a positive Tinel sign over a localized site yielding lancinating pain. Selective local anesthetic injections can be used to facilitate the diagnosis. Complete symptom relief after the injection will help the patient to realize the area of numbness that will develop after neuroma excision, transposition, or grafting. Initial management requires nonoperative measures, such as scar massage, desensitization, and TENS. Oral medications, including opioids, nonsteroidal antiinflammatory medications, antidepressants, anticonvulsants, and topical analgesics, have had varied success. There are many surgical techniques for symptomatic neuroma,

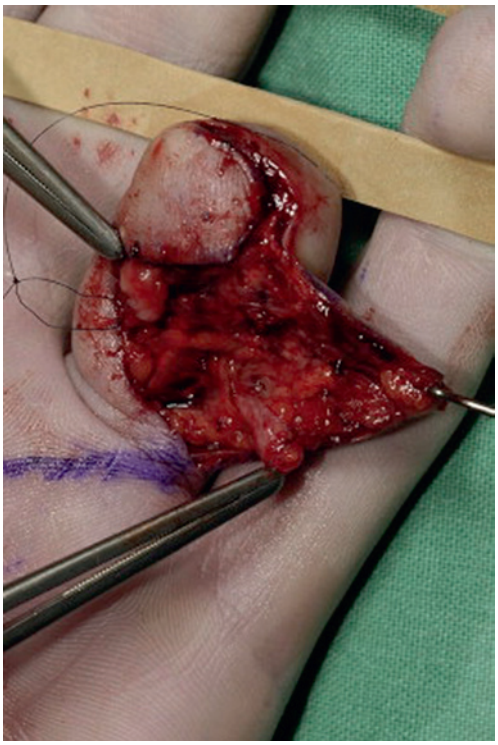

FIGURE 49.45 A digital nerve neuroma after an amputation. (Used from Van der Avoort DJJC, Hovius SER, Selles RW, et al: The incidence of symptomatic neuroma in amputation and neurorrhaphy patients. *J Plast Reconstr Aesthet Surg* 66:1330–1334, 2013, Figure 1.)

and they should be considered in patients refractory to nonoperative treatment who have had a positive response to a local anesthetic injection and symptom resolution. In patients whose pain is not aligned with the anatomic distribution of a nerve, caution is necessary when considering surgery, because these patients may have secondary gain issues or an underlying psychological pathologic condition. Surgical treatment of neuromas is centered around four main options: (1) neuroma resection; (2) primary microsurgical end-to-end coaptation or coaptation using a vein graft or neural tube; (3) containment of the neuroma, including translocation into muscle or bone; and (4) nerve translocation.[10,13,23,25,44,58,67,98,101,107,147] The preferred technique is impossible to determine due to the lack of prospective randomized comparative studies. My preference for the management of symptomatic digital nerve neuromas is to relocate them proximally into tissues outside the zone of injury, such as the interosseous muscle (Figure 49.46 and Table 49.3), or to suture them directly to each other.

CRITICAL POINTS *Postamputation Pain Management*

- Dysesthetic amputation stumps occur even with careful tissue management, especially with distal digital injuries.
- Desensitization programs may improve outcomes in digital amputations.
- Aggressive preoperative and postoperative pain management by a pain specialist may reduce the incidence of phantom pain.
- Amputation neuromas are often identified by clinical examination. The results of treatment vary, and the definitive technique remains elusive.

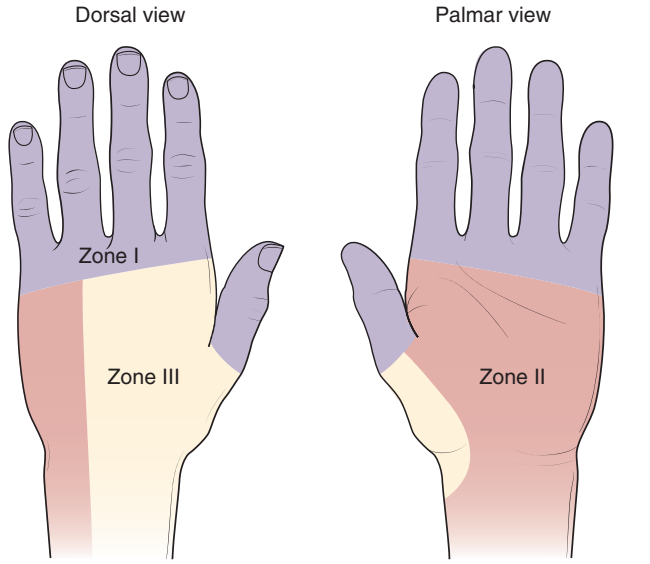

FIGURE 49.46 For preoperative planning in nerve relocation, the hand and distal forearm can be divided into three zones. Major Limb Amputations and Prosthetics

Rafael J. Diaz-Garcia and Paul S. Cederna

Amputation of the upper extremity takes its toll on both the patient and surgeon. The patient is devastated at the prospect of life with a disability and laments the potential loss of the independence we all take for granted. For the surgeon, the toll is much less, but feelings of sympathy and regret remain, as we wish we had another option. Nonetheless, it is important that surgeons who care for patients with hand and upper extremity injuries have an appreciation of the finer points of amputations. In addition, they should have a comfortable understanding of the treatment goals in postoperative rehabilitation and restoration of upper extremity function to maximize outcomes.

MAJOR LIMB AMPUTATIONS

Although the amputation of a digit is by far more common, major upper extremity amputations account for up to 25% of all amputations.[3-5,15] In the United States alone, approximately 41,000 people underwent transradial amputations in 2005. This prevalence has risen from previous estimates because of improved trauma and critical care medicine, which is preserving the life of severely injured patients; it is likely to continue to rise due to an aging population of patients with a higher incidence of diabetes and vascular disease. The effects of an upper extremity amputation are significant and greatly impact the quality of life. Up to a third of patients who undergo amputation of an upper extremity require a change in occupation, and almost two thirds discontinue vocations and hobbies as a consequence of the amputation.[43,48]

The technical principles of upper extremity amputations are fairly consistent, regardless of the indication for surgery or level of amputation:

- Preservation of functional residual limb length
- Durable coverage of the residual limb to allow for long-term prosthetic use
- Prevention of symptomatic neuromas
- Prevention of adjacent joint contractures
- Early prosthetic fitting (golden period)

Indications

Unlike in the lower extremity, the majority of upper extremity amputations are performed as treatment for acute trauma.[5,44] In Scandinavia, up to 90% of upper extremity amputations are trauma related.[2] Amputations may be performed acutely when the hand surgeon believes that the functional potential of the salvaged limb would be substantially worse than that of a prosthetic limb. At times, the surgeon will elect to perform multiple operative procedures in an attempt to salvage a hand or extremity but is unsuccessful in these attempts. Such attempts to salvage a severely damaged limb may even be detrimental to the health of the patient. In these cases, there is often severe and unreconstructible damage to the neurovascular supply of the extremity or severe injuries to the skeleton, either of which may make meaningful recovery nearly impossible.

Major upper extremity amputations may also be required following burns or infections or as treatment for malignant disease. Up to 26% of electrocution injuries require some form of major amputation.[16] Deep thermal burns result in amputations approximately 3.8% of the time, usually because of nonviable tissues, but at times for control of burn wound sepsis[41] (Figure 50.1). Most infections can be managed with antibiotics and surgical débridement, but some require amputation. For instance, invasive fungal infections such as mucormycosis almost uniformly require amputation; the mortality rate in this patient population may be as high as 92%.[17,30] Advances in radiation therapy, chemotherapy, and limb salvage surgical techniques have considerably reduced the need for upper extremity amputation in sarcoma patients over the past 40 years, but radical amputation remains a mainstay of treatment for recurrent disease or large tumors.[37,46]

Wrist Disarticulation and Transradial Amputation

After decades of research, the optimal level of amputation for patients who require removal of the hand remains controversial.[44] Wrist disarticulation preserves limb length, providing an arm with a longer lever for prosthetic control. In addition, the longer residual limb preserves the distal radioulnar joint, resulting in better pronation and supination.[42] The metaphyseal flare of the distal radius also provides a contour that aids in suspension of a terminal device (Figure 50.2). However, the benefits of a wrist disarticulation come at a cost. The prominence of the styloids of the distal radius and ulna can become pressure points, leading to breakdown of the residual limb within the socket. The additional residual limb length in a wrist disarticulation also can create limb-length discrepancies when a prosthesis is worn. In fact, a myoelectric terminal device may add several centimeters to the length of the residual limb, accentuating the limb-length discrepancy seen in patients who have undergone wrist disarticulation.[33] This not only presents an aesthetic concern but also makes it more difficult for a patient to reach the anatomic midline because greater shoulder abduction and scapular retraction are required to do so. For these reasons, patients with wrist disarticulations are more likely to abandon their prostheses than transradial amputees.[6,48] Ideally, the patient is afforded the opportunity to have a preoperative consultation with a physiatrist and a prosthetist so that he or she may make an educated choice between a wrist disarticulation

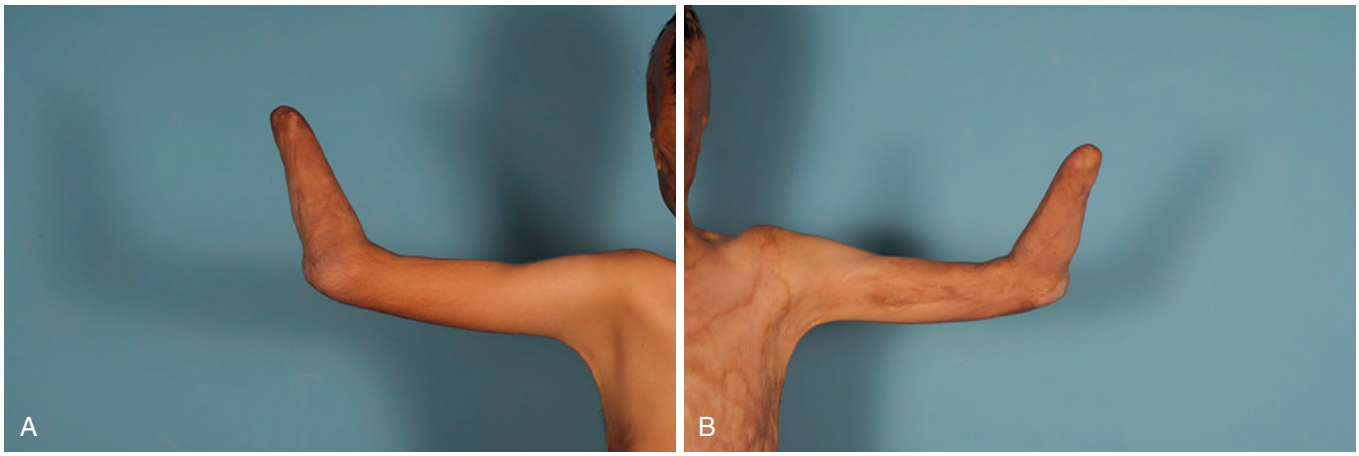

FIGURE 50.1 **A, B,** Thirty-four-year-old gentleman suffering more than 50% total body surface area burns to the head, trunk, and upper extremities, requiring bilateral transradial amputations.

FIGURE 50.2 The increased width provided by the metaphysis of the distal radius allows for easier prosthetic suspension with a wrist disarticulation in comparison with a transradial amputation.

and a transradial amputation. Given the usual indications, however, this is unfortunately rarely the case. Amputation 8 to 10 cm proximal to the ulnar styloid provides the greatest variety of prosthetic options for functional restoration of the extremity.[24,43] This preserves adequate pronation and supination and a reasonable lever arm for prosthetic control during flexion of the elbow. One form of amputation is not ideal for all patients, however, making the preoperative consultation critically important in the process. Patients who perform heavy labor frequently prefer a wrist disarticulation owing to the increased durability of a body-powered prosthetic, the increased lever arm length, and the preserved distal radioulnar joint.

As the transradial amputation becomes more proximal and approaches the elbow, the anticipated pronation and supination decrease. In fact, there is minimal pronation and supination once half of the initial forearm length is removed. Yet, preserving at least 5 cm of the ulna is sufficient for successful prosthetic fitting.[34] Once the level of amputation moves proximally above the elbow, the dramatic increase in the amount of work required to function with the prosthesis greatly increases the likelihood of abandonment.[6] Preserving the elbow joint should remain a high priority, even when complex reconstructive efforts such as free flaps are required to maintain this articulation.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Transradial Amputation

The skin incisions are designed with equal-length flaps along the volar and dorsal aspects of the forearm, in what is often referred to as a fish-mouth pattern. The incisions are designed so that the osteotomies in the radius and ulna will lie at least 1 to 2 cm proximal to the level of the skin incision (Figure 50.3). The arm is exsanguinated, and tourniquet control is used for hemostasis. The skin and subcutaneous tissues are elevated off of the underlying antebrachial fascia proximally past the level of the proposed osteotomies. The antebrachial fascia is incised at the level of the skin incision, and all of the neurovascular structures are individually identified. The radial and ulnar arteries are ligated with suture ties or vascular clips, and the interosseous vessels are cauterized. The nerves are dissected proximally and divided to ensure that they are positioned proximal to the level of the osteotomy. The flexor and extensor musculature is divided 1 cm distal to the level of the osteotomy. The periosteum is incised and a small cuff is elevated proximally. An oscillating saw is used to make the bony cuts, and edges are smoothed with a rasp. A myodesis is performed, first with the deeper muscle bellies fixed firmly to the underlying skeleton to establish durable bony coverage and to prevent bursitis from excessive excursion. The superficial musculature is then sutured in agonist/antagonist pairing over the end of the osteotomies to complete the myodesis. Care is taken to re-create physiologic tension to superficial muscle units to maximize postoperative contractions. The force of these contractions may ultimately be used to provide efferent motor control of a myoelectric prosthesis. The wound is closed in layers, and a bulky compressive dressing is applied.

Elbow Disarticulation and Transhumeral Amputation

Loss of the elbow joint has a significant adverse functional impact on the residual limb and greatly diminishes a patient's adaptation to meaningful use of a prosthesis. In these more proximal amputations, the elbow must be replaced with a

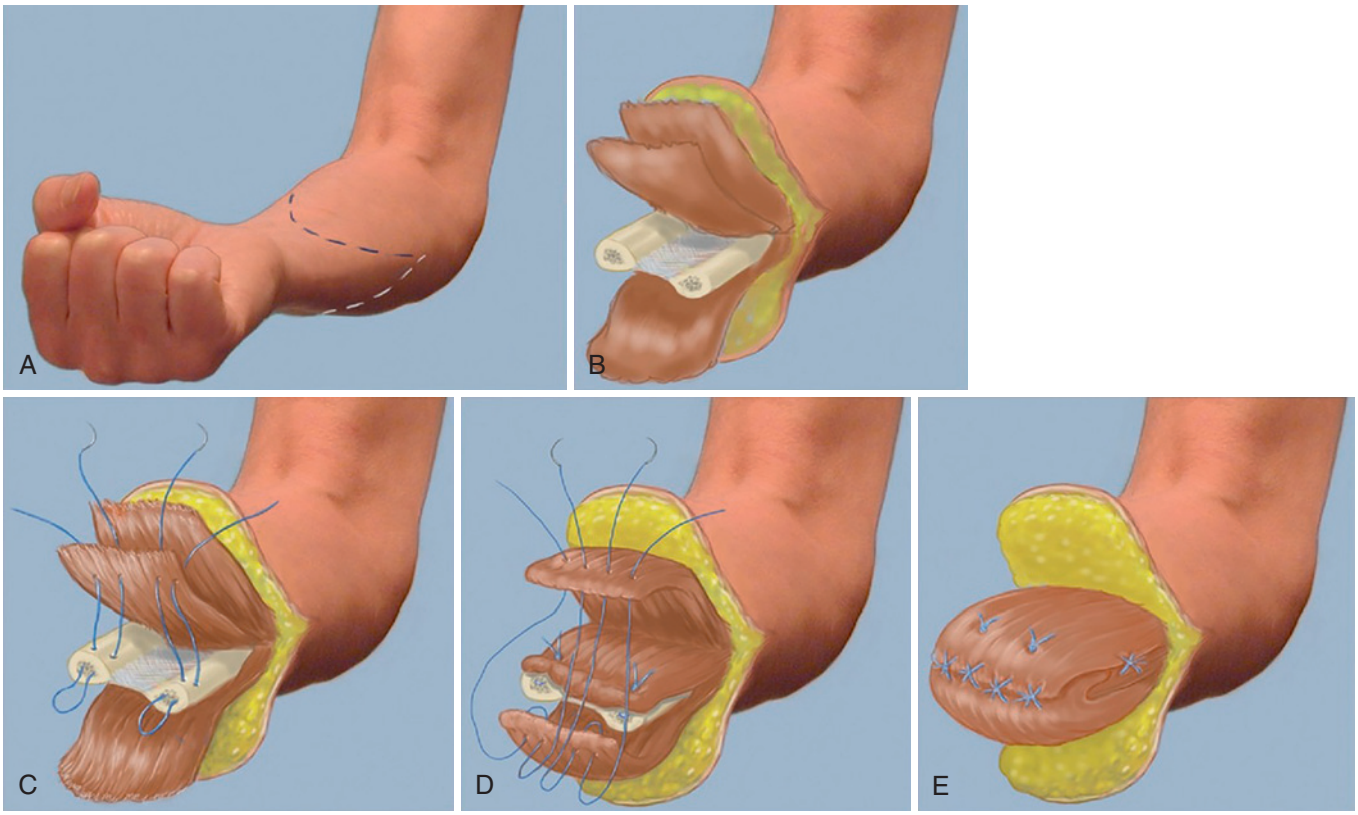

FIGURE 50.3 Artist's rendition of a planned, elective transradial amputation. **A,** A fish-mouth incision is designed 1 to 2 cm distal to the level of the planned osteotomies, which are usually 8 cm from the ulnar styloid. **B,** Soft tissues are elevated and osteotomies completed with an oscillating saw. **C,** A myodesis is completed with the deep musculature to the bone. **D** and **E,** Superficial musculature is sutured in agonist/antagonist pairing over top, trying to re-create physiologic tension. (From Marchessault JA, McKay PL, Hammert WC: Management of upper limb amputations. *J Hand Surg [Am]* 36(10):1718–1726, 2011.)

prosthetic component, which adds a substantial amount of weight and limits the utility of these devices. In addition, with above-the-elbow prostheses, more energy is required to perform daily functions, and thus, transhumeral amputees are more likely to abandon their prosthetics than their transradial counterparts.[6]

The discussion regarding elbow disarticulation versus transhumeral amputation is similar to the previous discussion regarding wrist disarticulation versus transradial amputation. There are advocates for both surgical approaches because each has its benefits and drawbacks. Preservation of the distal humerus conserves the flare of the condyles, which not only aid in the suspension of the device but also allow for transmission of rotation. These benefits come at a fairly high price, however. When an elbow disarticulation is performed, the greater length of the residual upper arm creates a limb-length discrepancy, which is particularly problematic when a patient uses a prosthetic device with an elbow articulation. In these situations, it is more difficult for the patient to reach the anatomic midline, and the asymmetry with the unaffected arm is fairly noticeable, unaesthetic, and functionally limiting.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Transhumeral Amputation

It is our preference to perform a transhumeral amputation rather than an elbow disarticulation because the benefits of the latter seem fairly minor. The exception is in the pediatric patient, where there is a high incidence of bony overgrowth following transhumeral amputation through the metaphysis, which ultimately may require surgical revision.[1] A sterile tourniquet is used to limit blood loss and facilitate identification of key structures in a bloodless field. After exsanguination, anterior and posterior flaps are designed 2 cm distal from the level of the planned osteotomy. Ideally, the osteotomy is planned 10 cm proximal to the olecranon tip to maximize prosthetic options. The brachial artery is securely ligated with a suture ligature, and the radial, median, and ulnar nerves are dissected proximally and divided to ensure that they are positioned proximal to the level of the osteotomy. The osteotomy is performed with an oscillating saw, and any bony edges are carefully rasped so they are smooth. The tourniquet is removed and hemostasis ensured. It is possible to perform an angulation osteotomy of the distal humerus to provide rotational control of the prosthesis.[28,32] This operation would only be performed, however, if there were extensive preoperative discussions with the physiatrist and prosthetist and it was determined that this would provide the optimal functional rehabilitation for the patient. This is not done routinely in all patients because it can create a pressure point in the residual limb. If it is planned, the amputation is performed more distally to account for the limb length lost with the angulation osteotomy. A myodesis is performed by securing the musculature from the anterior compartment to the

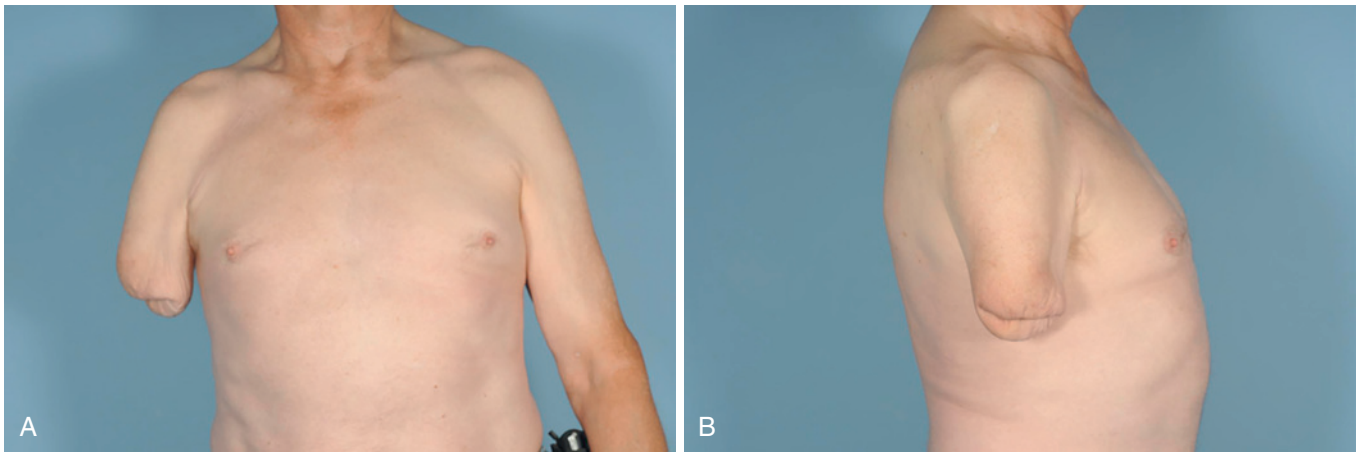

FIGURE 50.4 Elderly patient with transhumeral amputation, with no interest in prosthetic rehabilitation. **A,** Frontal view. **B,** Lateral view.

posterior compartment to cover the distal humeral edge. Unlike in transradial amputations, a closed suction drain is placed to avoid fluid collections. The skin is closed in layers, and a bulky compressive dressing is applied (Figure 50.4).

Interscapulothoracic Amputation

Interscapulothoracic (forequarter) amputation is the most radical and, luckily, least frequent amputation in surgical practice. This disfiguring procedure requires disarticulation of the entire shoulder girdle from the thoracic cavity. Although initially described in the setting of trauma in 1808, the surgical technique has not evolved much over two centuries because of the rarity of the procedure.[18] Its main clinical role today is as a last resort in the treatment of aggressive malignant disease. The use of forequarter amputation has continued to decline from 32% in the 1970s to 5% in a current series because of advances in radiation therapy, chemotherapy, and limb salvage surgical techniques.[37,46] Because most of these amputations are done for aggressive malignant conditions, the outcomes are generally poor. Over a 12-year span at a major orthopedic oncology center, the overall survival rate at 1 year was 42% and by 2 years, it was less than 20%.[37]

Planning the closure of the eventual defect is important because the amputation cannot proceed any more proximally if there is tension on the skin (Figure 50.5). This is particularly true in cases of recurrent sarcoma, where radiation damage to the surrounding tissues may present a dilemma and create additional challenges for soft tissue coverage. If the area of skin resection or previous irradiation will likely result in too much tension at the suture line, the surgeon should plan to fillet the forearm and use it as a fasciocutaneous free flap based on the brachial artery.[19,49]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Forequarter Amputation

The patient is placed in the lateral decubitus position, with all pressure points appropriately padded. Like most amputations, previous scars or recurrent malignant disease may affect the ultimate incision design. The classic design is an ellipse at the base of the shoulder and around the scapula, with a cephalad extension along the clavicle up to the sternocleidomastoid muscle to obtain proximal control of the subclavian vessels (Figure 50.6). The anterior portion of the incision is an extension of the deltopectoral groove inferiorly, and the posterior portion crosses the acromion and runs along the medial border of the protracted scapula. The natural skin redundancy over the retracted scapula is preserved to facilitate tension-free closure.

The operation is started anteriorly, exposing the entire clavicle by releasing the muscular attachments with electrocautery. An osteotomy is completed just lateral to the origin of the sternocleidomastoid with a Cobb elevator protecting the underlying vascular structures. The osteotomy provides excellent exposure of the subclavian artery and vein, which are divided and suture ligated. If a free flap is planned for coverage, vascular control is maintained with a combination of vessel loops and atraumatic vessel clamps to preserve the vasculature for microvascular transfer. Once control of the major vessels is obtained, the pectoralis major tendon is divided and retracted medially. The origins of the coracobrachialis and short head of the biceps are dissected off of the coracoid along with the insertion of the pectoralis minor. The transverse cervical and suprascapular arteries are ligated as they cross the surgical field. If the patient is younger than 50 years of age, the major branches of the brachial plexus should be cut and implanted into the pectoralis major and serratus anterior to allow for the possibility of targeted muscle reinnervation for prosthetic control (see Frontiers in Prosthetic Rehabilitation).

Attention is then directed posteriorly, where the incision is made along the medial border of the scapula, dissecting toward the muscular insertion of the rhomboids. As the muscle fascia is incised, the shoulder is flexed and adducted to bring the scapula off of the thorax. If one does not have sufficient help in the operating room, a hydraulic arm holder can be of great assistance. All of the muscular attachments are released superiorly and medially off of the scapula, leaving only the serratus anterior and latissimus dorsi muscles as attachments to the specimen. These tendons are divided, and the specimen is passed off for pathologic study. The skin is closed in a layered fashion over drains.

CURRENT PROSTHETIC REHABILITATION

The loss of an upper extremity is devastating, and current prosthetic options cannot adequately replace all the functions of the

FIGURE 50.5 **A,** Traumatic injury of the right upper extremity with multilevel injury made operative salvage futile. **B,** Axillary wound showing large brachial plexus nerve gaps secondary to avulsion injury. **C,** Radiographs illustrate the large segmental loss of proximal humerus. **D** and **E,** Final closure of amputation site with Jackson-Pratt drains in place.

human hand. Modern devices do not have ample degrees of freedom and lack sufficient sensory feedback. Every activity requires visual cues for direction because there is minimal tactile feedback from the terminal device. Thus, the upper extremity amputee must expend more energy—both physical and cognitive—to perform activities of daily living. The ultimate postoperative goal is for patients to regain functional independence and be able to participate in the vocational and recreational activities they enjoyed prior to surgery. However, as mentioned previously, 33% of patients require a change in occupation and 58% discontinue recreational activities.[43,48]

There are a multitude of factors that influence prosthetic rehabilitation, including the level of amputation, comorbidities, range of motion, strength, patient goals and preferences, and health insurance coverage. The level of amputation probably has the greatest impact on prosthetic rehabilitation because it determines (1) the functions that need to be replaced, (2) the length of the residual limb needed to provide stability and control of the terminal device, and (3) the prosthetic components that will be required to reestablish function. There are a wide variety of rehabilitative choices when developing a restorative plan after upper extremity loss, from passive cosmetic devices to futuristic robotic units with multiple degrees of freedom. Comprehensive coverage of all the options is beyond the scope of this chapter. We hope to provide you with a basic understanding of prosthetic rehabilitation and how it pertains to the hand surgeon, however.

Rehabilitation After Upper Extremity Amputation

Ideally, prosthetic rehabilitation commences before the major limb amputation even takes place. The patient should meet with a physiatrist prior to surgery, and there should be collaboration between the surgeon and physiatrist to create a rehabilitation care plan. The level of amputation should be discussed, focusing on the impact the various levels of amputation will have on functional outcome, prosthetic restoration, and rehabilitation. The physiatrist can also provide counseling and patient references that may better prepare the patient for the limb loss. Obviously, because most amputations of the upper extremity result from trauma, this is not a possibility in many cases. However, when possible, this is greatly beneficial to all patients physically and psychologically.

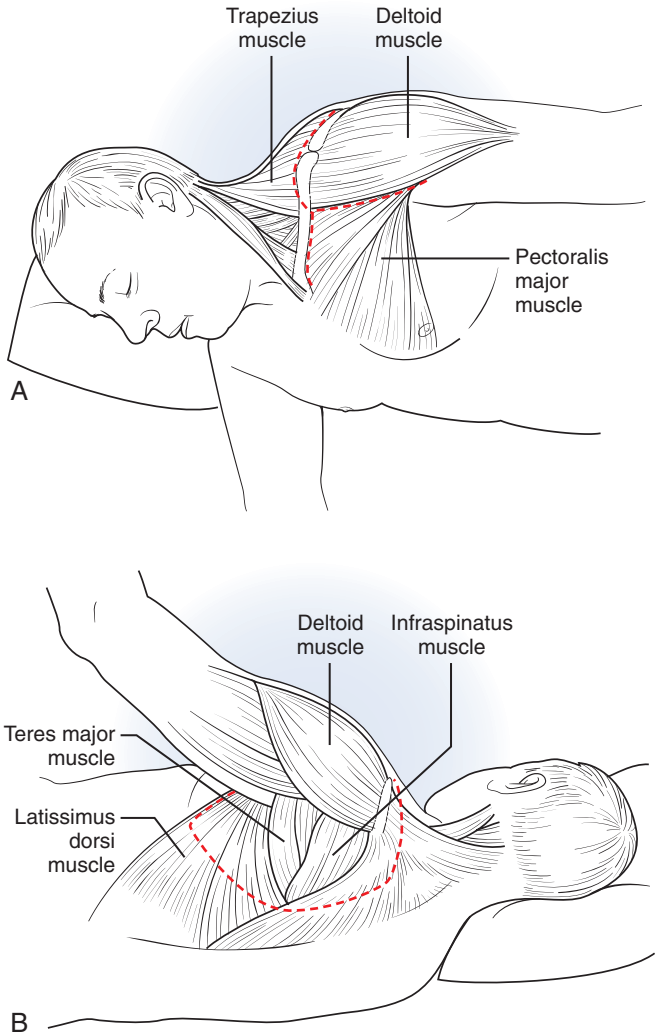

FIGURE 50.6 Anterior **(A)** and posterior **(B)** incision design for elective interscapulothoracic amputation. This allows for proximal access to the subclavian vessels and sufficient soft tissue for closure of the amputation site. (Redrawn with permission from Qadir R, Sidhu S, Romine L, et al: Interscapulothoracic [forequarter] amputation for malignant tumors involving the upper extremity: surgical technique and case series. *J Shoulder Elbow Surg* 23(6):e127–e133, 2014.)

If there are no contraindications, range-of-motion exercises of the residual limb should be initiated soon after surgery. Occupational therapy can provide gentle range of motion of the surgical limb and training in using the noninvolved arm for feeding, dressing, and self-care. The occupational therapist can also provide thermoplastic extensions for the residual limb, which can assist the patient in performing some bimanual skills before the permanent prosthesis can be fitted. In this early postoperative period, graded compression of the residual limb will help create a well-shaped recipient for the socket liner. Good pain control is of utmost importance; ongoing pain will delay recovery and participation in rehabilitation.

Barring any wound healing issues, a provisional prosthesis should be fitted as soon as possible. After upper extremity amputation, patients immediately begin using compensatory movements to be more functional, some of which persist even after completion of rehabilitation.[12] Motivation and interest peak early after limb loss; this is the optimal time to fit the patient for the prosthesis and begin rehabilitation, before the patient has adapted to life without the extremity. The first month after amputation is often referred to as *Malone's "golden period."* The successful rehabilitation rate drops to 42% for patients fitted after the initial 30 days postoperatively.[27] The main purpose of the provisional prosthesis is to acclimate the patient to the use of a prosthesis, hopefully providing a positive experience. As edema resolves, a final prosthesis can be designed and fitted; patients who undergo this step within 6 months are 16 times more likely to use the prosthesis over the long term.[7] It is critically important that the patient undergo counseling regarding all of the various types of terminal devices, including their capabilities and functionality, so the patient can select the device best suited to his or her needs. Even with good education and fitting, however, many patients ultimately abandon the prosthesis because of discomfort, lack of functional gains, appearance or weight of the device, lack of sensory feedback, short battery life, and financial constraints. A review of the literature shows that rejection rates are greater for passive-power prostheses, and approximately 20% of adults with amputations abandon all prosthetics and routinely use no terminal device.[8]

PROSTHETIC COMPONENTS AND OPTIONS

Prosthetic Designs

Upper extremity prostheses can be categorized in a variety of ways. The most obvious categorization is by level of amputation. As the amputation becomes more proximal, it is more difficult to suspend the prosthesis without the use of a harness and more functions need to be replaced with either locking or powered joints. For an individual patient, prostheses are best categorized by their source of power, whether passive, body-powered, externally powered, or hybrid. The *passive prosthesis* is considered a cosmetic terminal device because that is the use for which it is most commonly selected. Passive prostheses are usually lightweight and appear lifelike if fitted with a cosmetic silicone glove. Interestingly, they can also be quite functional, providing the ability to stabilize objects or having recreation-specific designs.

Body-powered prostheses are the most commonly prescribed prostheses in the upper extremity. They are lightweight and much less expensive than externally powered devices, particularly for transhumeral amputees. They harness scapular and humeral motion, and because they work through a relatively simple system of metal cables, joint locks, and rubber bands, they are durable and require very little maintenance. These qualities make them attractive to manual laborers, who are more likely to have suffered a traumatic amputation (Figure 50.7). Unfortunately, they do appear to be "mechanical" devices, have a bare hook, and are not aesthetically pleasing to some patients.

Although the designs of body-powered devices have not changed much in a century, *externally powered prostheses* have undergone extensive research and development. Early designs used pneumatics and hydraulics, but current myoelectric prosthetics are run by battery-powered motors housed in the artificial limb itself. Surface electromyographic electrodes detect electrical activity in the superficial musculature of the residual limb, allowing the patient to open and close the terminal device

FIGURE 50.7 A body-powered hook terminal device is durable and requires very little maintenance; it is therefore attractive to manual laborers. (Courtesy of Advanced Arm Dynamics, with permission.)

FIGURE 50.8 The new Michelangelo Hand from Otto Bock has multiple specific grip functions for mastering tasks such as gripping a key or holding a pen, enabling it to function more like a human hand. (Courtesy of Advanced Arm Dynamics, with permission.)

by activation of agonist and antagonist muscle groups. Externally powered prostheses have greater prehension strength (>30 pounds of pinch) than body-powered devices, which usually close on the basis of a series of rubber bands (Figure 50.8). However, each additional function greatly increases the cost of the device, its weight, and its required maintenance. Prototypes tested by the Department of Defense for transhumeral amputees cost upward of $100,000.

Once the patient is proficient in the use of the provisional prosthesis, the limb size and shape have stabilized, and the functional needs have been determined, decisions about the definitive restoration can be made. As stated previously, some patients may need more than one device to achieve their goals. Although the final prescription is an individualized decision, there are some general trends. *Myoelectric devices* are preferred for most transradial amputees due to their improved cosmesis, pinch strength, and anatomic suspension. *Hybrid prostheses* are usually preferred for proximal amputations, including transhumeral amputations and shoulder disarticulations (Figure 50.9). This is due to the lack of sufficient and distinct proximal muscle signals to power a complete myoelectric device. However, passive and body-powered devices can be fashioned for any level of amputation, the latter being the device of choice for the manual laborer because of its durability.

FIGURE 50.9 Transhumeral amputees can have reasonable function with the use of a hybrid prosthesis. (Courtesy of Advanced Arm Dynamics, with permission.)

Sockets and Suspension Systems

The socket is the very foundation of the prosthetic restoration. It must be comfortable to wear, or the patient is sure to discontinue its use. A test socket is created during the initial fitting of the provisional prosthesis. Based on patient feedback, a customized permanent socket is constructed out of carbon fiber and Kevlar to fit the final prosthesis. Sockets may be self-suspended or require a harness. Self-suspended sockets have an intimate fit that has direct translation of motion from the residual limb to the socket and, in turn, the prosthesis. Conversely, non–self-suspended sockets are easier to don but require a highly visible harness that is less cosmetically appealing. The harness is necessary in more proximal amputations, such as in a transhumeral amputee. As the prosthesis becomes heavier, it becomes more important to suspend the weight from the harness to prevent excessive force on the end of the residual limb. Suspension depends not only on the level of amputation but also on the control method for the prosthetic joints. For instance, a body-powered prosthesis requires an external suspension system to harness the scapular motion and translate it down the cable to a terminal device.

FRONTIERS IN PROSTHETIC REHABILITATION

In recent years, there has been an increase in awareness of the limitations of current prosthetic designs, as wounded servicepeople have attempted to reintegrate into society after limb loss. This awareness has resulted in significant increases in research funding and scientific discovery in the field. Although advances have been made, limitations abound, with upper extremity

prosthetic users uniformly dissatisfied with the prehensile function of the available terminal devices. There is insufficient control of multiple degrees of freedom and a lack of sensory feedback from the prosthetic devices, both of which are key in optimizing functional recovery following limb loss. Unfortunately, these problems are accentuated in patients with more proximal amputations because loss of the elbow joint decreases the muscles available for prosthetic control. Current and future researchers hope to address these shortcomings and create prosthetic devices with more degrees of freedom, better sensory feedback capabilities, and more intuitive control strategies.

Improved Prosthetic Control

In an attempt to create the ideal prosthetic that will provide the optimal functional recovery following limb loss, the largest obstacles stem from the lack of control and true sensory feedback. The perfect mechanical extremity would be useless if the patient were not able to control it consistently and precisely. Without proprioception and tactile feedback, there is a significant cognitive burden in doing everyday tasks because visual cues must be used for every act. An ideal control system would not only provide that crucial feedback to the user but also allow for simultaneous motion at multiple joints with volitional control. A high-fidelity neural-machine interface, both for motor control and for sensory feedback, is the ultimate goal. In attempting to reach this goal, three research paradigms have been developed to record high-fidelity signals for volitional control of a robotic extremity: (1) targeted-muscle reinnervation, (2) peripheral nerve interfaces, and (3) central nervous system interfaces.

Targeted-muscle reinnervation (TMR) is a creative and innovative approach to providing efferent motor signals for prosthetic control by innervating muscle territories (myosites) in proximal amputees. In conventional myoelectric devices, patients with transradial amputations will use their innervated wrist flexors and extensors to control the terminal device. In a more proximal amputation, however, there are minimal residual innervated muscles to provide an electromyographic signal for prosthetic control; in a transhumeral amputation or shoulder disarticulation, there are no innervated wrist flexors or extensors to provide myoelectric signals for control of prosthetic hand function. In these circumstances, there is limited ability to control hand function and elbow function simultaneously. Dumanian and colleagues have led a team at Northwestern University to create a solution for this problem with TMR. Target proximal muscles are denervated and then provided an alternative signal with nerve transfers.[13,14,20-22] The reinnervated muscles serve as biologic amplifiers of the previously lost motor commands. The muscle contractions are detected by surface electromyographic electrodes, which provide the appropriate control signals for the myoelectric prosthesis.

TMR patients have had great clinical success, though the number of patients remains small. They have demonstrated a seven-fold increase in efficiency in completing tasks with their prostheses, so that proximal amputees are able to control their devices at multiple articulations simultaneously.[11,14,20] Patients report that the control is more natural and intuitive, reducing the amount of necessary training. Recently, an in vivo regenerative peripheral nerve interface has been developed as a microscopic version of TMR. Nerve endings are implanted into muscle grafts with an applied electrode and wrapped in a bioelectric insulator, providing signal amplification with long-term stability and durability.[23,39] This interface strategy can be employed at the nerve fascicle level, providing the potential for higher-fidelity independent motor control of numerous joints simultaneously.

The peripheral nerve interface research and development community has spent a substantial amount of time and resources creating new, innovative, and highly technically advanced interface designs for providing improved motor control of prosthetic devices. These interfaces have been developed and refined in many different configurations and out of many different materials to record efferent motor action potentials from peripheral nerves in the residual limb. One of the peripheral nerve interface strategies uses *cuff electrodes*, implanted extraneural electrodes that surround the nerve and record action potentials from several fascicles within the nerve.[31,45] Cuff electrodes have been shown to be safe and effective for up to 3 years in humans, but they have limitations in selectivity. The small-amplitude neural signals can be difficult to isolate from adjacent muscle contractions or from adjacent fascicles, which may be providing different volitional control signals (i.e., index finger flexion versus middle finger flexion) within the same nerve.[36] Intraneural electrodes, such as intrafascicular electrodes and rigid multielectrode arrays, are placed within the peripheral nerve with direct axonal contact.[10,29] (Figure 50.10). This increased contact area with the axons improves the selectivity of the individual signals. However, the location of intraneural electrodes within the peripheral nerve leads to progressive fibrosis over time owing to (1) the initial procedure to place the electrode within the nerve, (2) foreign body reaction, and (3) micromotion. Scarring in the nerve causes progressive axonal damage, axonal pruning, and biofouling of the electrode, which ultimately results in loss of the signal.

The central nervous system has also been an attractive site for capturing motor commands and providing sensory

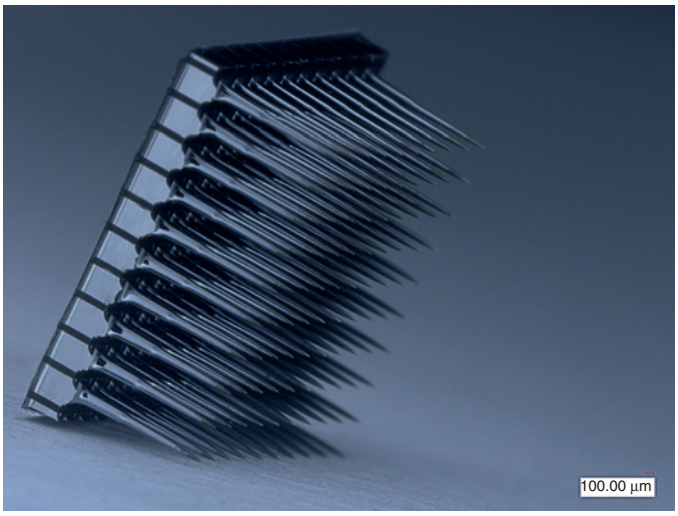

FIGURE 50.10 The Utah multielectrode array has become a benchmark for multichannel, high-density neural recordings, and is one of the peripheral nerve interfaces being used for prosthetic control. (Courtesy of Blackrock Microsystems, with permission.)

feedback to patients with limb loss or spinal cord injuries. Brain signals can be captured with electroencephalograms (EEGs) on the scalp or electrocorticograms (ECoGs) in the brain, and that electrical activity can be used to direct the motions of a robotic limb. There are significant limitations, however. EEG signals represent a large number of neurons, rather than individual cells, so there are limits in the resolution of the signal.[9,47] This makes it difficult to code movement for volitional intent consistently. Because the ECoG signals are derived directly from the motor cortex, they are more specific and have much better signal resolution, but gaining access requires a craniotomy, placing a foreign body on the surface of the brain, or penetrating the brain with an electrical probe. These implants have a limited functional life for reasons similar to those of intraneural electrodes; ECoG arrays lose fidelity and signal strength over time because of the fibrosis at the cortex/electrode contact area.[36] Nevertheless, there has been success in animals, who were able to execute complex tasks with these implanted interfaces, and some success in achieving control of a prosthetic limb with ECoG electrodes in humans.[9] These central nervous system interfaces are unlikely to be the answer in patients with upper extremity amputations but will undoubtedly serve a purpose among the spinal cord injury population.

Improved Prosthetic Design

The past 20 years has seen amazing advancements in the field of robotics. Although the advancements realized in robotic design and functionality have been astounding, the progress seen in prosthetic rehabilitation has been less dramatic. Functional gains in prosthetic limbs must be balanced with the added weight and size that comes with these designs. Furthermore, the average amputee lacks the means to pay for the complex robotic devices available at the cutting edge of the field. Nevertheless, prosthetic terminal devices are constantly being improved for the purposes of providing enhanced function in patients suffering from limb loss.

Sockets and liners provide a critical interface between the prosthetic device and the residual limb. Not only must they allow for the transfer of work from the organic structures to the mechanical structure, but they also must remain comfortable to allow the patient to use them over a full day. New materials are always under development in the hopes of greater durability and less weight. Polymers will continue to be developed with greater strength and pliability. *Computer-aided design and computer-aided manufacture* (CAD/CAM) has recently become an area of increased interest in prosthetics. Custom-fitted devices can be designed and produced more quickly and at a fraction of the usual cost.[40] Northwestern University's Prosthetics-Orthotics Center is at the forefront of the CAD/CAM movement with their "Squirt Shape" technique.[38] On the design side, they are using new technology such as the Inspeck 3D Mega Capturor optical system and ShapeMaker software. The former can digitize complex shapes such as residual limbs with the aid of up to 7,800,000 sampled points from a single camera, and the latter creates three-dimensional models that can be digitally modified to relieve pressure in a sensitive area by applying it in a more tolerant location. On the manufacturing side, they use a deposition modeler, which can extrude hundreds of layers of plastic, thermally bonded together, in any complex three-dimensional shape, including prosthetic sockets. Fabrication is totally automated, and thus, a finished product can be produced in less than an hour with a dollar's worth of raw materials. One can envision that centralized prosthetic centers could easily provide sockets and liners for patients with decreased fabrication errors and inconsistencies on a large scale. This is a dramatic shift from the current state of prosthetic rehabilitation, which is more art than science and is taught in an apprenticeship model.

Actuators convert available potential energy to actual work, and, much like batteries, are valued in terms of their power density. Engineered actuators are much more efficient than human muscle, yet have higher expectations still given the limited space for stored energy. The current gold standard is the brushless DC motor, which requires less maintenance and delivers a higher-powered output at a smaller size than its predecessors. Electromagnetic motors waste significant energy in the speeding up and slowing down with each movement, however. Potential alternatives are under development, such as mesofluidic actuation, which uses pressurized fluid for the creation of force and has a much greater power density than conventional electric motors. Although traditional hydraulics have lost their mechanical advantage when miniaturized, researchers have linked antagonistic joint movements and recently patented a fully mesofluidic actuated digit.[25,26] Another potential solution to the energy lost with brushless motors is *cobotics*. In cobotic actuation, a central electromagnetic motor spins continuously and has multiple outputs, which can actuate motion individually or in unison.[35] This would be ideal for the complex, multidimensional motions that the upper extremity must perform at multiple joints to have more naturalistic movements. Cobots preserve the energy lost in stopping/starting conventional electric motors, but current advances in development have yet to produce a cobot small enough to become a component of a terminal prosthetic device.

SUMMARY

A major amputation of an upper extremity can be severely disabling. The human hand is a true marvel that engineers have been trying to re-create since the Industrial Revolution. Our hands not only play a role in our ability to perform our daily activities but are also integral in how we communicate with others and how we view our own humanity. Early prosthetic rehabilitation is critical in maximizing patient outcomes; significant evidence demonstrates that delays in prosthetic rehabilitation lead to a greater likelihood of prosthetic abandonment over the long term. Current upper extremity prosthetic options have significant limitations, but they can often result in a patient's return to a fulfilling life at work and play.

The field of prosthetics and biomechanical engineering has seen a surge in interest and research funding in parallel to the surge of young men and women with limb loss returning from overseas conflicts. Lighter materials, smaller and faster processors, and newer batteries have contributed positively to the functional recovery of this patient population over the past decade. Significant challenges remain, however, because new devices are prohibitively expensive and still fail to provide the necessary haptic feedback for optimal functional restoration. Neural-machine interfaces are an exciting area of research and development but require much more study prior to integration

into clinical practice. Surely, the next decade will be an exciting time in the field of prosthetics and neural engineering, and one hopes that over time, the loss of a limb will become more of a hurdle than a disability.

CASE STUDY 50.1

JD is a 38-year-old right-handed woman with a history of mantle irradiation for Hodgkin lymphoma and previous papillary thyroid carcinoma. She presents with paresthesias in the two right ulnar digits and axillary discomfort. The workup done outside the hospital, which includes an axillary lymph node biopsy, has not led to a diagnosis.

The examination reveals a thin woman who appears to be well. She has mild weakness of digital abduction and key pinch in comparison with the contralateral, nondominant side. An exquisitely tender mass is present in the axilla.

What is the differential diagnosis of an isolated axillary mass?

ANS:

Adenitis	Cat-scratch disease	Metastatic cancer
Aneurysm of artery	Cystic hygroma	Sarcoma
Arteriovenous malformation	Hidradenitis	Schwannoma
Accessory breast tissue	Lymphangitis	Tuberculosis
Breast cancer	Lymphoma	

Magnetic resonance imaging studies (MRIs) are shown in eFigure 50.1. Biopsy guided by computed tomography shows histologic findings of a high-grade spindle cell tumor with fasciculating patterns.

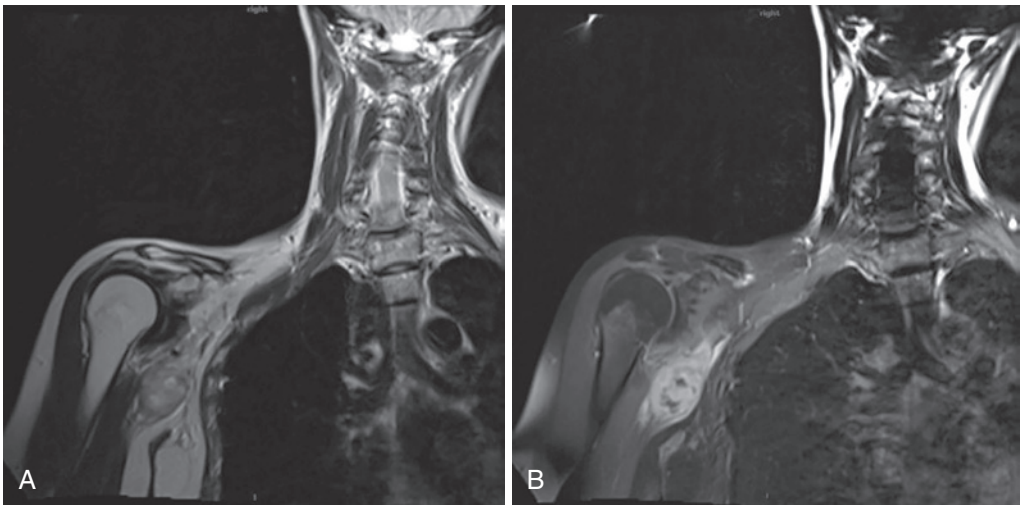
The tumor board consensus for diagnosis is a radiation-induced malignant peripheral nerve sheath tumor.

What is the treatment of choice for this type of tumor?

ANS: As for most sarcomas, the mainstay of treatment for malignant peripheral nerve sheath tumors is surgical resection with negative margins. Irradiation is often added preoperatively to make limb salvage more technically feasible. Chemotherapy is added for large, deep, and high-grade tumors, as well as for those with evidence of metastases.

The patient undergoes 11 courses of radiation therapy and 2 courses of chemotherapy with doxorubicin, ifosfamide, and mesna. A repeat MRI shows interval growth. The tumor board recommends interscapulothoracic amputation.

The surgical procedure is demonstrated in eFigure 50.2.



eFigure 50.1 **A** and **B,** Magnetic resonance images.

CASE STUDY 50.2

AM is a 67-year-old right-handed, critically ill man who developed ischemia of the left hand secondary to a thrombosed radial artery resulting from an arterial line and vasopressors. The patient underwent radial artery thrombectomy, carpal tunnel release, and hand fasciotomies. Intrinsic muscles appeared nonviable. Continued vasopressor usage led to gangrene of all digits and the distal palm, even with Doppler signals in palmar arches (eFigure 50.3).

What level of amputation would provide the most prosthetic options?

ANS: The patient could undergo a wrist disarticulation or a transradial amputation. The former preserves the distal radioulnar joint and maximum pronation and supination, and the latter offers the most options for prosthetic rehabilitation. The ideal level of amputation is 8 to 10 cm proximal from the styloids.

The surgical procedure is shown in eFigure 50.4.

COMPARTMENT SYNDROME

Acute compartment syndrome (ACS) of the extremity is a diagnosis requiring emergent surgical intervention. It is characterized by sustained elevation of tissue pressure within an osseofascial or fascial compartment that exceeds tissue perfusion pressure. This results in local circulatory impairment, ischemia, cellular anoxia, and ultimately tissue death. ACS represents the acute phase of the injury during which time surgical intervention can reduce the extent of irreversible muscle injury. Timely diagnosis and treatment are critical in reducing the extent of permanent changes within muscle and nerve tissue. Even with emergent treatment, there may be permanent disability in the affected extremity and a subsequent need for additional surgery, including amputation.[22] Volkmann ischemic contracture represents the late sequelae of compartment syndrome. This disorder has a spectrum of fixed muscle contractures and muscular and neurologic impairments. Numerous authors have contributed to our understanding and treatment of this condition. Table 51.1 summarizes some of the historical events in the recognition of this entity, its etiology, its pathologic findings, and its sequelae.

Types of Compartment Syndromes

Acute Compartment Syndrome

Acute compartment syndrome (ACS) occurs when tissue pressures rise high enough within an osseofascial compartment to cause tissue ischemia. The resultant tissue injury can range from reversible muscle swelling to permanent tissue necrosis depending on the magnitude and duration of tissue pressure elevation. When pathologic tissue pressure elevation has been present for less than 4 hours, ACS is in the early stage[39]; when pathologic tissue pressure elevation has been present for more than 4 hours, ACS is in the late stage.

Impending Compartment Syndrome

Impending compartment syndrome represents a clinical setting in which a compartment syndrome is at risk of developing; however, tissue pressure is not yet sufficiently elevated to cause muscle ischemia. Clinical scenarios in which this may occur include limb reperfusion after prolonged ischemia, posttraumatic swelling of a limb, or high-energy injuries.

Exercise-Induced or Exertional Compartment Syndrome

Exercise-induced compartment syndrome is a reversible tissue ischemia due to a noncompliant fascial compartment that is unable to accommodate muscle expansion occurring during exercise. It has been described in both the upper and lower extremities and is different from ACS in that the symptoms are reversible after cessation of exercise. Emergent surgery is not usually indicated.[10,90] Both traditional fasciotomy and endoscopically assisted fasciotomy have been used to treat exercise-induced compartment syndrome.

Crush Injury or Crush Syndrome

Crush injury is the external compression of an extremity, as might occur in a building collapse or construction injury or in an obtunded patient who lays on an extremity for a prolonged period. The compression of the extremity leads to muscle ischemia and reperfusion injury as the compression is relieved. This process of events can lead to compartment syndrome. *Crush syndrome* is a localized crush injury with systemic manifestations. Reperfusion of the affected extremity can rapidly release muscle breakdown products into the system, which can lead to renal failure or death.[13]

Neonatal Compartment Syndrome and Neonatal Volkmann Contracture

Both neonatal compartment syndrome and neonatal Volkmann contracture have been reported. Awareness of this diagnosis is important because early recognition and treatment can improve the functional outcome and growth in neonatal compartment syndrome. In addition to swelling of the forearm, there is often a characteristic skin lesion on the proximal lateral arm, known as the *sentinel lesion of neonatal compartment syndrome*.[66]

TABLE 51.1 Events in the Recognition and Understanding of Compartment Syndrome

Author and Year	Development
Volkmann, 1881[87a]	First thorough description of this entity with attribution of the cause to muscle ischemia
Leser, 1884[41a]	Animal investigations; concluded that the pathologic findings were a result of oxygen deprivation
Hildebrand, 1890[45a]	First to use the term *Volkmann's contracture*; now sometimes referred to as *Volkmann-Leser contracture*
Bardenhauer, 1906[4a]	Release of internal pressure through a forearm fasciotomy to treat an impending Volkmann contracture
Brooks, 1922, 1925[9a,9b]; Jepson, 1926[45a]	Animal model used to reproduce compartment syndrome through vascular occlusion; muscle necrosis could be prevented by surgical decompression of the muscle compartment
Griffiths, 1940[35a]	Emphasized arterial injury and reflex spasm of the collateral vessels as the sole source of muscle ischemia; minimized the role of tight external dressings as the cause of muscle ischemia
Seddon, 1956[74] and 1964[73]	Described the pattern of muscle infarction common in compartment syndrome (ellipsoid infarct) and treatment with infarct excision; also highlighted the importance of ischemic injury to nerves
Holden, 1975, 1979[41b,42]	Reestablished both intrinsic and extrinsic causes of muscle ischemia; distinguished two patterns of injury leading to muscle ischemia: Type 1: Arterial insult proximal to the site of ischemia Type 2: Elevated intrinsic pressure within the compartment from either internal or external sources
Matsen, 1975[57]	Unified concept of compartment syndrome
Whitesides, 1975[89]	Tissue pressures as a determinant of the need for fasciotomy

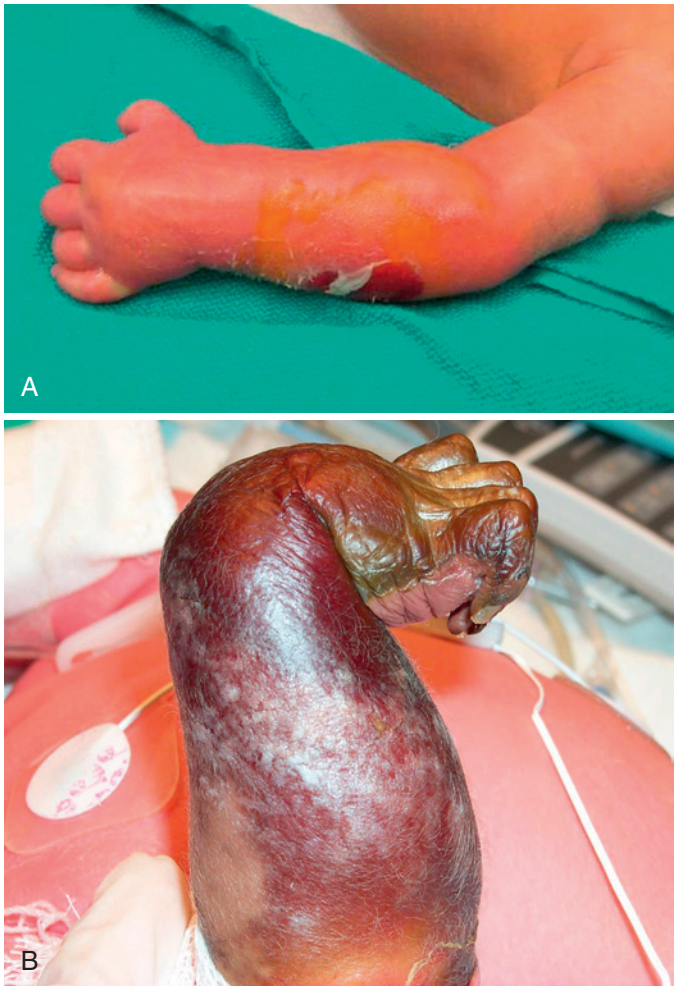

FIGURE 51.1 A, Neonatal compartment syndrome. Note the hallmark sentinel lesion at the lateral proximal forearm. **B,** Neonatal Volkmann contracture. The entire forearm is necrotic. This patient underwent amputation at the proximal forearm. (**A,** See Ragland RI, Moukoko D, Ezaki M, et al: Forearm compartment syndrome in the newborn: report of 24 cases. *J Hand Surg [Am]* 30(5):997–1003, 2005.)

Established neonatal Volkmann contracture cannot be improved by early intervention; however, awareness of this diagnosis can aid in counseling of the family and treatment of the patient (Figure 51.1, *A* and *B*).

Volkmann Ischemic Contracture

Volkmann ischemic contracture is the end result of prolonged ischemia, is associated with irreversible tissue necrosis, and has a spectrum of presentations.

Etiologic Findings and Incidence

Compartment syndrome in the upper extremity is most commonly associated with trauma. A variety of conditions and injuries can lead to ACS. These include fractures, penetrating trauma, closed soft tissue injuries, infection, animal and insect bites, extravasation injuries, ischemia-reperfusion injury, external compression by tight dressings or casts, burns, or crush injuries. Compartment syndrome in the absence of fracture should raise concern about an underlying bleeding disorder (Figure 51.2).

The incidence of upper extremity compartment syndrome is difficult to determine. The estimated incidence in pediatric upper extremity fractures is approximately 1%.[36] In a large series of trauma patients, the incidence of fasciotomy associated with all upper extremity traumas was 0.41%. Branco and colleagues[9] noted a decreasing incidence of the need for surgical fasciotomy over a 10-year period, despite stable injury severity scores, with the overall incidence for upper and lower extremity trauma decreasing from 3.2 to 0.7%. They suggested a possible explanation for the declining incidence as the diminished use of crystalloid for fluid resuscitation and the use of mannitol to decrease extracellular fluid volume. Fasciotomy rates associated with traumatic arterial injury ranged from 6.7 to 16%.[30,83]

Historically, ACS of the upper extremity in the pediatric population was most commonly reported in association with supracondylar humerus fractures. Likely, this was related to the historical treatment methods of casting with the elbow in a position of hyperflexion. Currently, pediatric fracture patterns most associated with forearm compartment syndrome are both-bone forearm fractures and supracondylar humerus fractures associated with distal radius fractures (i.e., floating elbow

FIGURE 51.2 This 4-year-old presented with hand and forearm swelling after minor trauma. Other areas of bruising were noted. After workup, the child was found to have hemophilia A. He underwent fasciotomy of his hand and forearm. **A,** Swelling of the hand and forearm. **B,** After dorsal fasciotomy of the hand and volar extended carpal tunnel release and forearm fasciotomy. **C,** Bruising of the periorbital region.

injury).[6,36,46,93] In adults, the most common upper extremity fractures associated with compartment syndrome are distal radius fractures and both-bone forearm fractures.[25,46]

Compartment syndrome is more prevalent in males younger than 35 years of age, penetrating trauma, open fractures, elbow dislocations, and vascular injuries.[9,25,58] The need for surgical fasciotomy increases dramatically when vascular injury is present.[22,30] Compartment syndrome in the hand is most commonly associated with intravenous injections.[63]

Pathophysiologic Findings

The pathophysiology of ACS is complex. Several theories and models have been developed. The common prerequisite is a soft tissue structure (usually fascia) that prevents muscle expansion when the muscle is exposed to increased fluid volume. In all cases, the final common pathway is cellular anoxia.

Matsen presented a "unified concept" of compartment syndrome that incorporates several mechanisms of vascular compromise all leading to cellular injury.[57] Increased compartmental pressure occurring from either internal injury (edema, reperfusion, or bleeding) or external injury (tight cast or dressing, pressure garment) causes a decreased perfusion gradient between arteriole and venous pressures and a resultant decrease in local tissue perfusion. Decreased tissue perfusion results in further tissue insult, increased capillary leakage, and further increase in intracompartmental pressure. This causes a vicious cycle of increasing cellular ischemia leading to further capillary leakage and swelling and increasing compartment pressures (Figure 51.3).

Ongoing ischemia eventually leads to cell death and lysis of the myocyte. Degradative enzymes are activated and released into the interstitial tissues, causing further tissue necrosis. The extent of muscle injury depends on the duration of ischemia and the metabolic rate of the tissue. Prolonged ischemia can ultimately lead to liquefactive necrosis of the muscle compartment.

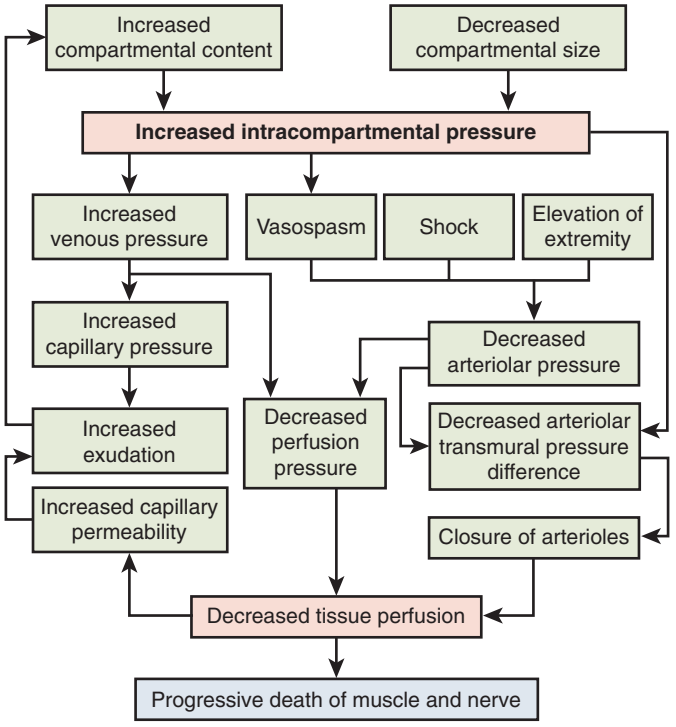

FIGURE 51.3 Schematic representation of factors contributing to the vicious cycle of compartment syndrome, based on the descriptions of Holden and the proposed unified concept theory of Matsen. (See Holden C: The pathology and prevention of Volkmann's ischaemic contracture. *J Bone Joint Surg Br* 61(3):296–300, 1979; and Matsen FA, 3rd: Compartmental syndrome: a unified concept. *Clin Orthop Relat Res* 113:8–14, 1975.)

Diagnosis

Diagnosis of Acute Compartment Syndrome

The diagnosis of ACS is principally based on clinical examination. Maintenance of a high index of suspicion, particularly in the setting of at-risk injuries and conditions, aids in the prompt recognition and treatment of this condition.

Although compartment syndrome is frequently associated with fractures, many other causes can also lead to ACS. Causes are commonly separated into intrinsic causes (typically, bleeding or swelling into a compartment) and extrinsic causes (applied external pressure preventing a compartment from expanding) (Box 51.1). The physician must keep this in mind because ACS not associated with fracture frequently has a delayed diagnosis and worse clinical outcomes.[43,65]

BOX 51.1 Injuries That May Lead to Compartment Syndrome

Intrinsic Injuries

High-energy fracture, usually in young male (open fractures more at risk than closed fractures)

Fracture in child

- Supracondylar fracture of humerus, especially one associated with distal radius fracture[6,44a]
- Both-bone forearm fractures (intramedullary nailing of pediatric both-bone and radial head fractures is associated with difficult reduction and prolonged tourniquet times[93])

Fracture in adult

- Distal radius fracture
- Upper extremity fractures associated with vascular injury
- Soft tissue trauma without fracture
- Blunt trauma without fracture or skin violation)

Penetrating trauma (usually from bleeding into otherwise closed compartment)

Vascular injury

- Trauma
- Iatrogenic procedures, such as venipuncture or arterial blood draw
- Reperfusion after prolonged ischemia
- Prophylactic fasciotomy should be considered after vascular repair[28,30]

Burns

- Edema associated with burn injury
- Electrical burns associated with deep muscle damage and edema
- Systemic inflammation and fluid resuscitation
- Burn eschar causes an extrinsic compression

Animal and insect bites (e.g., Crotalidae [pit viper] snakebite)

- Treatment of impending compartment syndrome from snakebite should be with antivenin
- (Crofab [ovine]; Antivenin Crotalidae Polyvalent ACP [equine])
- Rarely requires surgical decompression

Intravenous fluid extravasation (hypertonic fluids such as intravenous contrast material)

- Intraoperative fluid extravasation, particularly in patients where the arm position does not allow easy visualization of the extremity, and when infusion pumps are used[4b]

Infection

Bleeding disorders

- Coagulation disorders (e.g., von Willebrand hemophilia)
- Anticoagulation therapy
- Spontaneous bleeding may occur with no trauma or minor trauma

Extrinsic Injuries

Compressive casts or dressings

Burn eschar (circumferential inelastic eschar)

- Important to release fingers with dermotomies if burn involves the hand

Crush injury

- In obtunded patient during drug or alcohol overdose
- Resulting from coma, seizure, or hypoglycemic episode
- Building collapse
- Intraoperative positioning (prone or lateral positioning with poorly positioned axillary or chest roll causing axillary artery occlusion; also seen in the lower extremity with prolonged lithotomy position)

The timing of presentation can vary from within the first few hours of injury to several days following injury.[70,76]

The hallmarks of diagnosis of ACS have classically been described as the six *P*s of compartment syndrome (Table 51.2): pain, pressure, paresthesias, pallor, paresis, and pulselessness. Some authors have added or substituted poikilothermia of the extremity as one of the *P*s. This use of the term *poikilothermia* is not completely accurate but indicates that the affected extremity is cool relative to body temperature. In most series, pain has been the earliest and most reliable finding. However, pain peaks at 2 to 6 hours of ischemia and then gradually subsides as muscle necrosis progresses and nerve function becomes impaired. Therefore, patients with a late presentation of or late diagnosis of compartment syndrome have less pain than those with an earlier presentation.

It has been suggested that in pediatric patients, "it's the *A*s, not the *P*s" that signal ACS.[49] These *A*s are an increasing requirement for analgesia, the presence of anxiety (or restlessness), and the presence of agitation (or crying).[3,49] Children are unable to articulate the feeling of paresthesias, and sensibility testing is unreliable.

Certain conditions can make the clinical diagnosis of ACS challenging. Altered levels of consciousness as can occur in head trauma, a medically induced coma, or obtundation from other causes can obscure the normal pain response that is one of the early signs of compartment syndrome. Similarly, distracting pain from polytrauma, neurologic injury in the affected limb, and/or regional anesthetic blockade can mask the signs and symptoms of compartment syndrome. Diagnosis is also more

TABLE 51.2 Diagnostic Findings in Compartment Syndrome

Sign or Symptom	Description
Pain	Described as deep, constant, often poorly localized pain that is disproportionate to the physical findings; often poorly responsive to analgesics Pain is accentuated with passive stretching of the involved compartment. Although this is the most consistent and reliable finding, cases of "silent" compartment syndrome of the lower extremity have been reported (Badhe) and likely also occur in the upper extremity. Pain usually peaks at around 2 to 6 hours of ischemia and then subsides. Patients who present late with acute compartment syndrome may not report as much pain.
Pressure	Affected compartment(s) are firm and noncompressible; often described as "rock hard"
Paresthesias	Numbness or "pins-and-needles" sensation in the cutaneous distribution of the nerves that traverse the affected compartment
Pallor	Usually pale, but the extremity may also appear blotchy and often cool (see poikilothermia)
Paralysis	Late and unreliable finding. Muscle paralysis may be pain related. When true paralysis is present, this is a poor prognosticator for recovery.
Pulseless	Also usually a late finding and poor prognosticator for recovery

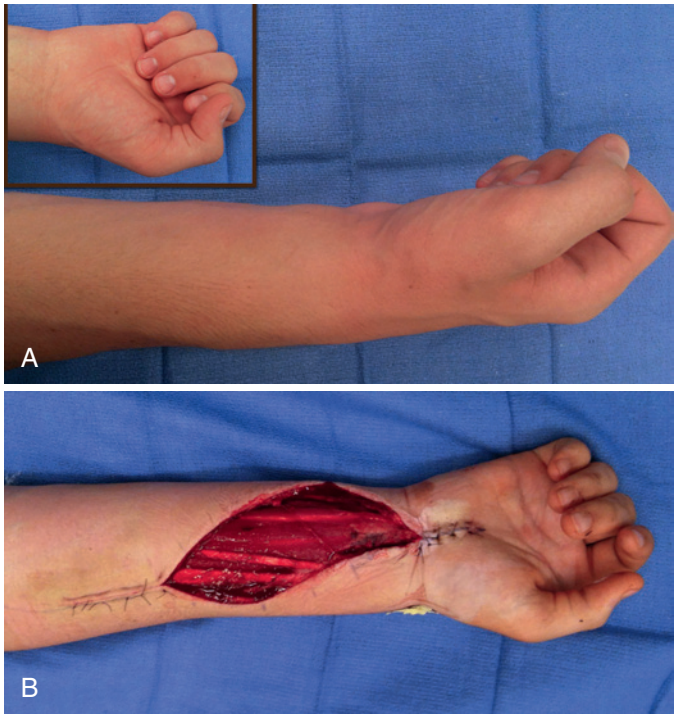

FIGURE 51.4 Localized compartment syndrome. This 16-year-old boy sustained a coronoid process fracture and a mildly angulated distal radius fracture through an old fracture malunion. He had pain and localized swelling at the distal forearm and subjective numbness in the median and ulnar distributions in the hand. His fingers were clenched and his thumb was flexed. He had pain with passive extension of the fingers. He underwent extended carpal tunnel release and fasciotomy. Compartment swelling was localized to the distal forearm. The proximal incision was closed at the time of primary surgery. Delayed primary wound closure was done after 4 days. **A,** Localized forearm swelling and clenched posture of the fingers and thumb. **B,** On postoperative day 2, persistent swelling of distal forearm musculature is present.

TABLE 51.3 Measurement of Compartment Pressures

Aspect of Measurement	Considerations
Patient position	Supine Measured extremity should be at heart level Measurements in uncooperative patients and children should be made with the patient sedated or in the operating room with the patient sedated
Needle	18-g straight, side-port, slit catheter, or wick
Transducer	Handheld digital (Stryker pressure transducer) Arterial line monitor
Needle placement	Perpendicular to muscle belly Several readings at multiple depths Near fracture site (see Figure 51.4, localized compartment) Near area of maximum tension
Threshold pressure	30 to 40 mm Hg Within 30 mm Hg of diastolic blood pressure or mean arterial pressure
Contraindications to measuring compartmental pressure	Underlying neurovascular structures at risk Coagulopathy Diffuse cellulitis

difficult in children and infants who may have difficulty in cooperating with examination, are nonverbal, or are apprehensive and crying. Also, the thicker layer of subcutaneous fat in children may contribute to a false sense of a soft compartment on palpation, further complicating the diagnosis. Diagnosis or exclusion of compartment syndrome on clinical grounds alone is often impossible.

If the clinician is uncertain of the diagnosis based on equivocal physical findings, compartment pressure can be measured (Figure 51.4 and Table 51.3). Several different methods can be used. Continuous pressure measurements can be obtained with a wick catheter or connection to a continuous pressure monitor.[59,89] Typically, the newer digital devices are used to assess or monitor the compartment.[7,21,38] These devices are sensitive to patient motion and should not supplant repeat clinical examinations. Although controversial, the thresholds/indications for fasciotomy are an absolute pressure greater than 30 to 40 mm Hg or pressures within 30 mm Hg of either the diastolic blood pressure or the mean arterial pressure.[79]

Although pulse oximetry of the affected extremity has not been found to be useful,[19,56] near-infrared spectroscopy (NIRS) may prove to be useful in the early diagnosis and monitoring of an impending compartment syndrome. This technique was proposed as a method of monitoring for compartment syndrome as early as 2001,[33] but it has not been widely adopted because of its cost and problems with availability of sensors and equipment. NIRS is noninvasive and capable of measuring the oxygenation state of at-risk tissues and may gain wider use in the future. NIRS is limited by the depth of tissue penetration (2 to 3 cm) and the presence of hematoma within the compartment.[20]

In these questionable clinical situations, the safer intervention is to perform a fasciotomy. Bulging of the muscle compartment and clinical softening of the extremity at the time of fasciotomy confirms the diagnosis.

Diagnosis of Exertional Compartment Syndrome

Chronic exertional compartment syndrome of the upper extremity has been described in the flexor compartment of the forearm and in the anconeus muscle; in the hand, it has been described specifically in the adductor of the thumb.[2,8,35,51,78,80,81] Patients with chronic exertional compartment syndrome typically complain of pain that starts as a dull ache within the first 30 minutes after starting an activity. Burning, cramping, or aching pain progresses as the activity is continued. The pain escalates to a level of discomfort where the patient can no longer continue or where it adversely affects the patient's performance. Activities associated with exertional compartment syndrome of the upper extremity include sports such as rowing, bicycle riding, or motorcycle riding or repeated episodes of manual labor requiring a prolonged grip or pinch. The pain and tissue firmness resolve spontaneously with cessation of the activities. Diagnostic studies have principally involved measurement of compartment pressures before, during, and after exercise.[8,10,84] More recently, magnetic resonance imaging has been used before and after exercise as a diagnostic tool. A signal change in

T2 imaging in an isolated fascial compartment associated with activity supports the diagnosis of exercise-induced compartment syndrome.[53]

PERTINENT ANATOMY

The compartments of the upper extremity are listed in Table 51.4. Any of these anatomic spaces can be affected by tissue pressure elevation. Although elevated tissue pressures are most commonly seen in osseofascial spaces, other tissue structures provide a rigid barrier that does not expand sufficiently to accommodate swelling. In the upper extremity, the fascial components and the skin can act as barriers that require decompression at the time of surgery.

Treatment

The goal of treatment is to prevent tissue necrosis, avert neurovascular compromise, and avoid permanent functional deficits. These devastating complications can be minimized or avoided with early recognition and prompt intervention.

The first step in treatment is to remove all possible extrinsic causes of pressure, including circumferential dressings, cast padding, and casts. Casts have been shown to restrict compartment expansion by 40%. Release of a cast and subsequent spreading reduces pressure elevation by 40 to 60% depending on the presence of dry or wet blood on the cast padding.[32] The limb should be elevated only to heart level. Although limb elevation may decrease swelling, it can also reduce perfusion to the affected limb, risking exacerbation of tissue ischemia.

A history of bleeding disorders or use of anticoagulation therapy should be obtained from the patient or family member. Laboratory analysis should include a complete blood count, prothrombin time, and partial thromboplastin time. If there is a suspicion of a bleeding disorder, a hematologist should be involved in the evaluation and treatment of the patient. Urinalysis for myoglobin, serum electrolytes, creatinine, and myoglobin should be obtained in the setting of prolonged ischemia, crush injury, or ischemia-reperfusion injury. Medical management of shock, hypoxia, metabolic acidosis, and electrolyte imbalance should be addressed immediately. Supportive care with vigorous hydration, correction of metabolic function, and treatment of hyperkalemia is necessary to prevent sequelae such as renal failure, shock, hypothermia, cardiac arrhythmias, or cardiac failure. Supportive care should be initiated in the emergency room but should not delay surgical treatment.

Hypertonic mannitol has been used to lower intracranial pressure. The use of mannitol in decreasing extremity swelling has been described in animal models and limited case studies. It has not gained widespread use for treatment of impending or acute compartment syndrome. Nonetheless, it has been hypothesized that the use of mannitol may have played a role in the decreased incidence of compartment syndrome in trauma patients at a single medical center over a 10-year time period.[9] Hypertonic mannitol has been found to decrease endothelial swelling and may help reduce muscle necrosis in its function as an oxygen-free radical scavenger.[62] In one clinical report, patients were given a 100-mL bolus of 20% mannitol, followed by an infusion of 10 g/hour for 6 to 24 hours.[11]

Emergent surgical decompression (fasciotomy, or release of the fascia overlying the affected compartments) performed as quickly and safely as possible is needed for ACS. Fasciotomy

TABLE 51.4 Compartments of the Upper Extremity

Compartments			Contents
Arm	Anterior		Biceps and brachialis muscles, brachial artery, and median nerve
	Posterior		Triceps muscle and ulnar and radial nerves
	Deltoid	Not technically a separate compartment but has a thick epimysium that may require decompression	
Forearm	Volar	Superficial	Flexor carpi radialis, palmaris longus, pronator teres, flexor carpi ulnaris, and flexor digitorum superficialis muscles
		Deep	Flexor digitorum profundus, flexor pollicis longus, pronator quadratus muscles,* and anterior interosseous nerve and artery
	Dorsal	Mobile wad	Brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis muscles

*Reported isolated involvement in exertional compartment syndrome.
†The supinator muscle is not typically a component of the extensor compartment, but decompression can be done through the brachioradialis/extensor carpi radialis longus interval.
‡Compression of the neurovascular structures by rigid Cleland and Grayson ligaments can lead to skin necrosis and/or loss of the finger.

within the first 8 hours after diagnosis is associated with a lower risk of permanent functional impairment. Release of the epimysium surrounding the muscle may also be necessary. Necrotic tissue should be excised because it may become a nidus for infection or lead to subsequent fibrosis and contracture. Questionable tissue should be left in place for a second look at a later date. Late fibrosis of necrotic muscle can lead to compression of the adjacent nerves and further impair extremity function. Other concomitant procedures may be indicated based on the cause of the compartment syndrome, including fracture reduction and stabilization, vascular repair, and nerve exploration if indicated. Nerve repair or grafting should be performed at the time of definitive wound closure.

Late or delayed diagnosis increases the risk for severe complications, including infection, neurologic injury, need for amputation, and death. In the past, concerns about an increased risk of infection have led some authors to recommend not performing a fasciotomy after 24 hours has elapsed since the onset of symptoms. We do not feel this risk outweighs potential benefits and no longer consider this a contraindication for surgery. Currently, there are more options for wound management and antibiotic therapy. Removal of necrotic muscle can decrease the severity of subsequent muscle fibrosis and joint contracture. Débridement of nonviable muscle improves the environment for the neurovascular structures and may allow early functional reconstruction of the lost muscle(s) by means of tendon transfers or free functional muscle transfers (FFMTs).

In addition, the length of time that elevated pressure sufficient to cause tissue necrosis has been present is often unclear, and some muscle preservation may be facilitated with late fasciotomy. In some cases, good results in children have been reported following fasciotomy as late as 72 hours after the injury (within the acute swelling phase).[29] Dramatic, essentially full, recovery has been reported following compartment syndrome of the lower leg in children after delayed presentation.[15]

Surgical Procedure

Indications. The indications for surgical fasciotomy are described previously. Our preference is to manage questionable cases of impending compartment syndrome with surgical decompression, provided the patient is stable enough for the procedure. Prophylactic fasciotomies should be performed following vascular repair/reconstruction where ischemia time exceeds 3 hours.[28] Shorter periods of ischemia do not eliminate the risk of developing compartment syndrome, and careful monitoring is necessary after vascular surgery.

Contraindications. Contraindications to fasciotomy are few. Coagulopathy should be corrected prior to surgical intervention. Plasma, factor, or platelet transfusion may be necessary to optimize the patient for surgery. Intubated patients who are not stable for surgery should be considered for a bedside fasciotomy using local anesthesia and sedation.[26]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

The surgical incision for the upper extremity is extensile from the brachium to the carpal tunnel. The extent of the release performed is tailored to the clinical and intraoperative findings. Release of the dorsal forearm and compartments of the hand requires separate incisions when indicated. A separate incision for a dermotomy of each of the fingers may also be added to prevent skin necrosis and loss of the fingers.

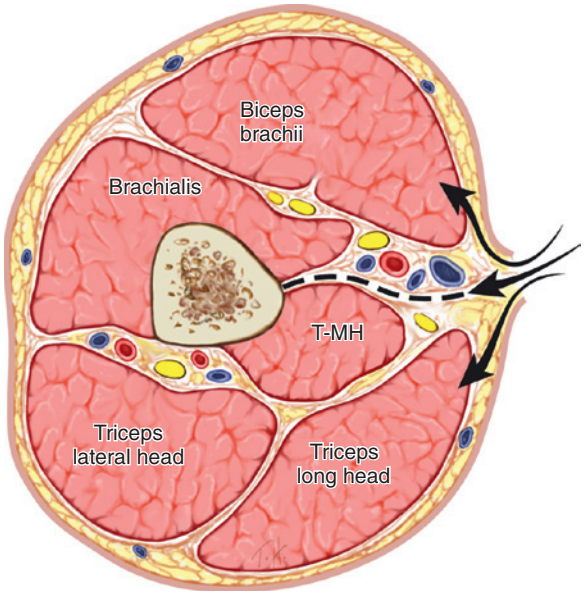

FIGURE 51.5 Cross section of the midarm with *arrows* showing the plane of dissection for decompression of the anterior and posterior compartments. Alternatively, separate anterior and posterior incisions can be used. *T-MH,* Triceps, medial head.

Release of the Compartments of the Arm. The anterior and posterior compartments of the arm can be decompressed through a single medial incision. This allows access to the neurovascular structures of the arm, the medial fascia of the biceps and brachialis in the anterior compartment, and the fascia of the triceps. Excision of the medial intermuscular septum will provide additional decompression of both compartments (Figure 51.5). The incision can be easily extended to the elbow crease and incorporated with the incision for decompression of the forearm. This also allows release of the lacertus fibrosus and access to the brachial artery. When there is no anticipated need to evaluate the brachial artery or to decompress the forearm compartments, fasciotomies can be performed through separate anterior and posterior midline incisions to decompress the flexor and extensor compartments, respectively.

Release of the Compartments of the Forearm. Several skin incisions have been described for the forearm. Because the surgical incisions are long and extensile, almost any incision can be used to decompress the forearm compartments (Figure 51.6). Because the incisions are left open, we prefer an incision that minimizes exposure of neurovascular structures and can be extended in a proximal direction into the medial arm and in a distal direction into the carpal tunnel (see Figure 51.6, *A* and *B*). Once the skin incision has been made, the antebrachial fascia is incised longitudinally from the lacertus fibrosus to the wrist flexion crease. This decompresses the superficial flexor compartment. The deep flexor compartment is most easily and safely exposed through the ulnar side of the forearm.[69] We begin at the mid to distal forearm and identify the interval between the flexor carpi ulnaris and flexor digitorum superficialis. The flexor digitorum profundus and flexor pollicis longus fascias are exposed and released through this interval (Figure 51.7). This is the most important component of this procedure because the

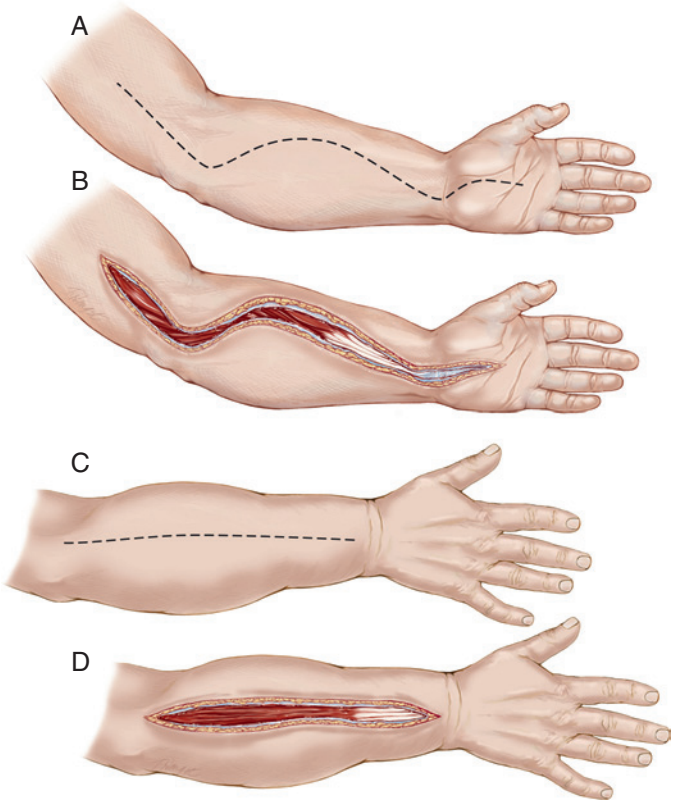

FIGURE 51.6 Extensile incision for decompression of the forearm: The incision can be extended proximally to decompress the arm and distally into the carpal tunnel. **A,** Line of skin incision for volar release. **B,** Volar incision opened from the midarm to the carpal tunnel. **C,** Line of the dorsal incision. **D,** Dorsal incision opened and fascia released.

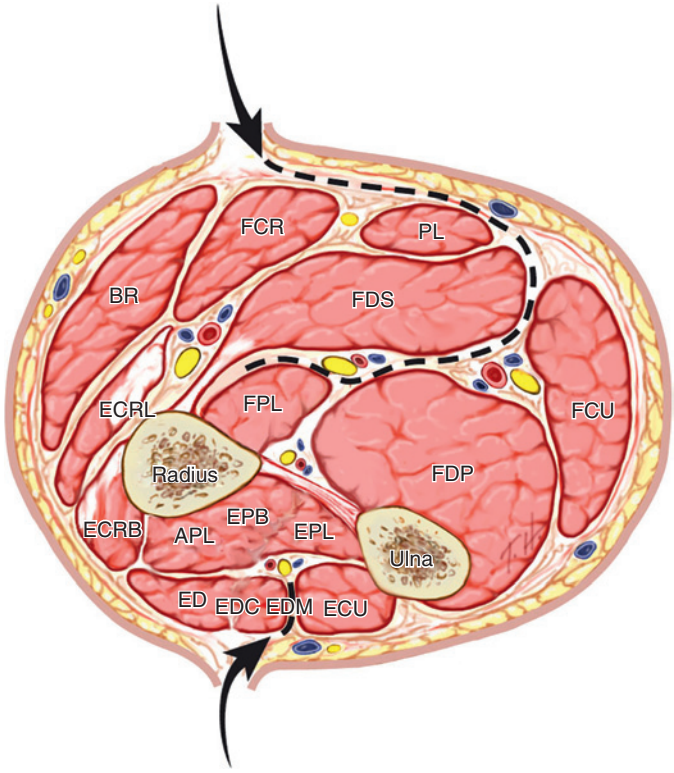

FIGURE 51.7 Cross section of the midforearm with *arrows* showing the plane of dissection for decompression of the superficial and deep flexor compartments of the volar forearm and the dorsal forearm. *APL,* Abductor pollicis longus; *BR,* brachioradialis; *ECRB,* extensor carpi radialis brevis; *ECRL,* extensor carpi radialis longus; *ECU,* extensor carpi ulnaris; *ED, EDC,* extensor digitorum communis; *EDM,* extensor digiti minimi; *EPB,* extensor pollicis brevis; *EPL,* extensor pollicis longus; *FCR,* flexor carpi radialis; *FCU,* flexor carpi ulnaris; *FDP,* flexor digitorum profundus; *FDS,* flexor digitorum superficialis; *FPL,* flexor pollicis longus; *PL,* palmaris longus.

deep flexor compartment is usually the one first and most affected by increased compartmental pressure. Through the same interval, the fascia overlying the pronator quadratus is released.

During the dissection, if the muscles appear pale after release of the fascia, additional release of the epimysium of the pale muscle should be performed. For these muscles, if the epimysium is not released, reperfusion injury will lead to additional swelling within the muscle and further muscle damage.

Clinical evaluation of the remaining tension in the dorsal forearm compartment and/or hand should be done to determine whether additional release of the extensor and hand compartments should be added.

The extensor compartments are released through a midline longitudinal dorsal incision extending from the lateral epicondyle to the distal radioulnar joint. This will allow release of the mobile wad and the extensor compartment (Figure 51.8 and see Figure 51.6, *C* and *D*).

Release of the Compartments of the Hand. The hand has 10 separate compartments. It is rarely necessary to release all 10 compartments, and intraoperative assessment and/or measurement of compartment pressures should be used to determine the extent of release needed (Figures 51.9 and 51.10).

Volar Release. Decompression should start with an extended carpal tunnel release. Carpal tunnel release will usually adequately release the Guyon canal without division of the volar carpal ligament (roof of the Guyon canal) and directly decompress the ulnar neurovascular structures. The carpal tunnel incision can be extended to the second volar web space. In the distal portion of the incision, the volar fascia of the adductor pollicis muscle can be released. Also, the fascia extending from the long finger metacarpal to the palmar fascia (separating the deep radial and ulnar midpalmar spaces) can be released. This will help decompress the volar interosseous muscles. The thenar and hypothenar muscles are decompressed through separate incisions as needed.

Dorsal Release. The dorsal interosseous muscles (and volar interosseous muscles) are decompressed through dorsal incisions between the second and third metacarpals and fourth and fifth metacarpals. The first dorsal interosseous muscle is decompressed through an incision placed in the first dorsal web space. The dorsal fascia of the adductor pollicis can also be released through this incision (see Figure 51.9).

Release of the Fingers. Tense swollen fingers can result in skin and subcutaneous tissue necrosis. The tight fibers of Cleland and Grayson ligaments can compress and obstruct the digital arteries. Dermotomy of all involved fingers reduces the risk of necrosis of the skin and possible loss of a digit. Dermotomies should be done in the midaxial plane to prevent subsequent contracture. When possible, the dermotomy should be performed on the side that will cause the least amount of scar irritation. The preferred locations for finger and thumb dermotomies are shown in Figure 51.9, *A* and *B*.

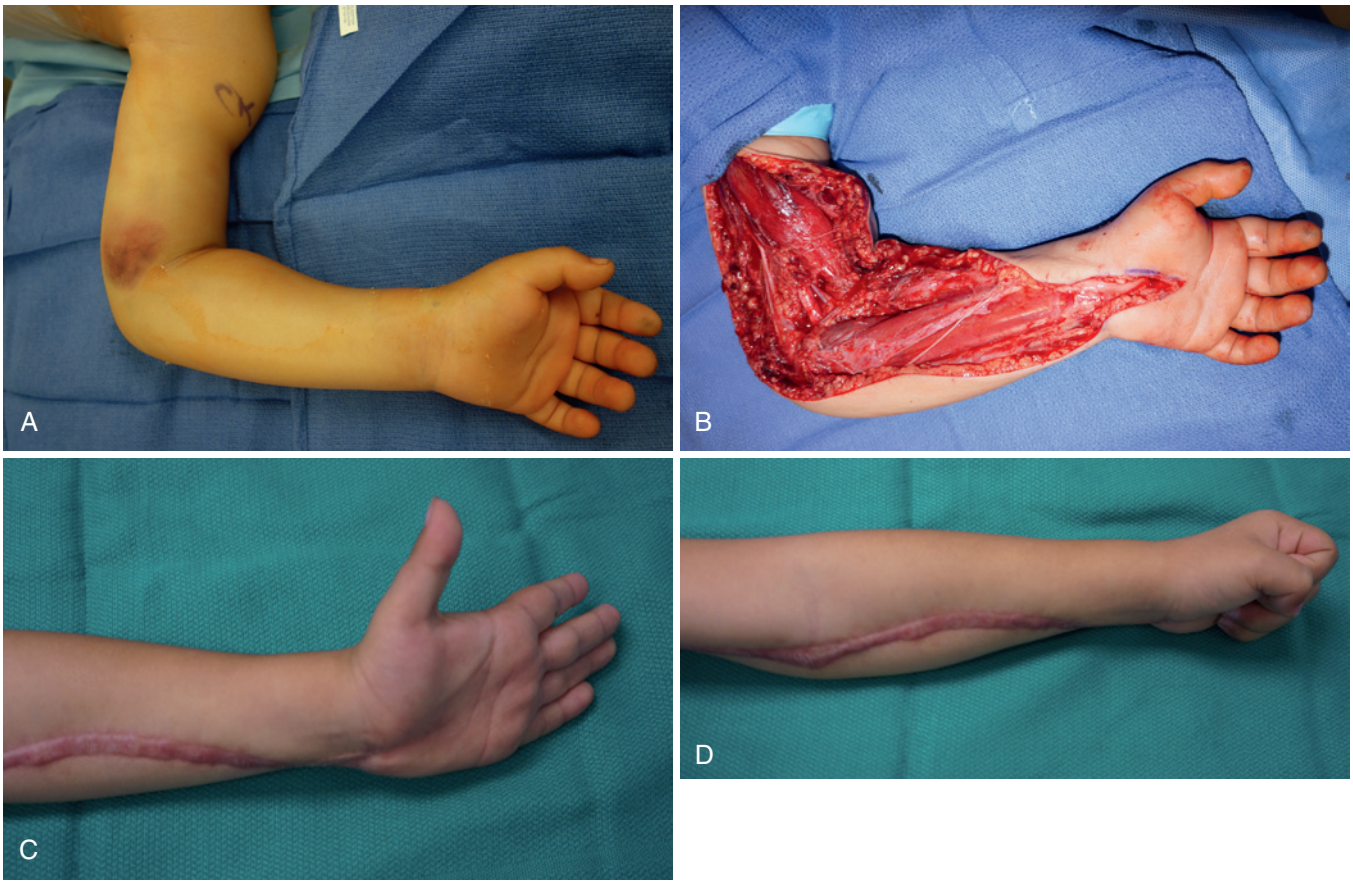

FIGURE 51.8 This 5-year-old patient sustained a type 3 100% displaced supracondylar humerus fracture that was treated with closed reduction and pinning. Approximately 6 hours after surgery, the patient had increased pain and analgesia requirements. On examination, the compartments were tense and swollen. He was taken emergently for fasciotomy of the arm and forearm. **A,** Appearance of the arm after closed reduction and pinning after patient returned to the operating room. **B,** Fasciotomy of the arm and forearm. **C,** Final finger and wrist extension after 6 months. **D,** Final finger flexion after 6 months.

See Case Study 51.1 and Video 51.1 for further information on compartment release of the arm, forearm, and hand.

Postoperative Management

All surgical incisions are left open. We prefer not to use retention sutures. Even if there is minimal swelling of the muscle(s) during the primary release, muscle swelling will usually increase after perfusion has improved. If nerves and arteries are not exposed, a negative-pressure wound dressing (e.g., VAC, Kinetic Concepts, Inc., San Antonio, TX) can be used. We use lower pressures for the negative pressure dressing than in other wounds, usually just enough to maintain good seal on the dressing. If nerves or arteries are exposed, we prefer to use a moist gauze dressing. Dressing changes should be done in the operating room at 24 to 48 hours. Partial delayed primary wound closure can be performed at that time if swelling has decreased and/or to provide coverage over open neurovascular structures. Definitive delayed primary wound closure should be performed only after swelling has decreased. Some cases will require repeat débridement of necrotic tissue. Split-thickness skin grafting for closure is necessary in many patients. Younger patients with high-energy or crush injuries are more likely to require split-thickness skin grafting at 48 hours.[25] In our practice, we prefer to manage the wound until swelling decreases sufficiently to allow delayed primary wound closure if possible, which may require 7 to 10 days. In the hand, only the incision for the carpal tunnel release should be considered for delayed primary wound closure. The other palmar and dorsal incisions as well as the dermotomy incisions will heal quickly by secondary intention. If the skin cannot be closed without tension, split-thickness skin grafting with or without dermal substitutes such as Integra (Integra, Plainsboro, NJ) should be used.

Therapy should be started immediately following surgery to promote maximum active and passive range of motion of the fingers. Splinting should be done for soft tissue stabilization and/or for treatment of other associated injuries. Cessation of therapy during healing of skin grafts may be necessary, but therapy should be resumed as soon as tissue healing allows. Once the soft tissues are adequately healed, nighttime splinting is continued to prevent contractures of the wrist and fingers. Splinting is continued until scars and soft tissues are mature and supple.

Outcomes and Expectations

Outcomes following fasciotomy depend on the duration and severity of the compartment pressure elevation and the resultant extent of muscle necrosis. Early prompt fasciotomy within the first 4 hours usually results in minimal sequelae. Delayed management results in muscle fibrosis and contracture that varies with the extent of muscle necrosis and nerve

CASE STUDY 51.1 Compartment Syndrome of the Upper Extremity

Surgical Approach to Treatment

All or portions of this approach can be used, depending on the clinical setting. The approach is extensile from the arm to the distal forearm, and separate incisions are required to release the extensor compartment (when indicated). Multiple incisions are used to release the compartments of the hand.

Fasciotomy of the Upper Extremity

Incisions are designed to provide the most coverage of neurovascular structures (at the time of later closure). Linear incisions across flexion creases are avoided. After the skin incision, the antebrachial fascia is released, allowing assessment of the superficial flexor compartment. The interval between the flexor digitorum superficialis and flexor carpi ulnaris is opened to provide access to the deep flexor compartment of the forearm.

After release of the flexor compartments, muscles are inspected and epimysiotomies are performed for tense or dysvascular muscles. Once the flexor compartments are released, the extensor compartment is assessed. If tense, this is released through a dorsal midline incision.

Release at the elbow requires division of the lacertus fibrosus with exploration of the median nerve and brachial artery. Fasciotomies in the hand are performed through a carpal tunnel release, release of the thenar and hypothenar eminences, and dorsal incisions for the release of the interosseous muscles.

Decompression of the fingers may be necessary to prevent digital loss. This is performed through midlateral incisions, avoiding pinching surfaces, including the radial border of the thumb, ulnar borders of the index and long fingers, and radial borders of the ring and small fingers.

The Cleland ligaments are released when necessary to decompress the digital arteries (see Video 51.1).

CRITICAL POINTS *Compartment Syndrome*

Diagnosis
- Diagnosis is usually a clinical one
- Pain is out of proportion to clinical findings
- Pain with passive motion
- Firm, "rock hard" compartment
- Objective findings include elevated compartment pressures and 30 to 40 mm Hg or within 30 mm of diastolic blood pressure or mean arterial pressure

Management
- Correct any underlying coagulopathy
- Perform emergent fasciotomy
- Perform vascular repair or reconstruction when indicated
- Treat associated injuries
- Repeat surgical débridement
- Close the wound with delayed primary closure, split-thickness skin graft, or flap
- Perform early reconstruction when indicated with tendon transfer or functional muscle transfer

Arm Management
- Anterior and posterior compartments
- Medial incision to decompress both compartments
- Deltoid may require epimysiotomy

Forearm Management
- Deep volar, superficial volar, and extensor compartments
- Deep compartment must be released
- Best decompressed through the interval between the flexor carpi ulnaris and the ulnar side of the flexor digitorum superficialis
- Extensor compartment may soften with release of volar compartments but requires separate assessment and release if indicated

Hand Management
- Ten separate compartments
- Start with extended carpal tunnel release
- Release additional compartments as necessary

Finger Management
- Tense, swollen fingers can result in digital necrosis
- Midlateral dermotomies are performed dorsal to the neurovascular bundles

Pitfalls
- Failure to diagnose in a timely manner
- Failure to adequately release compartments
- Inadequate excision of necrotic tissue leading to scarring and fibrosis around nerves

involvement. Secondary surgery is usually necessary to improve the outcome of these delayed cases.

Outcomes following fasciotomy for chronic exertional compartment syndrome are good. Preoperative symptoms of pain related to activity resolve, and 90% of patients are able to return to sports or other activities.[10,31,41,88,91]

Complications of compartment syndrome and its treatment are common. In a metaanalysis, Kalyani and colleagues reported a complication rate of 42% (18 of 43 patients).[46] Duckworth and associates reported a complication rate of 32% (29 of 99 patients). The most common complication was a neurologic deficit. Other complications included contracture, reflex sympathetic dystrophy, gangrene, muscle weakness, fracture nonunion, and soft tissue tethering associated with skin grafting.[25]

VOLKMANN CONTRACTURE

Volkmann ischemic contracture is the end result of prolonged ischemia and associated with irreversible tissue necrosis. Established Volkmann contracture has a much different presentation than ACS. It has a broad clinical spectrum, based on the extent of muscle necrosis and degree of nerve injury. Unlike ACS, patients with an ischemic contracture do not have pain but rather have deformity and dysfunction resulting from the

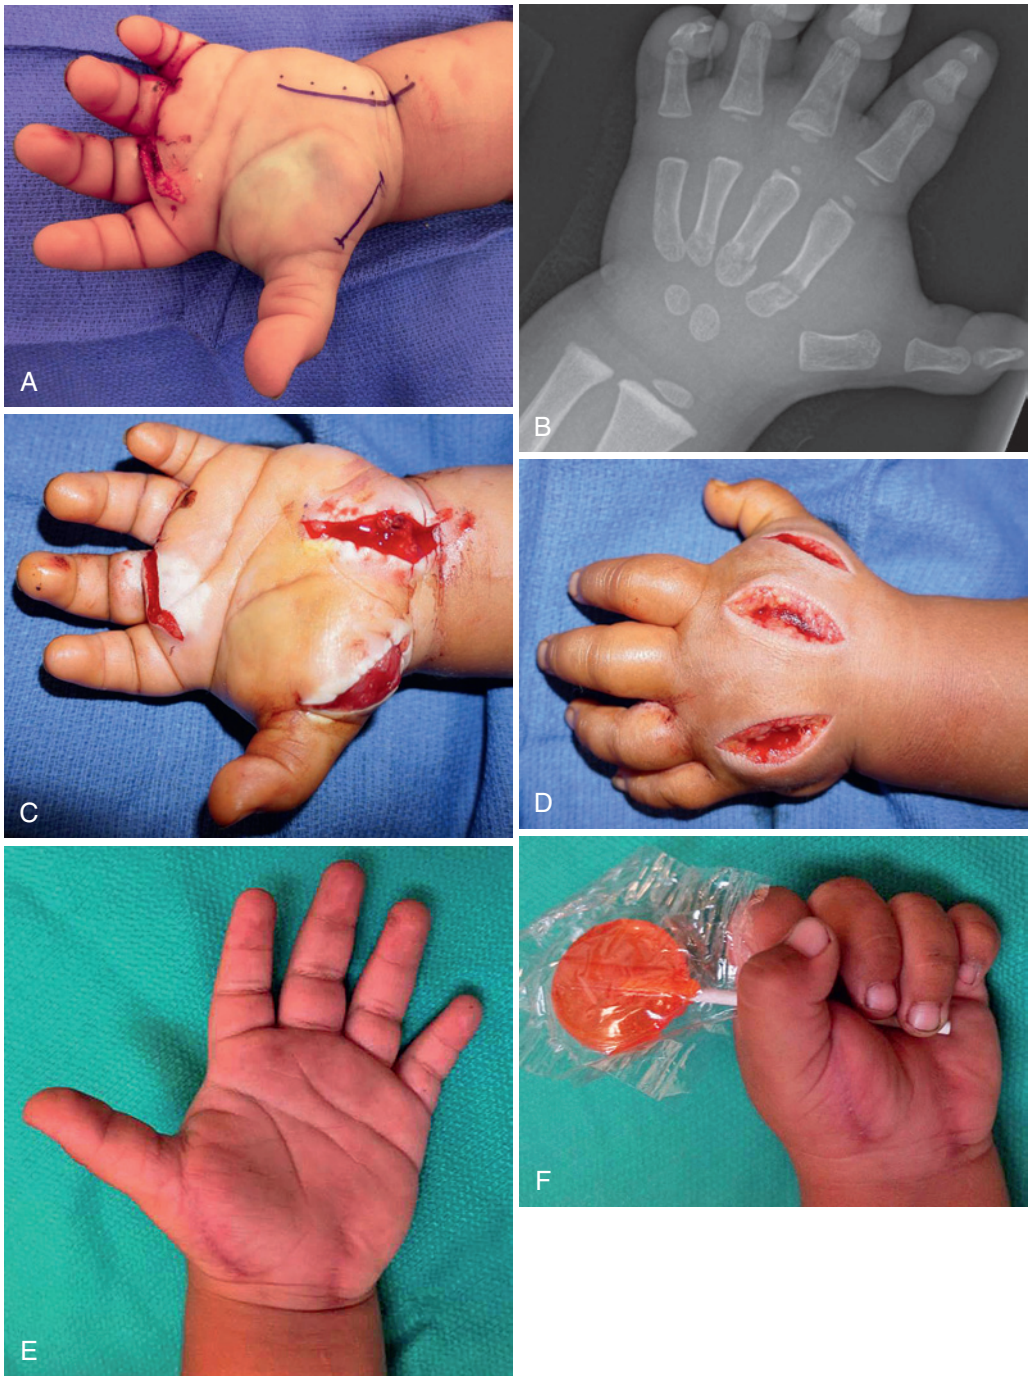

FIGURE 51.10 A 2-year-old sustained a crush injury to his left hand, with fractures of the second to fourth metacarpal bases and an open wound at the volar metacarpal heads. He presented with a tense swollen hand. He was taken emergently for fasciotomies of the hand and underwent percutaneous pinning of the displaced metacarpal base fractures. **A,** Appearance of the hand at presentation. **B,** Metacarpal base fractures, 100% displaced in the sagittal plane. **C,** Fasciotomies of the volar hand. **D,** Fasciotomies of the dorsal hand. **E,** Final extension at 9 months following injury. **F,** Final flexion at 9 months following injury.

ischemic event and subsequent muscle scarring and fibrosis. Nerve dysfunction can occur either from the initial trauma or subsequent ischemic insult or secondary to the fibrosis around the nerves. The muscle fibrosis and neurologic deficits lead to deformity of the joints distal to the site of ischemia. The deformity is progressive over the ensuing weeks to months. In children, an untreated deformity will progress until skeletal maturity because the ischemic muscles are unable to elongate during limb growth. Even when the contractures are treated, the affected extremity is shortened due to the tethering across the physis.

Classification

Several classification systems have been described for Volkmann contracture of the forearm. Most are based on the extent of muscle involvement and the severity of the clinical disability. The classification systems can be useful in guiding treatment plans for functional reconstruction. Most authors recognize the

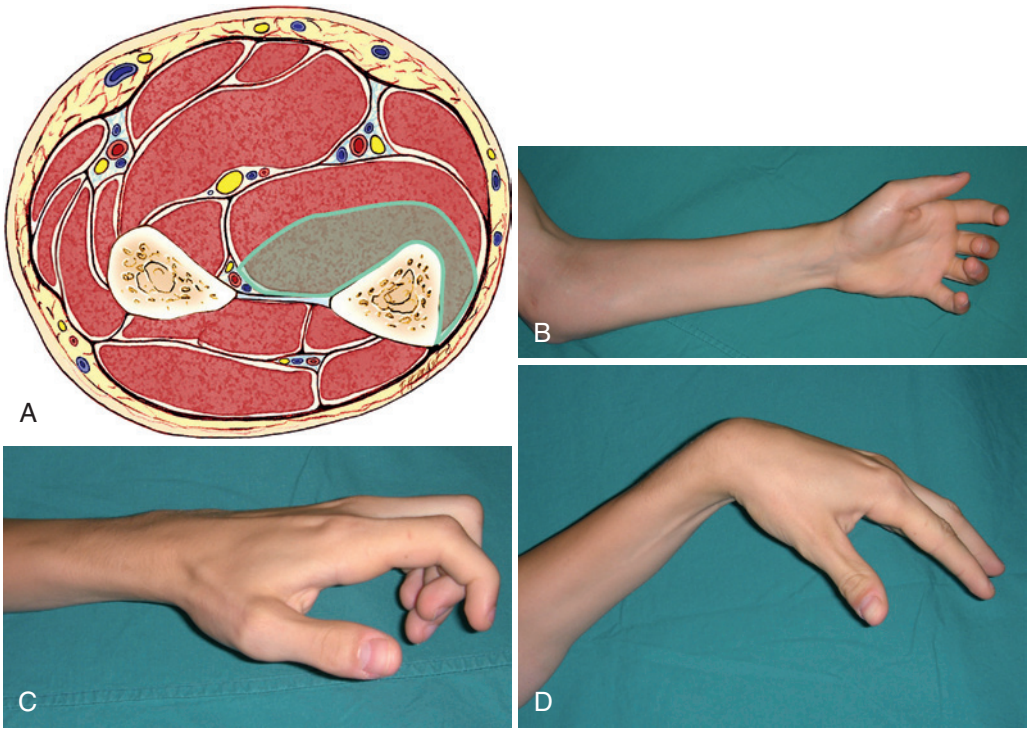

FIGURE 51.11 **A,** Cross-sectional representation of a mild Volkmann contracture (according to Tsuge classification) at the midforearm level. **B,** Volar clinical appearance of mild Volkmann contracture. **C,** Lateral view appearance of mild Volkmann contracture. **D,** Mild contracture allows for full extension of the fingers when the wrist is positioned in volar flexion.

TABLE 51.5 Tsuge Classification for Volkmann Contracture of the Forearm

Type	Findings	Treatment Options
Mild	Localized Volkmann contracture Usually involves principally the deep flexor compartment (flexor digitorum profundus of long and ring fingers most affected) Little or no nerve involvement	Nonsurgical treatment Stretching Splinting Must be maintained through skeletal maturity Surgical treatment Selective fractional lengthening Selective flexor origin slide
Moderate	Most or all of flexor digitorum profundus and flexor pollicis longus Partial flexor digitorum superficialis Neurologic impairment present Sensory in median nerve more than ulnar nerve	Surgical treatment Flexor origin slide Fractional lengthening Shortening of forearm Proximal row carpectomy
Severe	All of flexor compartment Varying involvement of extensor compartment Severe neurologic deficits, including sensory deficits and intrinsic dysfunction	Surgical treatment Tendon transfer Functional free muscle transfer Both may need to be performed Both may require adjunctive flexor slide, infarct excision, and/or contracture release Nerve reconstruction frequently necessary

tremendous variability of the clinical presentations and the subsequent limitations of the classification systems.[73,85,86,94]

The most commonly used, and our preferred, classification system is that proposed by Tsuge.[85] Established Volkmann contracture was divided into mild, moderate, and severe types, according to the extent of muscle involvement (Figures 51.11 through 51.13 and Table 51.5). Tsuge's category of severe contractures included cases of moderate tissue necrosis that were exacerbated by fixed joint contractures, a scarred soft tissue envelope, or failed surgeries.

Within each classification type, there is a broad range of clinical presentations. The heterogeneity of presentation makes it difficult to apply a specific treatment based solely on the classification system. The variability also confounds meaningful outcome and comparison studies.

Treatment

There is a limited role for the nonoperative treatment of established contracture. There may be some benefit from therapy to stretch and splint mild contractures. In children, splinting is

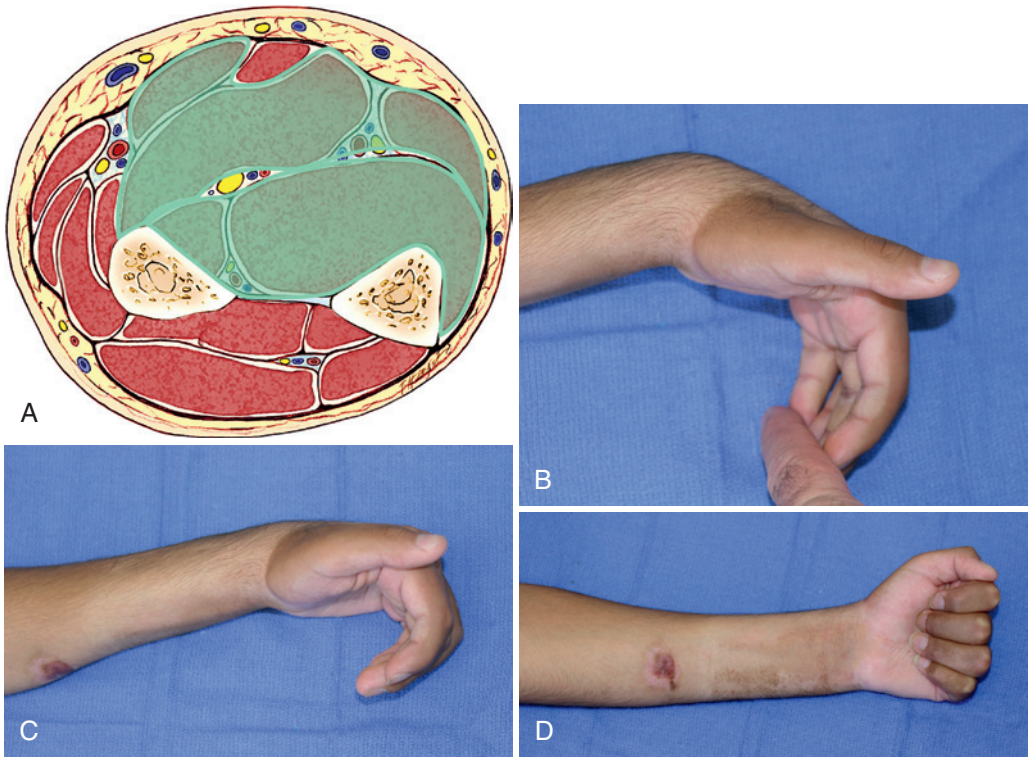

FIGURE 51.12 **A,** Cross-sectional representation of moderate Volkmann contracture (according to Tsuge classification) at the midforearm level. **B,** Patient with Tsuge moderate Volkmann contracture. With the wrist in a position of volar flexion, the fingers cannot be brought into full passive extension. **C,** Finger flexion contracture is worsened by the wrist being brought into a neutral position. **D,** Patient demonstrates full active finger flexion.

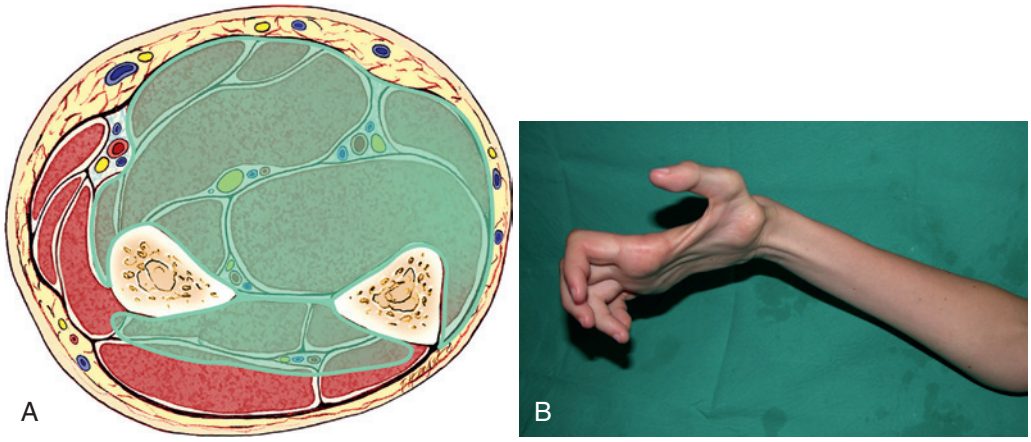

FIGURE 51.13 **A,** Cross-sectional representation of severe Volkmann contracture (according to Tsuge classification) at the midforearm level. **B,** Patient with severe contracture with extensive intrinsic wasting secondary to neurologic involvement at the forearm.

continued until skeletal maturity. Moderate and severe contractures are usually recalcitrant to therapy.

Operative Treatment

A variety of surgical techniques have been proposed, including bony and soft tissue management (Table 51.6).

Bone Procedures. Skeletal shortening or fusions are frequently performed in conjunction with some of the soft tissue procedures listed in Table 51.6. Shortening procedures include shortening osteotomy of the radius and ulna[68] and proximal row carpectomy.[34] These procedures have been used to match the skeletal length to the shortened fibrotic muscle. One concern with bone procedures is that the principal contracture is within the flexor compartment. Shortening the forearm indiscriminately lengthens the muscle resting length of both the flexor and extensor muscles, neglecting the predominant involvement of the contracture within the flexor compartment muscles. Shortening procedures raise additional concerns in children because the forearm is already shortened by the initial ischemic insult to the bone and growth plates.

Bony reconstructive procedures are useful for residual problems related to nerve dysfunction or for long-standing contractures not amenable to additional soft tissue release. Options include wrist fusion, trapeziometacarpal joint fusion, or thumb metacarpophalangeal joint fusion. Severe progressive finger deformities can also be managed with arthrodesis in a more

TABLE 51.6 Surgical Options for Management of Volkmann Ischemic Contracture of the Forearm

LATE MANAGEMENT OF COMPARTMENT SYNDROME; SURGICAL OPTIONS FOR THE FOREARM

Operation	Authors	Advantages	Disadvantages
Bone			
Proximal row carpectomy	Zancolli, 1979[94] Goldner, 1975[34]	Addresses wrist flexion contracture without causing additional scarring in the forearm	(1) Nonselective shortening of both extensors and flexors (2) Limb is already shortened from ischemic insult
Diaphyseal shortening	Rolands, 1905[68] Domanasiewicz, 2008[24a] Pavanini, 1975[64a]	Satisfactory correction of contracture Does not preclude other procedures	(1) Nonselective shortening of both extensors and flexors (2) Limb is already shortened from ischemic insult (3) High nonunion and refracture rate reported
Arthrodesis	Botte, 1998[8] Goldner, 1975[34]	Wrist: Maintains wrist in physiologic position; if additional tendon transfers are needed, if wrist is fused, one less donor muscle is needed and wrist extensor muscles are available as donors for finger function PIP: Fingers maintained in a more functional position; may be only option to correct intrinsic imbalance	Wrist: (1) Loss of tenodesis effect of wrist position (2) Decreased grip strength (3) Loss of motion PIP: (1) Loss of finger flexion (2) Resultant loss of grip strength
Soft Tissue			
Fractional or tendon "Z"-lengthening	Goldner, 1975[34]	Straightforward surgical release of flexion contracture	(1) Loss of active flexion (2) More disruption of muscle resting length and loss of flexion strength
Infarct excision with tendon reconstruction/ transfer	Seddon, 1964,[73] Seddon, 1956[74] Tsuge, 1975[85]	Tsuge advocated infarct excision for mild contractures with involvement of only one or two fingers	(1) Late infarct excision creates more scarring around nerves (2) Deficit created from scar excision is replaced with more scar tissue later
Flexor-pronator slide	Page, 1923[64] Scaglietti, 1957[72] Gosset, 1956[34a] Sharma, 2012[75]	Allows greatest correction of flexion contracture with least impact on muscle resting length	(1) Will not fully correct finger flexion contracture that is not passively correctable in maximal wrist flexion (2) Wide surgical dissection with potential injury to CIA/PIA
Functional free muscle transfer	Zuker, 1989,[96] Zuker, 2007[98] Manktelow, 1978[55a] Manktelow, 1989[55b] Doi, 1993[24]	Only procedure that can restore function for severe contracture according to Tsuge classification	(1) Difficult microsurgical procedure requiring an experienced team (2) Failure can only be remedied with a second functional free muscle transfer

functional position. These procedures are ideally done after skeletal maturity but may need to be performed earlier if there is progressive deformity. In these cases, we attempt to fuse the joint and preserve the growth plate (i.e., chondrodesis).

Soft Tissue Procedures. Soft tissue procedures include excision of the infarcted muscle, fractional or "Z"-lengthening of the affected muscles, muscle sliding operations (flexor origin muscle slide), neurolysis, tendon transfers, and functional free-tissue transfers, as well as combinations of these procedures.[16,17,27,34,37,45,50,52,67,73,74,82,85,86,96,98] Excision of scarred fibrotic nerves without distal function followed by nerve grafting has been described to try and establish some protective sensation in the hand.[44] Fixed contractures of the joints can be addressed with soft tissue release, including capsulectomy and collateral ligament recession or excision, depending on the joints involved.

❖ AUTHORS' PREFERRED METHODS OF TREATMENT

Our preferred methods of treatment depend on the general classification of severity of contracture, individualized to the patient presentation.

Mild (Localized) Type (Deep Flexor Compartment Without Neurologic Deficit). For mild contractures that have failed to respond to nonsurgical management, our preferred treatment is a muscle sliding operation initially described by Page and subsequently endorsed by several others.[52,61,64,72-75,85] We have found this procedure effective as long as good active finger flexion is present. We do not combine this procedure with infarct excision, nor have we found it necessary to release the distal insertion of the pronator teres to correct pronation contracture.[52,85]

A limited flexor slide may be done for mild deformity, affecting only a portion of the flexor digitorum profundus. Because the flexor digitorum profundus originates solely from the ulna, the flexor pronator mass does not have to be released from the medial epicondyle and the ulnar nerve does not have to be transposed. This limited approach reduces potential scarring and vascular compromise to the remaining muscles and nerves in the flexor compartment.

Moderate Type (Deep and Superficial Flexor Compartment With Neurologic Deficit). For moderate deformity, we prefer a flexor muscle origin slide to correct the tightness of the flexors, provided that there is still adequate remaining strength in the

flexors. Because neurologic impairment is characteristic of the moderate injury, we combine the flexor slide with neurolysis of both the median and ulnar nerves. A separate incision to release the carpal tunnel may also be needed. Depending on the functional deficits, tendon transfer can be combined with flexor origin slide, either as a staged or simultaneous procedure.

Reconstruction of Thumb Function. Our preferred transfer for thumb flexion is to transfer the brachioradialis or extensor carpi radialis longus to the flexor pollicis longus. The extensor indicis proprius can be used for thumb opposition at a later date.

Reconstruction of Finger Flexion. When the finger flexors are very weak or absent, an FFMT may produce a better functional result than a tendon transfer. However, if an FFMT is not an option, tendon transfers may be considered depending on the availability of donors. The best option is transfer of the extensor carpi radialis longus to the flexor digitorum profundus because this transfer is synergistic and easy to relearn. Other lesser options include the biceps brachii elongated with graft, the brachioradialis, the extensor carpi ulnaris, and the extensor indicis proprius. Many of these secondary options do not have sufficient excursion to match the flexor muscles, but in the absence of other options, they can provide some improvement in grasp. Lastly, if there is minimal involvement of the flexor digitorum superficialis muscle, this muscle can be used as a donor to the flexor digitorum profundus

Nerve Reconstruction. When sensory impairment is severe and there has been no recovery, the nerve should be carefully evaluated at surgery. A densely scarred atrophic nerve or avascular nerve requires resection back to fascicles that appear healthy followed by sural nerve grafting to restore protective sensation to the hand (Figure 51.14).

Severe Type (Superficial and Deep Flexor Compartments, Extensor Compartment, and Severe Neurologic Deficits). Severe contractures are best treated with FFMTs.[16,18,24,45,50,92,95,96] The donor vessels are usually either the radial or anterior interosseous artery for an end-to-end anastomosis or the brachial artery for an end-to-side procedure. The donor motor nerve is the anterior interosseous nerve, which should be resected back to fascicles that appear healthy. Our preference for the donor muscle is the gracilis. For severe contractures with extensive involvement of both flexor and extensor compartments, a double free muscle transfer should be considered. Tendon transfer, nerve graft reconstruction, and late osseous reconstructive procedures may improve final functional outcomes.

Surgical Techniques

Flexor Pronator Slide. Both volar and ulnar incisions have been described for the surgical approach for a flexor pronator slide.[64,85] We favor the incision and technique initially described by Page[64] with minor modifications (Figure 51.15). The surgical incision begins on the medial distal arm and continues along the ulnar border of the forearm all the way to the wrist. The ulnar nerve is identified and mobilized for several centimeters proximal and distal to the medial epicondyle, including proximal release at the arcade of Struthers. Approximately 4 to 6 cm of intermuscular septum between the brachialis and triceps is excised to prevent kinking of the ulnar nerve after transposition. The flexor pronator mass is elevated off of the medial epicondyle, taking care to preserve the medial collateral ligament and elbow joint capsule. Inadvertent disruption of the joint capsule is repaired. The origins of the flexor carpi ulnaris,

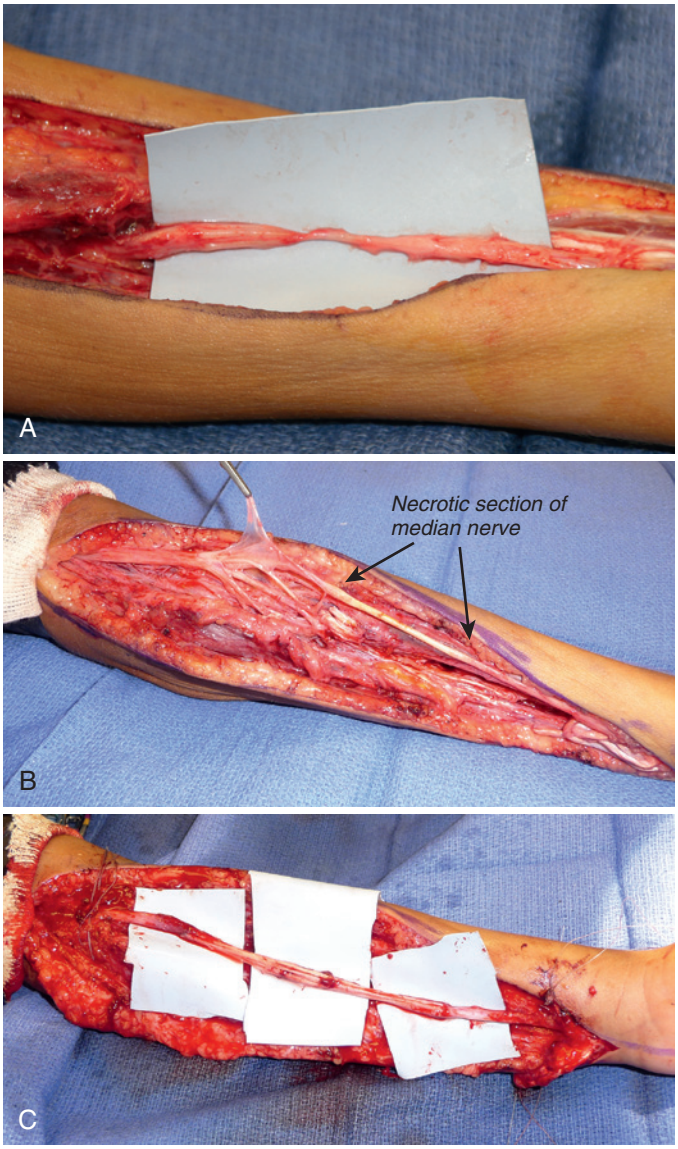

FIGURE 51.14 **A,** Scarred nerve. **B,** Avascular nerve. **C,** Reconstructed nerve.

flexor digitorum profundus, and flexor digitorum superficialis are mobilized off of the ulna and interosseous membrane. The dissection is carried out above the periosteum toward the radius. The common interosseous artery arises as a branch of the ulnar artery and must be protected. This artery crosses the flexor digitorum profundus, where it bifurcates into the anterior and posterior interosseous arteries (see Figure 51.15, *C*). The posterior interosseous artery enters the posterior compartment at the proximal edge of the interosseous membrane. Because the posterior interosseous artery is the dominant blood supply to the extensor compartment, protection of this branch is mandatory.

Continuing the dissection toward the radius, the origin of the flexor pollicis longus is released from proximal to distal. Special attention is needed in this area to protect the anterior interosseous nerve. Throughout the procedure, the wrist and fingers are manipulated to check whether the contracture is improving and to help determine whether there are still areas of tightness within the muscle origin. The dissection must

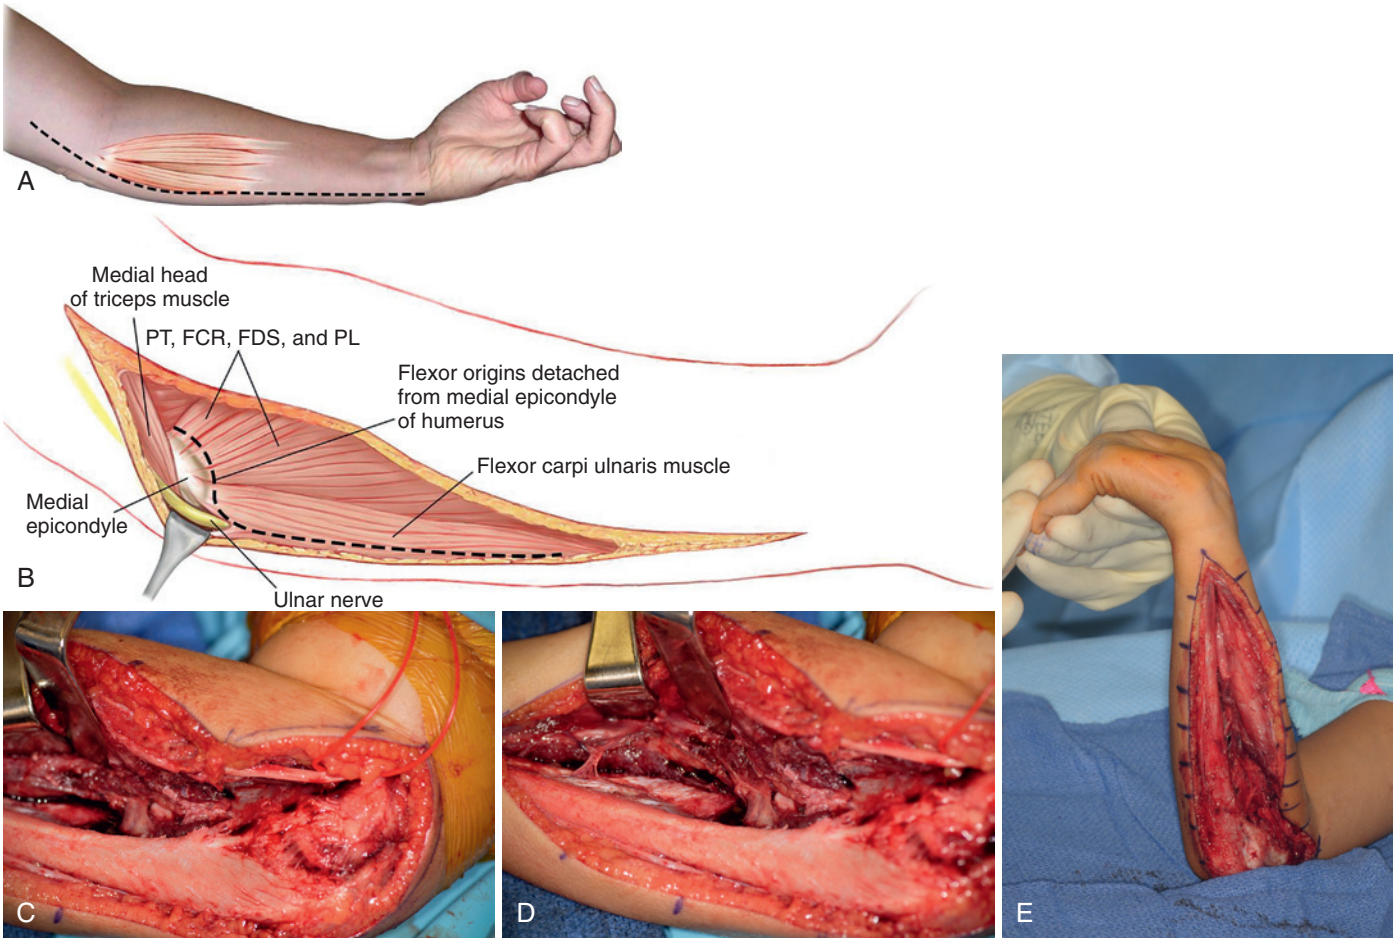

FIGURE 51.15 **A,** Diagram of surgical incision for flexor origin slide. **B,** Schematic diagram of deeper layer of dissection for flexor origin slide. **C,** Ulnar incision with ulnar nerve identified and mobilized. Flexor pronator mass elevated from the medial epicondyle with preservation of the medial collateral ligament and elbow joint capsule. **D,** Dissection proceeds in a radial direction with protection of the interosseous arteries. **E,** Complete release heralded by full finger wrist extension with the wrist held in extension. *FCR*, Flexor carpi radialis; *FDS*, flexor digitorum superficialis; *PL*, palmaris longus; *PT*, pronator teres.

often be carried down to the level of the wrist to release adhesions between the flexor tendons and pronator quadratus before full correction is achieved. If necessary, the carpal tunnel should be opened and tendon adhesions released in this area. It has been our experience that the lacertus fibrosus and superficial fascia around the antecubital fossa are often tight and are contributing to the residual elbow flexion contracture. The fascia can also tether the superficial flexors of the wrist and fingers, contributing to incomplete correction of the wrist and fingers with the muscle sliding only. Release of this fascia helps correct the deformity and also prevents median nerve compression between the heads of the pronator teres. Slight undercorrection, which can be addressed by postoperative splinting and rehabilitation, may decrease the reduction in muscle power resulting from the muscle slide. When a pronation contracture is present and has not been corrected by the release of the flexor-pronator origin, we release the pronator quadratus from the distal ulna. Even with a complete release of both the pronators and the volar distal radioulnar joint capsule, complete correction of the pronation deformity may not be possible due to fibrosis and contracture of the interosseous membrane. At the completion of the muscle slide, the ulnar nerve is transposed to an anterior subcutaneous position. The hand is casted in a position of forearm supination with the wrist and fingers in full extension. Immobilization is continued for a period of 6 weeks to allow the flexor pronator to heal adequately to its new origin (Figure 51.16 and Case Study 51.2).

Restoration of Extrinsic Flexor Function. For moderate contractures, a muscle slide may leave adequate flexor muscle function. Commonly, flexor strength and excursion are weakened and can benefit from flexor reconstruction. The options for tendon transfer depend on the extent of muscle necrosis in the forearm. Donor muscles from the extensor compartment can be used to reconstruct finger flexion and thumb flexion and opposition. Our preferred transfers are transfer of the extensor carpi radialis longus through the interosseous membrane to the flexor digitorum profundus, transfer of the brachioradialis to the flexor pollicis longus, and transfer of the extensor indicis proprius to restore opposition of the thumb.

Secondary options may be available in the flexor compartment when there is involvement of the deep flexor compartment only. A transfer of the flexor digitorum superficialis to the

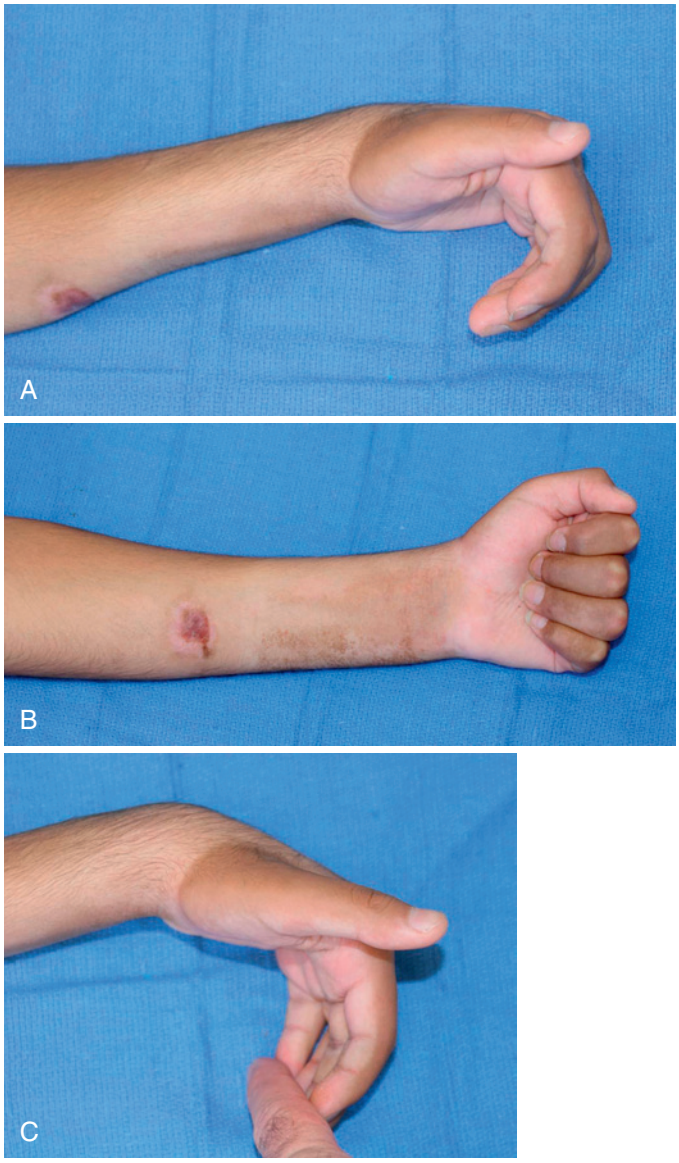
CASE STUDY 51.2 Moderate Volkmann Contracture

A 15-year-old right hand dominant football player sustained a minimally displaced but angulated left both-bone forearm fracture. The fracture was treated in a long-arm cast with extreme molding at the midforearm. When the cast was removed at 6 weeks, the patient was noted to have a flexion contracture of the thumb and fingers. The fingers could be extended only with maximum wrist flexion. He could actively flex his fingers into a full fist. The patient was seen in the hand surgery department at 9 months after injury (eFigure 51.1).

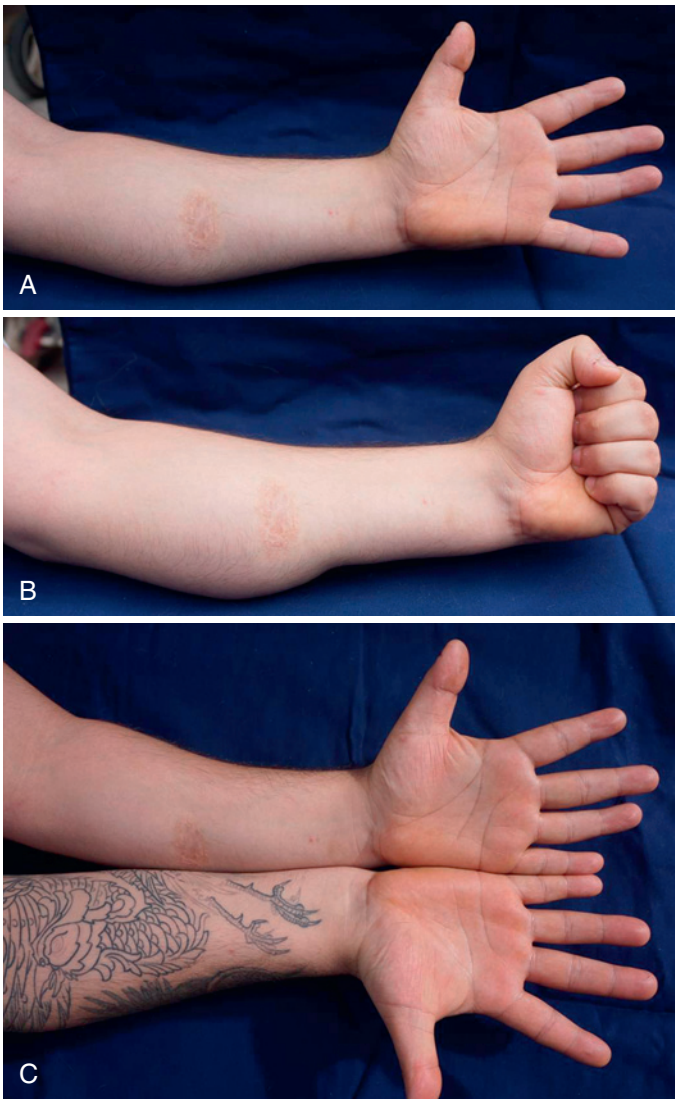
At 9 months following injury, the patient underwent a flexor origin slide. A cast was applied with the wrist, fingers, and thumb in maximum extension for 6 weeks after surgery. At the time of cast removal, the patient was seen in therapy. A nighttime extension splint was made and recommended for use for 1 year after surgery. (The patient reported that he used this splint only for a few weeks.)

At 10 years of follow-up, the patient is working in light construction and builds motorcycles.

He feels happy with the outcome and grip strength, although he reports occasional fatigue in the forearm with prolonged use (eFigure 51.2 and Video 51.2).



eFIGURE 51.1 Moderate Volkmann contracture. **A** and **B,** Presentation at 9 months following injury. **C,** Intraoperative passive extension.



eFIGURE 51.2 Ten-year follow-up after flexor origin slide. **A,** Full finger extension with wrist in full extension; slight thumb interphalangeal flexion. **B,** Full thumb and finger flexion with grip strength 85% of contralateral side. **C,** Mild shortening of the affected forearm.

CRITICAL POINTS *Flexor Pronator Slide for Volkmann Contracture*

Preoperative Planning

- Indications include mild and moderate contractures of the forearm muscles
- Special evaluations include clinical examination of flexor muscle strength and preoperative magnetic resonance angiogram or arteriogram when indicated for previous vascular injury or by an abnormal vascular examination
- Bipolar cautery is useful for this procedure

Surgical Technique

- Incision from ulnar side from middle third to distal third junction of the arm, following the course of the ulnar nerve and continuing along the border of the forearm to the wrist flexion crease (extensile ulnar approach)
- Mobilize and transpose the ulnar nerve
- Release the flexor-pronator origin off of the medial epicondyle, preserving the medial collateral ligament and joint capsule
- Release the origins of the flexor carpi ulnaris, flexor digitorum profundus, flexor digitorum superficialis, and flexor pollicis longus from the ulna and intermuscular septum, working from proximal to distal and ulnar to radial
- Identify and protect the common interosseous artery and its division into the anterior and posterior interosseous arteries
- Frequently passively extend the wrist and fingers to identify structures that remain tight; the release is complete when full passive wrist and finger extension is achieved
- A separate release of the carpal tunnel and release of tendon adhesions in this area may be necessary if complete slide fails to achieve full extension
- Residual pronation contracture is addressed by release of the pronator quadratus from its ulnar origin and release of the volar dorsal radioulnar joint capsule; complete correction may not be possible due to interosseous membrane tightness
- A large drain is placed below the flexor pronator mass (it is removed on the first postoperative day)
- No fascial closure; skin and subcutaneous tissue only are closed

Postoperative Care

- Immobilization in long-arm cast with the elbow at 90 degrees and the forearm in supination; the wrist and fingers are in full extension, and the thumb is in abduction and extension; the initial cast should be bivalved if swelling is a concern
- Duration of immobilization is 2 to 3 weeks in a long-arm cast; convert to short-arm cast with wrist and finger extension and thumb abduction-extension for an additional 3 to 4 weeks (full 6 weeks postoperatively)
- Rehabilitation: Begin elbow motion and nerve gliding at time of conversion from long-arm cast to short-arm cast; begin wrist and finger range-of-motion exercises with therapy guidance at time of cast removal; strengthening may begin as tolerated starting at 6 weeks; custom thermoplast orthosis at night until skeletal maturity
- Activities: The patient may return to sports when adequate strength and motion allow participation in the sport of choice; we encourage swimming activities to develop strength and motion

flexor digitorum profundus will provide the patient with good flexor strength and sufficient excursion to achieve functional grasp. Also, the flexor carpi radialis and flexor carpi ulnaris may be spared and available as donor muscles for transfers. Neither of these muscles has excursion matching that of the flexor digitorum muscles.

When the extensor compartment has been compromised by the ischemic event, the muscles are not available for transfer. For these patients, the only option for functional reconstruction remains an FFMT.

CRITICAL POINTS *Tendon Transfer for Finger and Thumb Flexion*

Preoperative Planning

- Careful preoperative clinical assessment of available donor muscle strength

Surgical Technique

- Extensor carpi radialis longus to flexor digitorum profundus, brachioradialis to flexor pollicis longus, or extensor indicis proprius to radial side of the thumb metacarpal
- The extensor carpi radialis longus is harvested from the radial base of the index metacarpal through a longitudinal incision.
- The harvest incision of the extensor carpi radialis longus is extended or a separate proximal incision is made at the junction of the middle third and distal third of the forearm to create a tunnel through the interosseous membrane.
- The brachioradialis is exposed through the same incision used to expose the extensor carpi radialis longus proximally. The brachioradialis must be freed from the forearm fascial attachments to improve excursion.
- The extensor indicis proprius is exposed through a separate incision at the metacarpophalangeal and mobilized proximally.
- A volar incision is made at the distal third of the volar forearm to identify and mobilize the flexor digitorum profundus tendons. The flexor pollicis longus is identified through the same incision. The flexor digitorum superficialis tendons are excised. The flexor digitorum profundus tendons are sutured together as a single tendon unit.
- The extensor carpi radialis longus is transferred through the interosseous membrane; the opening created in the interosseous membrane must be sufficient in size to prevent constriction of the transferred muscle-tendon unit.
- The extensor carpi radialis longus is woven into the flexor digitorum profundus tendons using a weave technique.
- The tenorrhaphy is placed under sufficient tension to restore the resting cascade of the fingers but still allow full passive extension of the fingers with the wrist in neutral position.
- The brachioradialis to flexor pollicis longus transfer is completed in a similar manner.
- The extensor indicis proprius is mobilized proximally, then passed through a subcutaneous tunnel around the ulnar side of the wrist. An ulnar-sided incision around the level of the pisiform is made to retrieve the extensor indicis proprius and to create a subcutaneous tunnel from the ulnar wrist to the radial side of the thumb metacarpal neck.
- The extensor indicis proprius is secured to the radial side of the thumb metacarpal neck with the thumb in a position of abduction and pronation, as described by Burkhalter.[12]

Postoperative Care

- Immobilization is in a splint or cast: Dorsal block with wrist at 30 degrees of flexion, metacarpophalangeals at 70+ degrees of flexion, thumb in abduction and pronation with interphalangeal joint in neutral
- The duration of immobilization is 4 weeks, during which time the patient is instructed in passive range-of-motion exercises
- At 4 weeks, a thermoplast splint may be worn full time and place-and-hold exercises may begin.
- At 6 weeks, the transition is made to nighttime use of the splint only.
- Rehabilitation with place-and-hold exercises beginning at 4 weeks; passive extension after 6 weeks
- Activities: The patient may return to sports when there is adequate strength and motion to participate in the sport of choice; minimum of 6 months after tendon transfer

FIGURE 51.16 This 42-year-old woman sustained an isolated brachial artery laceration and had a dysvascular forearm and hand. She underwent repair of the artery. She presented 1 year after injury with inability to straighten her fingers with the wrist in a neutral position (Holden type 1 contracture). **A,** Finger extension with the wrist in neutral. Flexor pollicis longus is spared. **B,** Finger extension with the wrist in neutral. **C,** Finger flexion. **D,** Flexor origin slide with release of flexor pronator mass and flexor digitorum profundus. The ulnar nerve is transposed anteriorly. The wrist and fingers are extended throughout the procedure until full extension of the fingers is achieved with the wrist in full extension. **E,** Finger flexion at 6 months. **F,** Finger and wrist extension at 6 months.

Restoration of Extrinsic Flexor Function: Free Functional Muscle Transfer. Functional reconstruction following Volkmann ischemic contracture was the first clinical application of FFMT. Several different donor muscles have been used to restore finger flexion, including the pectoralis major (lateral portion), medial gastrocnemius, latissimus dorsi, and gracilis. When using the latissimus dorsi muscle, we place the caudad portion of the muscle as the origin on the medial epicondyle and use the tendinous portion to attach to the profundus tendons. The gracilis (and also latissimus) has independent neuromuscular territories that can be separated and used to restore independent thumb and finger flexion. If the latissimus dorsi is being used for functional reconstruction and independent neuromuscular territories are needed, the latissimus cannot be reversed. The tendinous insertion of the latissimus dorsi should become the neoorigin of the forearm flexors, and the muscle should be separated distally to reconstruct finger and thumb flexion independently.

Our preferred muscle for reconstruction is the gracilis, due to its size match, excursion, and power. Specific points related to FFMT in the setting of Volkmann ischemic contracture are highlighted here.

Prior to FFMT, procedues may be necessary to prepare the recipient site. Excision of the infarcted muscle is not necessary

because the tendons are released distal to the area of muscle infarct. However, fixed contractures and tendon adhesions distal to the planned tenorraphy site need to be addressed.

The median and ulnar nerves (if clinically impaired) are explored. Areas of necrotic or constricted nerve are excised and grafted using a sural nerve graft. If both the median and ulnar nerves are affected over a long distance and there is not enough sural nerve graft, the median nerve should have priority of reconstruction using autogenous graft. Ulnar nerve reconstruction can be performed or augmented with nerve allograft if necessary. We prioritize median nerve function because of the importance of radial-sided sensation for pinch as well as the higher likelihood of recovery in both sensory and motor function.[14,47,48,60] In our experience, the median nerve is more frequently and more severely affected, likely due to its anatomic location.

At the time of FFMT, surgical incisions are planned to provide the best soft tissue coverage over the transferred muscle and tenorraphy site. The recipient site should be prepared *before* the donor muscle is harvested. A two-team approach is frequently used, but division of the donor tendon insertion should not be completed until the recipient vessels and motor nerve are identified. This is particularly important when using an FFMT for reconstruction in patients with Volkmann contracture. In these cases, it is often necessary to obtain intraoperative frozen sections to identify healthy fascicles of the recipient motor nerve. In addition, the vascular anastomosis should be performed proximal to the ischemic tissue bed. Even though an adequate arterial inflow may be found within the reconstruction site, the venous outflow is unreliable. The vascular pedicle and recipient nerve should be mobilized as much as possible to obtain sufficient length for proper positioning of the transplanted muscle.

The vascular anastomosis is completed first, and the muscle is allowed to perfuse for 10 to 15 minutes until the venous outflow does not appear overly dark. The anastomosis is completed as quickly as possible to minimize permanent ischemic changes to the muscle. Irreversible muscle loss increases with time in a nonlinear relationship.[5] It is our experience that if the muscle ischemia time exceeds 2 hours, the muscle will likely survive but the function will never be good. If the cause of the prolonged ischemia time can be identified (ususally, compromised venous outflow leading to reperfusion problems) and rectified (e.g., vein grafting to different recipient vessels), the surgeon can consider harvesting a different donor muscle at the same procedure.

The muscle is secured to its new origin site on the medial epicondyle using nonabsorbable suture. The origin may be secured to the periosteum and surrounding fascia. Bone tunnels or suture anchors can also be used. The muscle neoorigin should be spread out as much as possible. The tendons of the flexor digitorum superficialis are excised from the musculotendinous junction to the wrist flexion crease. The wrist and fingers are flexed so that after transection, the cut ends of the flexor digitorum superficialis will be distal to the carpal canal. The flexor digitorum profundus is divided just distal to the musculotendinous junction. The tendons are sutured side to side, with tensioning of the position to re-create the normal cascade of the fingers (Figure 51.17). When traction is applied to the sutured tendons, the fingers should all touch the midpalmar crease. The flexor pollicis longus tendon is transected distal to its musculotendinous junction. Traction is applied along the tendon to ensure proper tendon gliding. Flexor pollicis longus function is reconstucted separately using a tendon transfer if available (either the brachioradialis or extensor carpi radialis longus). If these muscles are not functional, independent flexor pollicis longus function can be restored by using the separate neuromuscular territories of the gracilis muscle to allow independent finger and thumb flexion. The transferred muscle is stretched to restore its resting length, and the site for the distal tenorraphy is marked with the wrist and fingers in full extension. The neurorraphy is completed last; its site is placed as close as possible to the transplanted muscle. Wound closure should be performed with attention to avoiding compression of the vascular pedicles. Tight skin closures should be avoided at all costs because a compartment-like syndrome or venous outflow obstruction can occur when the reperfused muscle swells following the surgery.

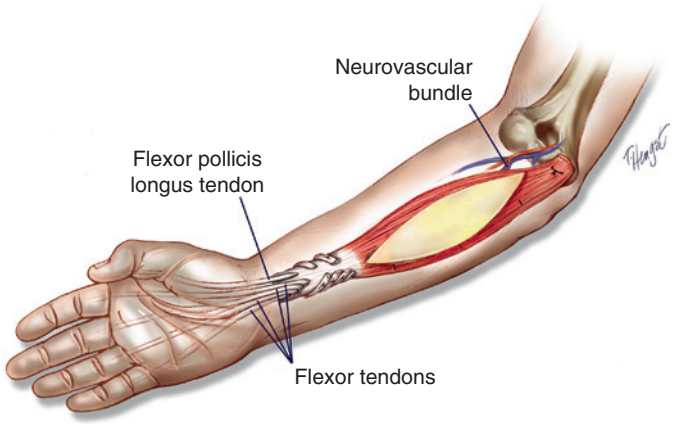


FIGURE 51.17 Schematic drawing of gracilis muscle used for free functional muscle transfer for reconstruction of finger flexion.

Transfer of Gracilis Muscle. The gracilis muscle is usually harvested with the patient supine in a frogleg position. Either the ipsilateral or contralateral gracilis can be used for finger flexor reconstruction because the recipient vascular pedicle and obturator nerve have sufficient length to accommodate the distance to the recipient site. Technique highlights are listed in the critical points box.

Outcomes

Outcomes following Volkmann contracture in the upper extremity are difficult to assess. Studies are limited by the small numbers of patients, the great variability in the initial presentations, the varied surgical techniques used, and the difficulty in tracking patients over the long term as they grow to skeletal maturity. Ultee and Hovius attempted to provide some information regarding outcomes.[87] They found that all patients who had developed the contracture during childhood had a relatively shortened extremity. Substantial improvements in hand function were noted in patients who underwent FFMT. Tendon lengthening alone often resulted in recurrence of contracture. Finally, in patients who had sufficient remaining muscle, procedures that combined infarct excision, tenolysis, neurolysis, and tendon transfer produced good hand function.[87] Sundararaj and Mani noted improvement in sensory function in conjunction with neurolysis.[82]

CRITICAL POINTS *Free Functional Muscle Transfer for Finger Flexion*

Preoperative Planning

- Indications are no active finger flexion and no available tendon transfers
- Microsurgical instrumentation and magnification are required

Surgical Technique

Preparation of the Donor Site

- Extensile surgical incision along the forearm
- Excision of necrotic and/or fibrotic muscle may not be necessary after division of the flexor tendons
- Neurolysis of the median and ulnar nerves
- Nerve reconstruction when indicated using sural nerve autograft
- Identification and preparation of the recipient nerve: recipient nerve options are the anterior interosseous nerve and the median nerve; recipient artery and vein options are the anterior interosseous artery (end-to-end), radial artery (end-to-end), ulnar artery (end-to-end), and brachial artery (end-to-side)

Harvest of the Gracilis

- Frog position of the leg; a sandbag can be used to help positioning
- Mark the axis of dissection of the gracilis from the pubic tubercle to the tendon insertion of the pes anserinus
- A distal incision is made and the tendon of the gracilis is identified between the sartorius and the semitendinosus
- Tension applied to the distal tendon will help identify the axis of the muscle
- A skin paddle is incorporated into the surgical incision
- Dissection is carried down to the fascia; the gracilis is harvested within its fascial sheath (Figure 51.18); a wide harvest of fascia is taken anterior to the gracilis
- The resting length of the gracilis is marked with the hip in full abduction and the knee in full extension; marking sutures are placed at 5-cm intervals
- Dissection is best completed from distal to proximal and from posterior to anterior
- The tendon is released distally
- The muscle origin is divided after the neurovascular pedicle is mobilized and isolated
- The dominant vascular pedicle enters the muscle proximally on the anterior deep surface; the vascular pedicle arises from the profunda femoral artery; the obturator nerve enters the muscle proximal to the dominant pedicle; the nerve is stimulated to ensure that it produces a muscle contraction
- The nerve is divided and the vascular pedicle is ligated *only* after the recipient site is ready

Muscle Transfer

- Arterial and venous anastomosis first; allow muscle to perfuse for 10 minutes
- Establish and secure new muscle origin at the medial epicondyle; reset the muscle resting length; the resting length is reset with the wrist and fingers in full extension
- Use a weave to secure the gracilis tendon to the flexor digitorum profundus and flexor pollicis longus; although the resting length is set with the wrist and fingers in extension, once that has been established, the repair is performed with the wrist and fingers in flexion to minimize tension at the repair site; flexor pollicis longus function is reconstructed with a tendon transfer (extensor carpi radialis longus or brachioradialis); alternatively, the separate neuromuscular territory of the gracilis can be used to create separate functional reconstruction for thumb flexion; this requires two motor donor nerves
- Neurorraphy is completed last; the neurorraphy is completed close to the transplanted muscle

Postoperative Care

- Immobilization is with a long-arm splint followed by a long-arm cast, with the elbow at 90 degrees of flexion, wrist at 30 degrees of flexion, and metacarpophalangeals at 90 degrees of flexion; the thumb is in palmar abduction and interphalangeal flexion
- Duration of immobilization is 4 to 6 weeks
- Rehabilitation: After cast removal, gentle passive range of motion; more firm passive motion may start at 3 months; muscle stimulation may also start at 3 months; light and progressive strengthening after onset of muscle reinnervation
- Activities: The patient should not participate in sports until at least 1 year after reinnervation, and then only when he or she has adequate strength and motion to participate in sport of choice

Outcomes of Flexor Origin Slide. Since the original description of this procedure by Page in 1923, there have been few reports about it.[27,72,75,85] The most detailed report of outcomes for this procedure was published by Sharma and colleagues, who reported on patients with moderate Volkmann contracture with no fixed joint contractures, noting improvements in dexterity, sensibility, ability to flex and extend the fingers, and grip strength. In 15 of 19 patients, dexterity scores were in the good range. In 14 of 19, grip strength was in the good range and reached 20 to 87% of that of the contralateral hand (average, 75%). The authors attribute their good outcomes to careful patient selection and emphasis on postoperative therapy.[75]

In our experience, substantial functional improvement of mild and moderate contractures can result following flexor muscle slide and nerve reconstruction when indicated. Normal function is not anticipated, but a hand with protective sensation and functional grasp can often be achieved.

A flexor origin slide for severe contractures can improve passive finger and wrist motion and is useful as a first stage of treatment before functional reconstruction with tendon transfer or FFMT (Figure 51.19 and Case Study 51.3). All of these procedures have better outcomes in patients with preserved hand intrinsic function.

Outcomes of Free Functional Muscle Transfer. Since the first case report of an FFMT for reconstruction of finger flexion, several other case reports and small series have been reported. Zuker and colleagues reported on a series of FFMTs performed in 1991 for seven patients using a gracilis donor muscle. All patients achieved less than 2 cm of pulp to palm grip. Grip strength was approximately 25% of the contralateral side. All patients achieved a functional nondominant hand.[97] In 2011, they reported on a modification in their technique to provide independent thumb flexion by separating the fascicles of the obturator nerve and using two donor nerves, providing separate innervation to the neuromuscular territories of the gracilis muscle.[97] Krimmer and associates used the gracilis muscle in 15 patients with the primary indication being Volkmann contracture. Reinnervation occurred in 13 of 15 muscles. Ten patients achieved full active motion.[50] Liu and coworkers used the medial gastrocnemius muscle in 20 patients, reporting electromyographic activity at 6 to 20 months. Functional outcomes were reported as satisfactory, but the clinical pictures suggest

CASE STUDY 51.3 **Severe Volkmann Contracture**

A 5-year-old boy developed a severe Volkmann contracture after a supracondylar humerus fracture. One year later the patient underwent a flexor origin slide to reduce the contracture at the wrist and fingers. At 2 years following injury, he underwent a free functional muscle transfer to restore finger and thumb flexion. Nerve grafting of the median nerve was performed at the same time (see Figure 51.19 and Video 51.3).

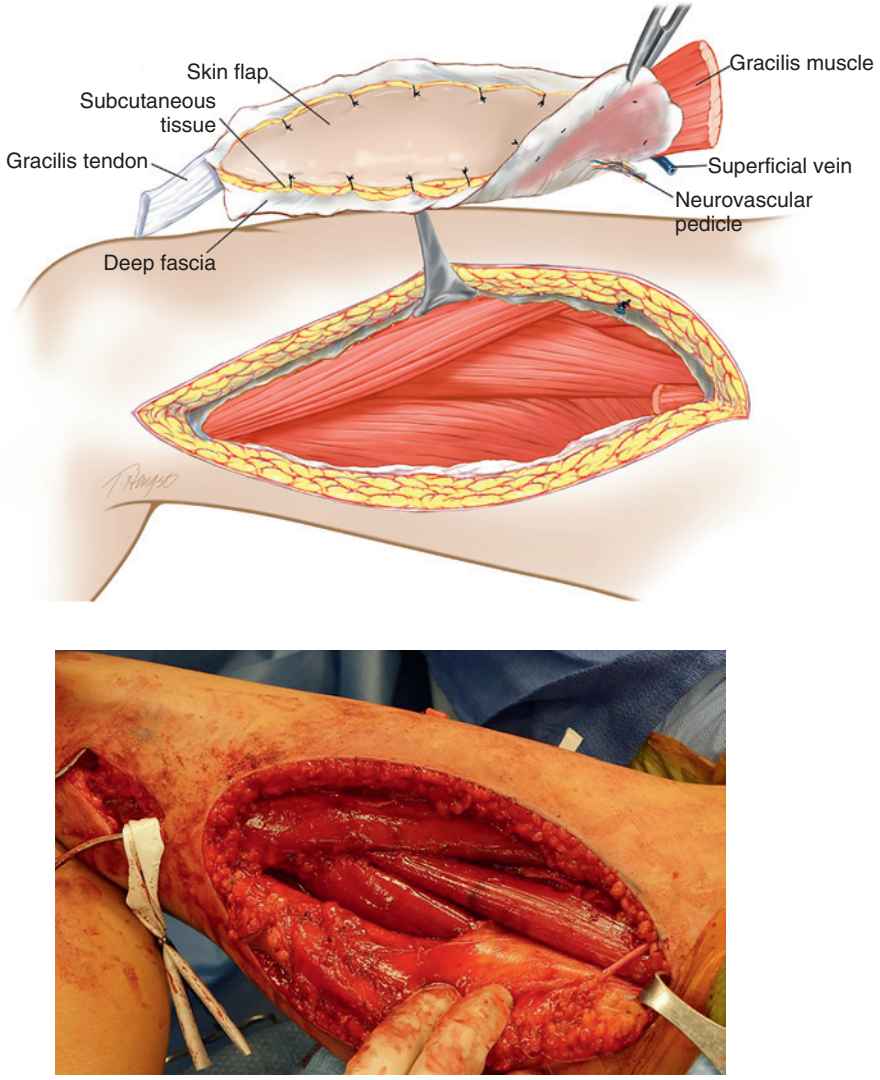

FIGURE 51.18 Dissection of gracilis.

incomplete finger flexion, likely related to the short excursion of the muscle.[55]

Restoration of Intrinsic Function After Volkmann Contracture of the Forearm

Nerve Dysfunction Associated With Forearm Compartment Syndrome. Intrinsic dysfunction in the setting of a Volkmann ischemic contracture of the forearm results from nerve ischemia in the forearm. Intrinsic dysfunction remains an extremely difficult problem to address both operatively and nonoperatively. Nerve reconstruction is performed when there is absent sensory and motor function or a clearly necrotic nerve is identified at the time of exploration. Some recovery of sensation can be expected. Motor recovery is less predictable. There are few available tendon transfers for functional restoration because donor tendons are often necessary for extrinsic flexor reconstruction. If protective sensation is not improved with neurolysis or nerve reconstruction, nerve transfer from the dorsal sensory branch of the radial nerve to the ulnar digital nerve of the thumb and radial digital nerve of the index finger should be considered for restoration of sensate pinch. Also, if ulnar nerve function is intact, transfer of the common digital nerve to the fourth web space to the radial digital nerve of the index finger and ulnar digital nerve of the thumb is another option for sensory restoration for pinch.

Volkmann Contracture of the Hand

Volkmann contracture isolated to the hand is much less common than contracture in the forearm. Little is written about this problem, and treatment options are limited. Volkmann contracture of the hand commonly involves contracture of the first web space with the inability to open the thumb for grasp. The fingers assume variable degrees of the intrinsic-plus posture, with metacarpophalangeal joint flexion and proximal interphalangeal joint extension secondary to ischemia within the interosseous muscles. In combination with the thumb deformity, the hand cannot be opened sufficiently to grasp even medium-sized objects (Figure 51.20).

The first web space contracture is addressed with excision of the first dorsal interosseous muscle and the fibrotic portion of the adductor pollicis. Options to maintain the web space include placement of a bone block from the iliac crest between the thumb and index metacarpal shafts, or fusion of the

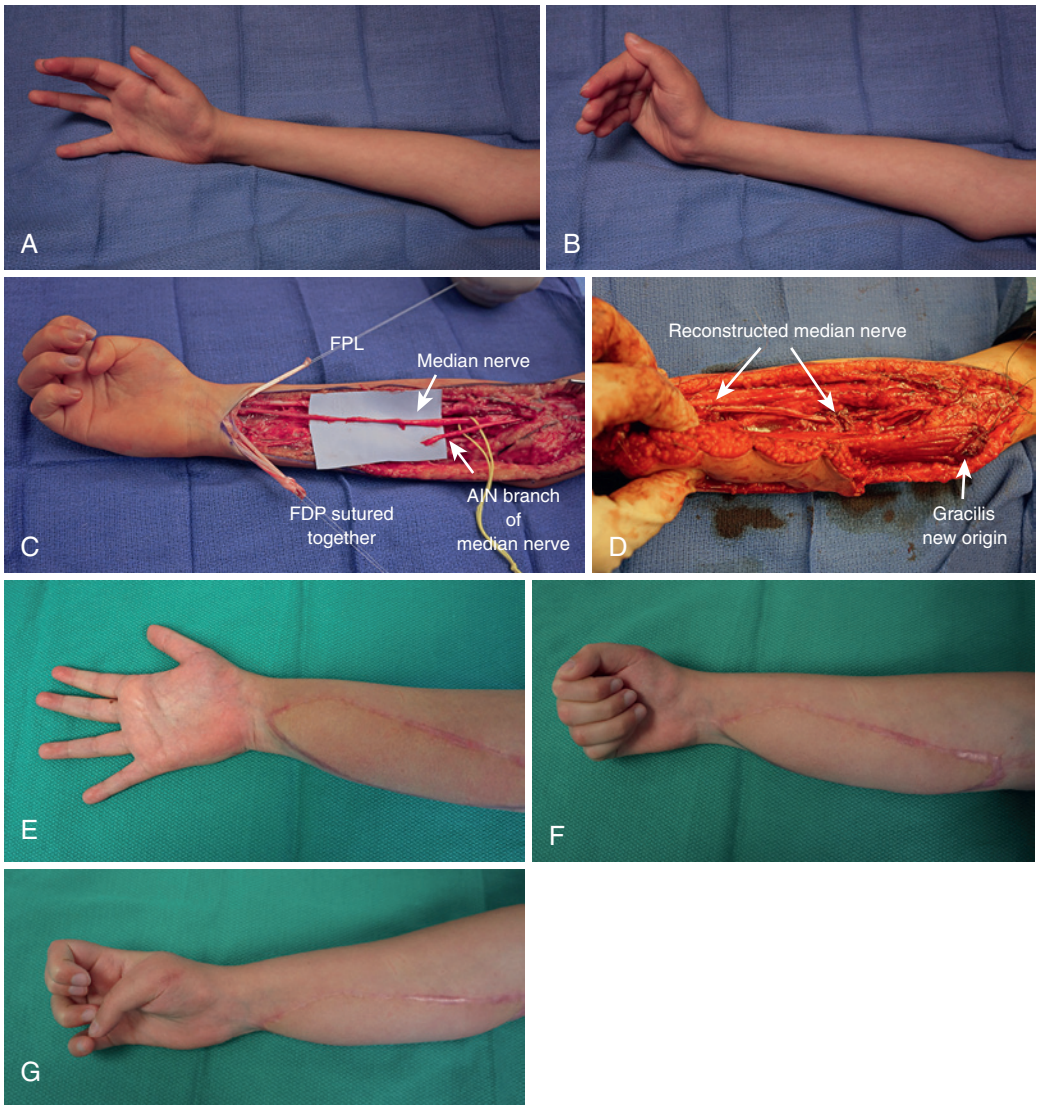

FIGURE 51.19 This 5-year-old boy developed a Volkmann contracture after sustaining a supracondylar humerus fracture. One year after his initial injury, he underwent a flexor origin slide to reduce wrist and finger flexion contractures. One year later he underwent a free functional muscle transfer of the gracilis for restoration of finger flexion. The extensor carpi radialis longus was transferred to restore flexor pollicis longus function. An opponensplasty was performed 9 months later using the extensor indicis proprius. **A,** Preoperative extension 1 year after flexor origin slide. **B,** Preoperative flexion. **C,** Necrotic flexor muscles have been partially resected. The flexor digitorum profundus tendons are sutured together distally. The flexor pollicis longus tendon has been independently separated. The median nerve has been dissected. The anterior interosseous nerve (AIN) branch has been isolated for neurorrhaphy to the nerve to the gracilis. **D,** Insetting of functional free gracilis muscle. The median nerve has been reconstructed with a sural nerve graft over a 7-cm segment. **E,** Finger and wrist extension at 1 year after functional free gracilis transfer and median nerve reconstruction. **F,** Finger and thumb flexion at 1 year after his last surgery. **G,** Opposition to small finger at 1 year. See Video 51.3. *AIN,* Anterior interosseous nerve; *FDP,* flexor digitorum profundus; *FPL*, flexor pollicis longus.

trapeziometacarpal joint. If skin is deficient, these procedures may require augmentation with a four-flap "Z"-plasty, pedicled rotational flap, or even free tissue transfer. Our preferred technique would be dependent upon the extent of contracture. The choice of free tissue transfer would depend on the body habitus of the patient, but a posterior interosseous forearm rotational flap or a free lateral arm flap would be our first choice. Sacrifice of the index finger with a ray resection may be a good alternative for some patients, particularly those with substantial dysfunction of the index finger. This provides an adequate web space for grasp, removes the need for tissue transfer, and allows the resected index metacarpal to be used as a bone block between the first and third metacarpals to maintain the web space.

Intrinsic tightness of the fingers clinically presents as a metacarpophalangeal joint flexion and interphalangeal joint extension. Intrinsic tightness can sometimes be distinguished from joint contracture by performing an intrinsic tightness test.

Milder cases of intrinsic contracture can be addressed with excision of portions of the oblique and lateral bands at the level of the distal third of the proximal phalanx.[40,54,77] Fixed joint contractures are addressed with concomitant capsulectomy and collateral ligament releases as needed. Intrinsic muscle sliding procedures have been described but have limited indications

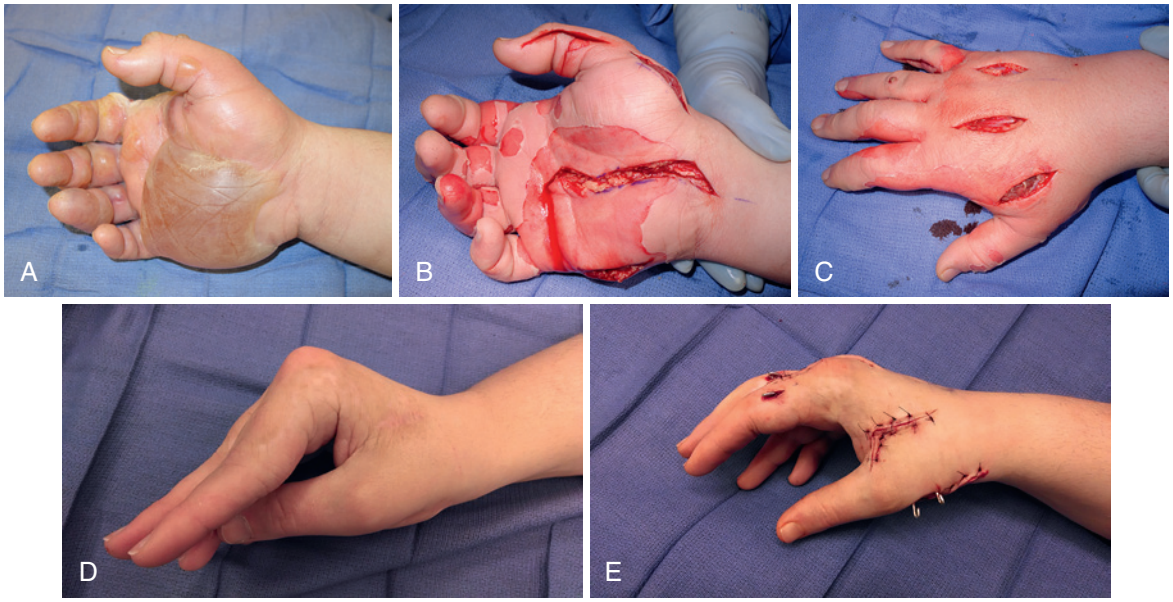

FIGURE 51.20 A 38-year-old diabetic presented to the orthopedic department more than 24 hours after lying on his hand for an unknown period of time during a diabetic coma. **A,** Appearance of the hand at time of presentation. **B,** Fasciotomy performed immediately after presentation, volar incisions. **C,** Fasciotomy performed immediately after presentation, dorsal incisions. **D,** Volkmann contracture of the hand developed despite release. **E,** First web space release with excision of fibrotic muscles and release of the intrinsics to the index and long fingers at the level of the metacarpophalangeal joint.

with severe contractures. These muscle sliding procedures have better outcomes with some underlying intrinsic muscle function preservation. Tenolysis of the flexor and extensor tendons and release of the intrinsic muscles at their insertion may be necessary to treat severe contractures. Despite these extensive releases, overcorrection of the contracture is not typically seen.

There is a limited role for tendon transfers in treatment of these deformities. Tendon transfers such as the flexor digitorum superficialis (ring finger) or extensor indicis proprius for reconstruction of opposition may improve function after addressing the contracture.

Complications

Complications can be seen with any surgical procedures. Specific complications related to surgery for Volkmann contracture are listed below.

Complications of Tendon Transfer. The most difficult aspect of performing a tendon transfer is establishing the appropriate tension of the transfer. Overtensioning or undertensioning can limit the functional outcome. Incorrect tensioning can be addressed with secondary surgery to tighten or loosen the transfer.

Complications of Flexor Origin Slide. Hematoma formation and wound dehiscence are potential complications. The use of a drain and judicious closure will minimize these complications. Sharma and Swamy reported on 19 patients with two events of wound dehiscence that healed by secondary intention.[75]

Complications of Functional Free Muscle Transfer. FFMT is a complex procedure associated with multiple potential complications, which can be divided into acute and long-term complications and also into those at donor sites and those at recipient sites.

Acute complications at the recipient site include flap loss, partial flap loss (either skin paddle or partial muscle loss),

CRITICAL POINTS *Late Management of Volkmann Contracture*

Pitfalls and Their Prevention

- Distinguishing Volkmann contracture from pseudo–Volkmann contracture is important:
  Historical features may favor one diagnosis over the other; clinical findings of nerve involvement are less likely in pseudo–Volkmann contracture; magnetic resonance imaging will not show ischemic muscle changes in pseudo–Volkmann contracture
- Failure to address severe muscle necrosis with wide excision of necrotic or fibrotic muscle may result in nerve ischemia and contracture: When necrotic and/or fibrotic muscle is identified, early excision of it and reconstruction of the compartment with healthy soft tissue will limit scarring and ischemia of the nerves
- Progressive or recurrent deformity during growth: regardless of the treatment provided this will occur. Night splinting should be continued through skeletal maturity
- Flexor-pronator slide: (1) Incomplete correction at the time of surgery will not improve postoperatively with therapy; obtain maximum correction during surgery; (2) injury to the common interosseous artery (which supplies the dorsal forearm compartment) can be prevented by careful dissection, especially in the proximal third of the forearm
- Free functional muscle transfer: (1) With prolonged surgical ischemia (>2 hours), even if the muscle survives, muscle function will likely be poor; consider a second muscle transfer; (2) therapy that is too aggressive during the early stage of healing can lead to rupture of muscle fibers; use gentle rehabilitation for the first 6 months following FFMT

Common Complications

- If the deformity recurs after a soft tissue procedure, arthrodesis of the wrist may be necessary and may need to be combined with proximal row carpectomy
- Inadequate active range of motion or strength after flexor origin slide may need to be managed with FFMT

hematoma, and infection. *Long-term complications at the recipient site* include scarring and tendon adhesions requiring revision surgery, attenuation at the tendon repair site, and inadequate recovery of muscle power for the desired level of function. In pediatric patients, the bone growth may be more rapid than the transferred muscle growth, which can lead to joint contracture.

Acute complications at the donor site include hematoma or seroma formation. The latissimus dorsi donor site is frequently complicated by seroma formation. Quilting and use of fibrin sealant at the donor site may reduce this complication.[4] Drains are a prerequisite to lessen this complication and should be retained until the patient is ambulating and drain output is less than 25 mL in 24 hours. Several authors have reported transient peroneal or sciatic nerve palsy related to intraoperative positioning.[1,23] *Long-term donor site complications* include painful unsightly scarring, donor site pain or dysesthesia, and functional losses. Russell and colleagues investigated changes in shoulder girdle function following latissimus dorsi harvest, noting a 5% to 10% decrease in shoulder girdle strength.[71] Deutinger and colleagues measured a decrease in adductor strength of 11% following harvest of the gracilis muscle.[23] Despite the measured decrease in muscle strength, the relative weakness is rarely noted by the patient, and therefore this possibility is not a contraindication for donor selection.

Management of Venomous Injuries

Vidal Haddad, Jr., and Trajano Sardenberg

Many venomous animals can cause injuries to humans. The injuries are induced by substances called toxins that are produced or stored in the body of these animals and inoculated (i.e., injected) into victims by their venom apparatus, as seen in snakes, spiders, and scorpions.[3,9,11] Toxins can also cause lesions from contact when the animal is handled or crushed, as happens with some species of beetles.[9,26,40] In this situation, they are called poisonous animals, as they do not cause active envenomation.

Toxins can interact and cause lesions in the tissues, organs, and systems of other animals. The mixture of toxins in a venomous animal represents its venom, and venomous animals use the toxins or venom as a defense against predators and to obtain food. The effects are variable, but mainly the blood, nervous system, and tissue at the inoculation site are affected (e.g., hemolytic, neurotoxic, and necrotic effects). Some envenomations cause minimal local manifestations because of their mainly neurotoxic and hemolytic actions. However, coagulant/anticoagulant and proteolytic venom fractions can cause severe necrosis, which facilitates significant secondary bacterial infection. Such lesions can be classified into two types according to the depth of action: (1) surface (or cutaneous) lesions are the result of contact with irritating substances from certain invertebrate species, whereas (2) inoculation lesions occur when venom is injected deep into the dermis and subcutaneous tissue and causes variable degrees of skin necrosis. Some necroses are superficial, as with cnidarians (jellyfish), whereas others are deep and severe, as caused by snakes and some spiders.[3]

Many conditions can lead to human envenomation in the extremities, especially in the lower and upper limbs. One profile for bites by snakes includes male farmers working outside without foot or leg protection. Envenomation often occurs in the hands because of their exploratory function, especially in children. Adult hand injuries occur mainly to farmers and fishermen as a result of the characteristics of their work. Academically, hand envenomation can also be characterized according to animal groups, but the groups will always possess venom with coagulant and proteolytic actions that cause superficial or deep tissue necrosis.

THE MAIN GROUPS OF VENOMOUS ANIMALS ASSOCIATED WITH HAND ENVENOMATION WITH LOCAL MANIFESTATIONS

Caterpillars

Envenomation by caterpillars is the most common of all injuries by venomous animals around the world. Caterpillars of the Saturniidae and Megalopygidae families cause the majority of injuries, and their hollow bristles contain toxins capable of provoking intense pain and a mild inflammatory reaction at the point of contact (Figure 52.1).[6,9,19,26] As a rule, the pain is out of proportion to the mild erythema and edema observed. Occasionally, local superficial necrosis occurs. The injury can be treated by a regional anesthetic block to control the pain. There are no later sequelae as a result of this type of envenomation.

Spiders

Most spider bites cause minimal local and systemic effects in humans, with variable pain intensity and healing without sequelae; the only treatment necessary for these injuries is analgesia and hygienic measures at the bite site.[35,37,52,58,60] Spider bites that cause systemic complications and risk to life, such as in bites by *Latrodectus* (the black widow), *Atrax* (the funnel web spider), and *Phoneutria* (the banana spider), do not cause significant manifestations at the bite site. A spider associated with severe local effects, including marked tissue necrosis, is the cosmopolitan brown "recluse" spider (genus *Loxosceles*) that lives in some regions of Africa; the North, Central, and South Americas; Australia; and some places in Asia and Europe.[14,19,33,36,45,61,63–65] *Loxosceles* spiders often live in home environments, mainly in dark places, and can bite when crushed against a victim's body. The incidence of arm and hand spider bites is about 15% to30%, and they can cause severe functional problems and long periods of incapacity; these are important injuries that specialists in upper-extremity surgery should become familiar with.[12,34,42,45,57]

Brown recluse spider venom is a mix of proteins. The most important fraction is sphingomyelinase D, which causes skin necrosis, vasculitis, and hemolysis.[14,15,19,33,36,45,47,61,62,63,65] There are two classic manifestations: cutaneous loxoscelism and viscerocutaneous loxoscelism. The initial bite may be minimally painful and go unnoticed. In 2 to 6 h a burning pain arises along with local erythema and blanching of the skin with eventual cyanosis and edema. Occasionally, hemorrhagic blisters develop. In 3 to 7 days necrosis is evident (Figure 52.2).[7,9,10,14,26,38,41,44,55,56] If skin lesions are absent after 2 to 3 days, soft tissue necrosis is unlikely.[33,55] Systemic alterations, if they occur, will be present within 24 to 72 h after the bite and include fever, arthralgias, vomiting, hemolysis, petechiae, and urticaria, with disseminated intravascular coagulation and renal failure being at the severe end of the spectrum.[10,33,44,52,55]

The gold standard for diagnosis is capture and identification of the spider, a situation that rarely occurs and unfortunately leaves clinical diagnosis as the most important method.[7,9,10,14,18,26,38,41,44,48,49,55,56,66] We must remember that the

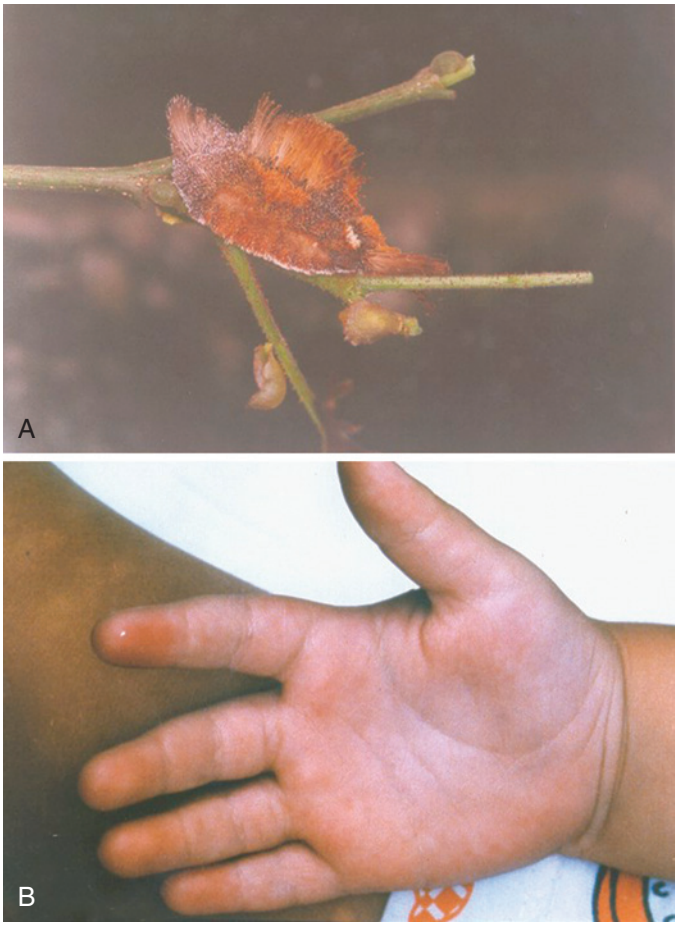

FIGURE 52.1 Caterpillar of the Megalopygidae family **(A)** and injuries in a child **(B)**. The pain was intense, but local inflammation was discrete. (Photographs courtesy of Vidal Haddad, Jr.)

FIGURE 52.2 **A,** *Loxosceles,* the brown recluse spider. **B,** The venom of this spider has a potent necrotic effect. Considerable necrosis occurred in the fifth finger of a woman after a brown spider bite (she saw the spider). (**A,** Photograph courtesy of Vidal Haddad, Jr.; **B,** photograph courtesy of Dr. Jefferson Braga Silva, Brazil.)

clinical appearance of the necrotic injury in the skin is not specific to the bite of spiders and may be caused by several medical conditions, such as erysipelas, cellulitis, necrotizing fasciitis, and fungal and bacterial infections, as well as other animal envenomations.[8,10,67] Serologic diagnosis is currently in the experimental stage.[20,39,59]

There is no standard treatment for spider bites.[17,54,60] Skin integrity should be maintained to prevent infection and local circulation preserved,[54] specifically with hand lesions, to maintain articular mobility and skin sensitivity. The initial phases of treatment should include rest, cold packs, elevation of the limb, intensive cleaning, tetanus prophylaxis, systemic analgesics, and gentle passive and active articular mobilization.[55,60] Moderate or severe bites (with significant necrosis) are treated with antibiotics (e.g., dapsone), corticosteroids, surgical excision, and antivenin.[10,33,51,60,61] Dapsone is an antibiotic from the sulfone group with antimicrobial and antiinflammatory properties; it is commonly used for leprosy and many inflammatory skin diseases.[69,72] Use of dapsone is based on its capacity to block the diapedesis of neutrophils. Dapsone is used in later phases (48 h after envenomation) and the recommended dose is 100 to 300 mg/d.[69] There are no conclusive studies of the efficacy of dapsone or corticosteroids for spider bites, however.[5,7,9,10,14,16,26,38,41,44,55,56,70] Antibiotics are only used in the presence of secondary infection of necrotic lesions.

Antivenin is routinely used in Brazil, and studies have shown that it can prevent necrosis when used in the first 12 h after envenomation.[33,44,55] Unfortunately, this medication is not presently available in the United States. Surgical treatment includes debridement and excision of necrotic tissue and coverage with grafts or flaps once viable tissue is reached. The question involves the time to initiate intervention because necrosis can be active for up to 2 to 8 weeks after the bite. Rees and coauthors reported that late surgery gave better results in their study series.[53] Clinical experience indicates that management consisting of debridement, hygiene measures, and waiting for stabilization of the tissue necrosis is prudent initial treatment.[4,10,17,33,53,55,61,68,71]

Snakes

The most important envenomations by snakes are from the Elapidae and Viperidae families. Bites by the Elapidae family cause discrete skin manifestations, mainly as a result of their neurotoxic and myolytic effects. The snakes include the African and Asian cobras, the African green and black mambas, the American coral snake, the Australian Elapidae snakes, the taipans, and brown snakes. Envenomation can be very severe, and patients sustaining significant envenomation should be identified early. The typical facial symptom is called "drunken face" because of eyelid ptosis, and this should not be confused with other situations such as myasthenia gravis or alcoholic intoxication. Muscular paralysis is the main clinical effect of the bites.

FIGURE 52.3 **A,** *Crotalus durissus*, the South American rattlesnake of the Viperidae family. The venom is mainly neurotoxic, but it can cause skin necrosis. **B,** The Viperidae rattlesnake family causes extremely severe necrosis of the skin and deep structures in humans. This snake is a spotted jararaca (*Bothrops matogrossensis*). (Photographs courtesy of Vidal Haddad, Jr.)

FIGURE 52.4 Edema and erythema are the early signs after the bite of a Viperidae snake. The edema is sometimes so pronounced that it causes compression and ischemia in hand structures. (Photograph courtesy of João Luiz Costa Cardoso, Butantan Institute, São Paulo, Brazil.)

Envenomation by the Viperidae induces necrosis of the skin and deep structures. Snakes in this family are found around the world; the most common associated with human bites are the European and Asiatic vipers and the African vipers such as the Gaboon viper (*Bitis gabonica*), the puff adder (*Bitis arietans*), and the saw-scaled viper (*Echis carinatus*). In the New World, necrotic and inflammatory lesions can be associated with *Lachesis* (bushmasters) and *Agkistrodon* (the North American cottonmouth and copperhead), but mainly with snakes of the *Crotalus* (rattlesnakes) and *Bothrops* genera, which are very common in Central and South America (Figure 52.3). The venom of all these snakes can induce intense inflammation, edema, and necrosis at the bite site (Figure 52.4).[8,9,26,50]

The intensity of the necrosis caused by envenomation is variable and modulated by the capacity of the venom fractions to destroy tissue. Bites inoculate venom into subcutaneous tissue or muscle, and bite marks may be invisible. Edema at the site of injury occurs very early and can be extremely intense; pain is proportional to the edema. When present, the coagulant and anticoagulant factors in venom cause local and systemic effects, and they can affect systemic coagulation and induce hemorrhage. Skin blisters are common (Figure 52.5).

Large areas of necrosis and inflammation can simulate erysipelas and cellulitis. These findings can also occur in the presence of a secondary bacterial infection, a common complication

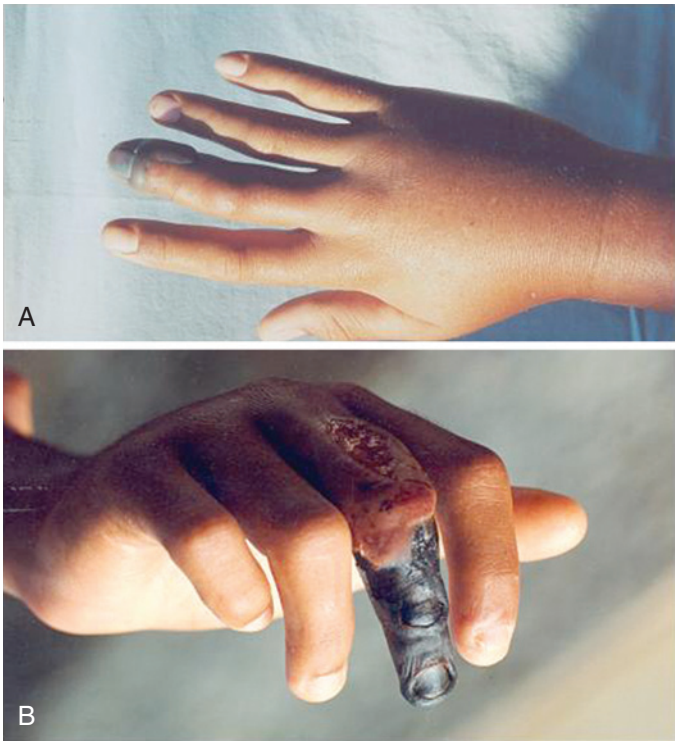

FIGURE 52.5 **A,** Hemorrhagic bullae and edema with necrosis are common complications of Viperidae bites. The ischemia and necrosis can be severe. **B,** Snakebites in the extremities are potentially severe because of their terminal circulation. Necrosis and amputation of the fingers can occur, especially in patients who do not begin treatment soon enough. (Photographs courtesy of João Luiz Costa Cardoso, Butantan Institute, São Paulo, Brazil.)

FIGURE 52.6 The severe inflammation and necrosis in this patient was aggravated by secondary bacterial infection. There is risk for compartment syndrome. (Photograph courtesy of João Luiz Costa Cardoso, Butantan Institute, São Paulo, Brazil.)

in envenomations that leads to extension of necrosis and ulcers at the bite site (Figure 52.6). Abscess formation can be seen at the bite site as well and is usually caused by gram-negative and anaerobic bacilli. Occasionally, amputation of the compromised extremity is necessary because of necrosis and infection. This is common in fingers and is due to the compromise of their circulation, and the necrosis can extend proximally to muscles, tendons, and bones.[8,50]

A rare but very severe complication is compartment syndrome, which is an increase in pressure in a closed compartment that results in abnormal neuromuscular function because of compression of muscles, nerves, and vessels. This syndrome is a result of necrosis and inflammation and is most commonly found in the fingers, legs, and dorsal and ventral regions of the forearm. The most valuable signs and symptoms to help in the diagnosis of compartment syndrome is pain that is not proportional to the edema and limitations in neuromuscular action. The gold standard in the United States for evaluation of this syndrome is measurement of compartment pressure. Systemic hypotension may be present in patients with normal peripheral pulses. Treatment of compartment syndrome consists of fasciotomy, which is more effective when performed early.

Antivenin (specific for various genera) is the only worthwhile treatment, but it has little effect on local complications. The primary antivenin used in the United States today is CroFab®, a sheep-derived antivenin that was approved for use by the U.S. Food and Drug Administration in October 2000 and is marketed by Savage Laboratories. It consists of purified Fab immunoglobulin fragments obtained from sheep immunized with the venom of the western diamondback, eastern diamondback, and Mojave rattlesnakes and the cottonmouth or water moccasin.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT OF SNAKEBITE

Pit viper bites differ from other compartment syndromes in that the venom is injected directly into the skin and subcutaneous tissue with immediate resultant tissue edema, ecchymosis, and rapid swelling. The venom may or may not be injected into a closed compartment, but it usually is. The severe swelling of the skin and soft tissues outside a compartment can be of such a degree that the circulation will be impaired, particularly with bites on the digits of the hand. When a snakebite victim in whom the tissues of the envenomated extremity have the appearance of an impaired blood supply or compartment syndrome, or both, is first seen, the patient is prepared for surgery. This is regardless of whether antivenin was or is being administered; however, surgery is started only after blood coagulation studies have been completed.

The skin and subcutaneous swelling can be so great that the blood supply is impaired, which may result in subsequent tissue loss. If such swelling is noted, fasciotomy of the underlying compartment as described earlier is done at the same time, without measuring compartment pressures. If the swelling is severe enough to necessitate a dermotomy, the fascia has been penetrated and intracompartmental swelling is present. Failure to release skin that is too tight and is compromising local blood flow can lead to significant tissue loss in the hand, which may necessitate later replacement. Local tissue necrosis at the site of the fang marks is debrided, but no other debridement is done at this time.

If after a snakebite no clinical evidence of impending tissue loss secondary to severe swelling exists and there is no clinical evidence of a compartment syndrome, no surgery is performed. As emphasized previously, the pain and degree of swelling after a pit viper bite can make the clinical diagnosis of compartment syndrome a difficult one and may necessitate continuous intracompartmental pressure monitoring. The guidelines for decompression of the soft tissues outside a compartment are nebulous and based on past experience; however, the question of whether a closed compartment needs to be opened should be settled by measuring compartment pressure.

Cnidarians (Jellyfish, Portuguese Man o' War, Anemones, Corals)

These marine animals have a round structure with several tentacles that have defensive cells called *cnidoblasts*; they contain nematocysts—the organelles that can fire a thin tube filled with neurotoxic and necrotizing venom (Figure 52.7). One tentacle has millions of these small structures and can cause significant envenomation in humans. A typical sting from a cnidarian causes immediate intense pain on contact with the animal, even

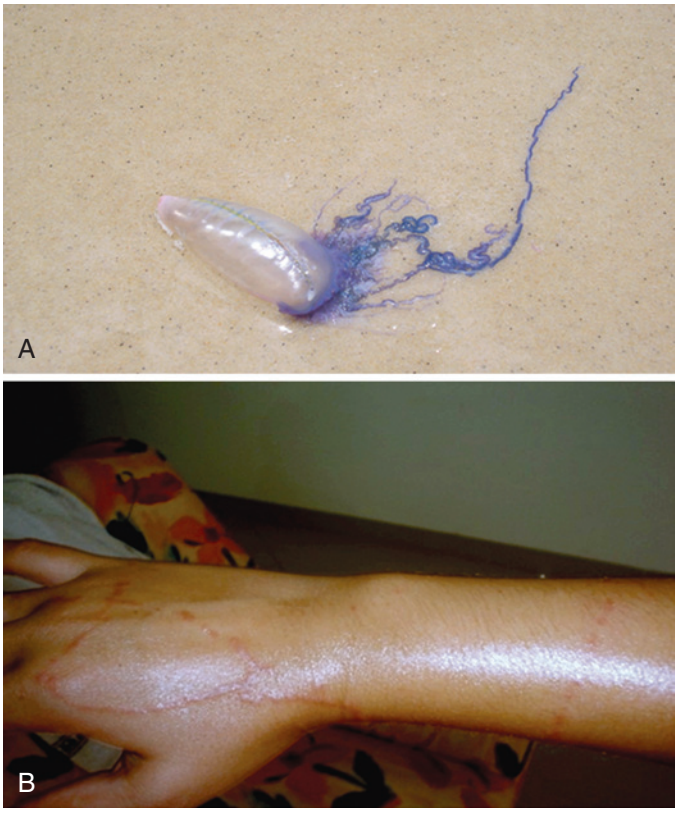

FIGURE 52.7 **A,** The Portuguese man o' war (PMW; *Physalia phisalis*) is a cnidarian that causes human injuries all around the world. **B,** Typical lesions caused by PMW. The superficial necrosis has linear aspect, like rosary beads. The pain is very severe and lesions occur soon after contact, even when the patient is still in the water. (**A,** Courtesy of Ana M. de Cerqueira, Rio de Janeiro, Brazil; **B,** courtesy of Lucia Fransozo, São Paulo State, Brazil).

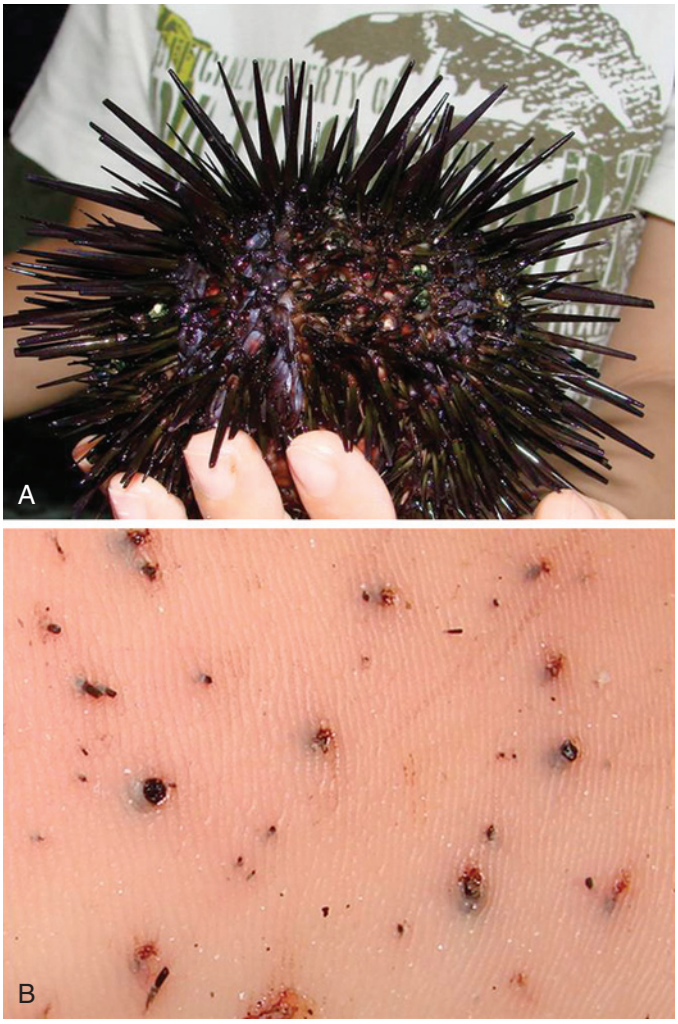

FIGURE 52.8 Black sea urchin **(A)** and spines in the skin of a victim **(B)**. Early extraction of the spines is very important to prevent complications such as bacterial infections and foreign body granulomas.

while in the water. There is also the instant appearance of erythematous crossing linear plaques reproducing the shape of the tentacles.[9,22–24,26,27,32] These lesions can become vesiculobullous. There are reports of vascular spasm and digit necrosis after unidentified jellyfish stings.[13]

Jellyfish "burn" (an incorrect term because it is not a real burn but an envenomation) should be treated at the time of the incident with ice-water compresses (avoid freshwater, which triggers more nematocysts by osmosis) and bathed with vinegar hopefully to stabilize nematocyst firing. In the hospital, analgesia is important for pain control.[9,22–24,26,27,32]

Sea Urchins

Sea urchins and some species of starfish can cause lesions in humans from their spines. The body spines are composed of calcium carbonate and can be venomous.[46] Spines left in the wound can provoke a foreign body reaction and bacterial infection.[31] Therefore, early spine extraction through an elliptical incision at the point of contact (spines are visible in most situations) is very important. The use of hot water has been described, as has hot candle wax, vinegar, and urine; however, these are only measures for controlling the pain from injuries caused by venomous sea urchins. In most cases the problem is resolved by early spine extraction or later extraction in the presence of a foreign body reaction (Figure 52.8). The recommended action is total spine extraction with large-caliber needles[31] or through an elliptical incision under magnification.

Venomous Fish

The severe pharmacologic action of all fish venoms is similar: intense pain as a result of neurotoxicity together with variable skin necrosis, depending on venom intensity and the common secondary infection. The most venomous fish include the Scorpaenidae family: the stonefish (*Synanceia* genus), the scorpionfish (*Scorpaena* genus), and the lionfish (*Pterois* genus) (Figure 52.9). Marine and freshwater stingrays and catfish are important venomous fish as well.[9,23,25–30,50]

Hand envenomation from marine and freshwater catfish is common, and bacterial infections and retention of stinger fragments can lead to severe complications, such as osteomyelitis, and the need for ray amputation (Figures 52.10 and 52.11; Case Study 52.1). The most common organisms causing these infections are *Edwardsiella tarda*, *Vibrio* species, and *Aeromonas hydrophila*. Antibiotics recommended for the initial phases of

FIGURE 52.9 **A,** The lionfish is a fish of the Scorpaenidae family and is the most venomous fish in the world. Even so, it is sold as an aquarium fish worldwide, increasing the risk for serious accidents. **B,** Note the edema and erythema caused by a puncture from the dorsal fin ray of a lionfish. The pain is very severe, and there are no specific measures for treating this kind of injury. (Photographs courtesy of Vidal Haddad, Jr.)

FIGURE 52.11 **A,** Early laceration in the hand of an amateur fisherman caused by a catfish. The pain was excruciating and persisted for about 24 h. **B,** Radiologic examination of the patient's hand showing a common complication from catfish injury: a broken stinger fragment. Apart from envenomation, a fragment in the wound can cause additional inflammation and secondary infections. (Photographs courtesy of Vidal Haddad, Jr.)

FIGURE 52.10 Marine and freshwater catfish have three serrated stingers that can cause perforations, lacerations, and inflammatory phenomena in humans. It is not uncommon to find secondary infections and broken stingers in wounds. (Photograph courtesy of Vidal Haddad, Jr.)

envenomation are aminoglycosides or ciprofloxacin, but aggressive debridement is the most effective measure when infection is already established.[2,21,29,43]

Stingrays cause severe envenomation by puncturing the victim with their bony caudal stinger or stingers and introducing venom. The pain is intense, and necrosis tends to become established within 24 h after injury. Initial management consists of submersion of the affected part in hot water (104°F), which denatures the proteins in the venom. Pain will recur if the extremity is removed from the water too soon. Care must be taken to make sure that the water is not too hot and that the limb is not left in too long to avoid burns. If the wound persists, ulcers can be extensive and are slow to heal (Figure 52.12).

Injury by stingrays can be confused with various diseases that cause ulcers in the lower limbs, such as a tropical ulcer, pyoderma gangrenosum, sickle cell anemia, and ulcers associated with venous stasis and bullous erysipelas. Nonvenomous fish can cause severe trauma, including lacerations and bacterial infections. Sharks, barracudas, and moray eels can inflict this kind of hand injury (Figure 52.13).

Immersing the compromised part in tolerably hot water is important in the initial phase of any venomous fish incident; this causes vasodilation and counteracts the vasoconstriction provoked by the venom.[1] Resulting tissue necrosis may well lead to the need for coverage with surgical flaps or skin grafting.

CASE STUDY 52.1

A female, 42 years old, was wounded in the third finger of the right hand by a catfish (see eFigure 52.1) when she was taking the fish off the hook. The patient presented intense pain, edema, and erythema for almost 6 hours. She used alcohol on the wound without relief of the pain. After three days, there were still local erythema and edema (see eFigure 52.2), without fever or purulent discharge in the orifice of entry of the sting.

Points of discussion include:

- Absence of infection (which is very common): without fever or malaise.
- Edema and erythema without pain: absence of envenomation (lasts about 1 day).
- Is there a foreign body?

After viewing eFigure 52.3, what is your option of treatment in this case?

a. Antibiotic therapy
b. Immersion in hot water
c. Surgical intervention
d. Observation

ANS: c, Surgical intervention

Now see eFigure 52.4. Injuries by catfish are the most common envenomation caused by fish in marine or freshwater environments (about 80%). Initially: intense pain is caused by the venom. Treatment: hot water (vasodilatation). Complications: bacterial and fungal infections and retention of fragments of the stinger; it should receive the attention of a hand surgeon.

FIGURE 52.12 Laceration in a fisherman's hand (at 30 days) caused by the sting of a marine stingray. Note the mild necrosis. In the initial phase, pain and edema were intense. *Right,* A marine stingray (*Rhinoptera bonasus*) associated with envenomation in fishermen. (Photographs courtesy of Vidal Haddad, Jr.)

CRITICAL POINTS *Venomous Injuries of the Hand*

General
- Envenomation often occurs in the hands because of their exploratory function, especially in children.
- There are no significant sequelae from the majority of envenomations by animals such as caterpillars, bees, jellyfish, and others.

Spiders
- Brown recluse spider bites can cause skin necrosis.
- Initial treatment should include rest, cold packs, elevation of the limb, intensive cleaning, tetanus prophylaxis, systemic analgesics, and gently passive and active articular mobilization.
- Moderate and severe bites are treated with antibiotics (e.g., dapsone) and corticosteroids and often surgical excision.
- The skin necrosis can be active for up to 2 to 8 weeks after the bite; extensive debridement, or flaps or skin grafting (or both) should be delayed until after week 6 to 8 of the necrosis.

Snakes
- Envenomation by snakes of the Viperidae family causes skin and deep necrosis.
- The tissue necrosis is variable and modulated by the capacity of the venom fractions to destroy tissue; the necrosis can extend to muscles, tendons, and bones.
- Large areas of necrosis and inflammation can occur, as well as abscesses caused by gram-negative and anaerobic bacilli.
- Amputation of the compromised part may be necessary as a result of necrosis and infection, especially in fingers because of poor terminal circulation.
- Antivenin (specific for various genera) is the only worthwhile treatment, but it has little effect on local complications.
- A rare but very severe complication is compartment syndrome. Treatment is by fasciotomy, which should be done early.

Cnidarians (Jellyfish)
- Treatment at time of the accident includes water compresses and bathing the part with vinegar, which may stabilize nematocyst firing.
- Avoid freshwater, which triggers more nematocysts by osmosis.

Sea Urchins
- The spines must be extracted early to prevent inflammation and infection at the puncture sites, especially to prevent foreign-body granulomas, which must be extracted by surgery.

Venomous Fish
- Immersing the compromised part in extremely, but tolerably, hot water (104°F) is important in the initial phase of any venomous fish incident; this causes vasodilation and counteracts the vasoconstriction induced by the venom.
- Chronic ulcers are candidates for surgical flaps or skin grafting.
- Bacterial infections and retention of stinger fragments are common and can cause severe complications such as osteomyelitis.

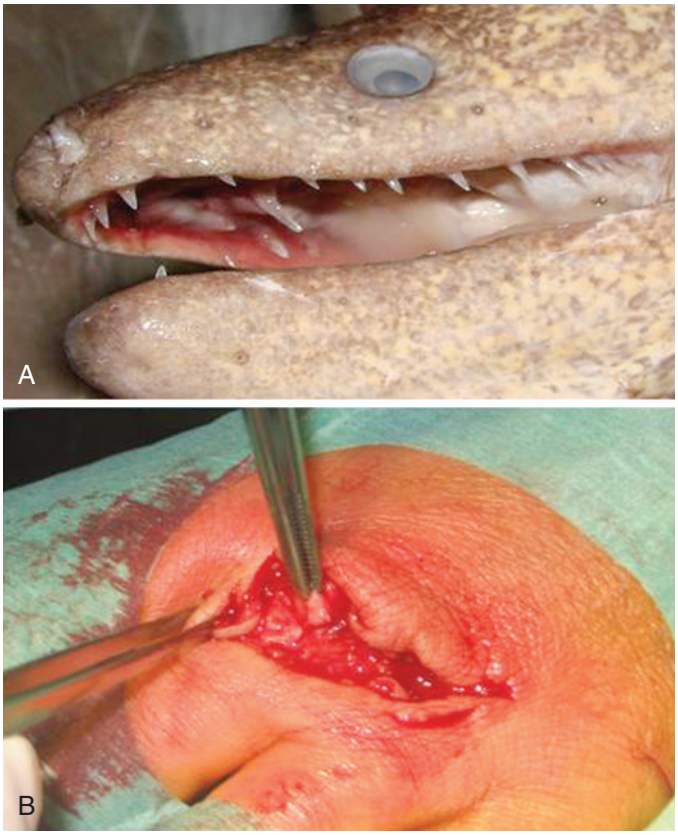

FIGURE 52.13 **A,** *Muraena helena*, a species of moray eel associated with human injuries. They are not aggressive but can occasionally bite. **B,** The lesions caused by moray eels lacerate and result in tissue loss. There is current evidence that their saliva contains toxins associated with the disproportionate pain observed in patients after bites. (**A,** Courtesy of Vidal Haddad, Jr.; **B,** courtesy of João Pedro Barreiros, Azores, Portugal.)

EXPECTED OUTCOMES

- There are no later problems from the majority of envenomations by animals. In this category we can include caterpillars, bees, jellyfish, and others.
- The question about the treatment of brown spider bites involves the time of intervention because necrosis can be active for up to 2 to 8 weeks after the bite. Late surgery gave better results in one series.
- The intensity of necrosis after envenomation by snakebites is variable and modulated by the capacity of the venom fractions to destroy tissue. Extensive necrosis and inflammation can simulate erysipelas and cellulitis and can even be present when secondary bacterial infection occurs; this is a common complication in envenomation that leads to extension of the necrosis and ulcers at the bite site. Abscess formation can be seen at the bite site and is caused by gram-negative and anaerobic bacilli. Occasionally, amputation of the compromised part is necessary as a result of necrosis and infection. This is common for fingers because of their terminal circulation. The necrosis can extend to muscles, tendons, and bones.
- In most cases of injury caused by sea urchin spines, the problem is early spine extraction or late extraction in the presence of nodules caused by reaction to a foreign body.
- Hand envenomation by marine and freshwater catfish is common, and bacterial infections and retention of stinger fragments can cause severe complications, such as osteomyelitis, and the need for ray amputation.

A Practical Guide for Complex Regional Pain Syndrome in the Acute Stage and Late Stage

L. Andrew Koman, Beth Paterson Smith, and Thomas L. Smith

The classification of abnormal, posttraumatic pain is complicated and encompassed in the term *complex regional pain syndrome* (CRPS).[135] The term *reflex sympathetic dystrophy* (RSD), a descriptor of posttraumatic pain, is established in the lay, medical, and legal literature despite the absence of defined pathophysiologic findings and consistent clinical symptoms and signs. RSD is a condition considered to be present in a subset of patients contained within the broader category of CRPS. Even with introduction of the name CRPS, much of the contemporary literature uses RSD, algodystrophy, and other descriptors. The purpose of this chapter is to present diagnostic criteria that define clinical subtypes of CRPS and to provide a practical approach for treatment in the acute and chronic stages of this dynamic process.

GENERAL CONSIDERATIONS IN COMPLEX REGIONAL PAIN SYNDROME

Clinical Definitions

The diagnosis of CRPS is contingent on the presence of regional pain combined with autonomic dysfunction, atrophy, and functional impairment (Figure 53.1 and Box 53.1) affecting musculoskeletal, neural, and vascular structures.[32] Type 1, or "classic," RSD is not associated with an identifiable peripheral nerve injury. Type 1 CRPS is initiated by trauma and is often associated with swelling as a result of dependency, extensive trauma, or a cast or bandage that was quite tight. Type 2 is associated with an identifiable peripheral nerve injury (causalgia). Type 3 includes nontraumatic causes producing extremity pain such as myofascial syndrome (Table 53.1).[39] The type 3 category of CRPS is controversial; however, its use expands the concept to include all extremity pain pathologic conditions. This chapter discusses only CRPS type 1 and type 2.

Budapest Criteria

The International Association for the Study of Pain (ISAP) recommended and endorsed specific diagnostic criteria based upon a consensus process conducted through a "by invitation only" workshop held in the fall of 2003 (Box 53.2). Subsequent internal and external validation studies and modifications of decision rules support a sensitivity of 0.70 and a specificity of 0.94. While not perfect, with a tendency toward overdiagnosis, these criteria are clinically superior to previous criteria but subject to observer variability (Box 53.3).[57]

The distinction "major nerve damage" is confusing as a discriminator for type 2 versus type 1 CRPS, and injury to an identifiable named nerve is appropriate to designate a diagnosis as type 2. Historically, causalgia was associated with an injury to a "major" mixed motor and sensory nerve (e.g., the median or sciatic nerve).

Neuropathic pain is defined as pain initiated or caused by a primary lesion or lesions or dysfunction of the peripheral nervous system or central nervous system (CNS). *Nociceptive pain* results from damage to tissues as a result of thermal, mechanical, chemical, or other irritants. Neuropathic pain may be associated with CRPS type 2, or it may be considered a distinct entity, depending on its source (Table 53.2). Mononeuropathy, if symptoms and signs extend beyond the nerve distribution, may constitute CRPS type 2.

The diagnosis of CRPS is based on the patient's history and physical examination and relies on the intuition, experience, and clinical judgment of the physician.

Diagnostic criteria based upon consensus recommendations are a valuable but not an infallible tool that aids the diagnosis.

Although attempts have been made to establish these diagnostic tools, serum biomarkers or laboratory findings cannot be used to make the diagnosis of CRPS.[1,2,56,66,94] Early recognition along with prompt treatment of CRPS is important to minimize permanent loss of function. However, despite prompt recognition and treatment, patients with CRPS may experience permanent impairment and disability.[17] Many patients also face loss or suspension of work, changes in occupation, and psychological disorders.[42]

CRPS may include sympathetically maintained pain (SMP) or sympathetically independent pain (SIP). These terms recognize the dynamic nature of dystrophic responses and stress the value of reliable and consistent clinical observations and descriptions. The diagnosis of SMP is based on pain relief with sympatholytic medications or sympathetic blocks[109,110]; however, SMP may become SIP over time. Objective and reproducible methods to assess pain, quantify trophic changes, define autonomic dysfunction, and measure functional impairment are important to provide consistent treatment regimens and reliably assess outcomes.[77,78]

Physiology of Pain

Normally, pain is perceived only in the presence of actual or impending cellular tissue damage; persistent pain is pathologic in the absence of continued trauma. Painful peripheral nociceptive experiences that include cellular damage produce secondary inflammation by activating and sensitizing polymodal low-threshold mechanoreceptors and nociceptor afferent neurons, which produce, in theory, ectopic chemosensitivity to α-adrenergic agonists.[28] This information is relayed via the process of *transduction* through small myelinated (Aδ), large myelinated (Aβ), and small unmyelinated (C) afferent fibers to the dorsal horn of the spinal cord, where *sensitization* of wide–dynamic range (WDR) neurons contributes to central nociceptive discharge (Figure 53.2, *A*).[28] Within the dorsal horn, excitatory amino acids serve as the principal neurotransmitters. Transmitters include *N*-glutamate, aspartate, α-amino-3-hydroxy-5-methyl-4-isoxazopropionic acid (AMPA), *N*-methyl-D-aspartate (NMDA), and substance P. Of these, the NMDA receptor-transmitter interaction produces long-lasting potentials, is refractory to stimulation, and is theorized to play an

TABLE 53.1 Types of Complex Regional Pain Syndromes

Type	Description
Type 1	Reflex sympathetic dystrophy (pain, functional impairment, autonomic dysfunction, dystrophic changes without clinical peripheral nerve lesion/injury)
Type 2	Causalgia (pain, functional impairment, autonomic dysfunction, dystrophic changes with a diagnosable peripheral nerve injury)
Type 3*	Other pain dysfunction problems (e.g., myofascial pain)

*Not discussed in this chapter.

BOX 53.2 International Association for the Study of Pain Budapest Diagnostic Criteria for Complex Regional Pain Syndrome (CRPS)*

1. The presence of an initiating noxious event, or a cause if immobilization†
2. Continuing pain, allodynia, or hyperalgesia in which the pain is disproportionate to any known inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain (can be a sign or symptom)
4. This diagnosis is excluded by the existence of other conditions that would otherwise account for the degree of pain and dysfunction

*If seen without "major nerve damage," diagnose CRPS I; if seen in the presence of "major nerve damage," diagnose CRPS II.
†Not required for diagnosis; 5% to 10% of patients will not have this.

BOX 53.3 Proposed Refinement of Original Budapest Clinical Diagnostic Criteria for Complex Regional Pain Syndrome

1. Continuing pain that is disproportionate to any inciting event
2. Must report at least one symptom in *three of the four* following categories:
   - *Sensory:* report of hyperesthesia and/or allodynia
   - *Vasomotor:* reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry
   - *Sudomotor/edema:* reports of edema and/or sweating changes and/or sweating asymmetry
   - *Motor/trophic:* reports of decreased range of motion and/or motor dysfunction (weaknesses, tremor, dystonia) and/or trophic changes (hair, nails, skin)
3. Must display at least one sign at time of evaluation in *two or more* of the following categories:
   - *Sensory:* evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement)
   - *Vasomotor:* evidence of temperature asymmetry and/or skin color changes and/or asymmetry
   - *Sudomotor/edema:* evidence of edema and/or sweating changes and/or sweating asymmetry
   - *Motor/trophic:* evidence of decreased range of motion and/or motor dysfunction (weakness, tremor, systonia) and/or trophic changes (hair, nails, skin)
4. There is no other diagnosis that better explains the signs and symptoms

TABLE 53.2 Terms Used in Complex Regional Pain Syndrome

Term	Definition
Pain	Unpleasant perception associated with actual or potential cellular damage
Analgesia	Absence of pain in response to an insult that should produce pain
Neuropathic pain	Pain initiated or produced by a primary lesion or lesions or dysfunction of the peripheral or central nervous system
Nociception	Response to an unpleasant (noxious) stimulus that produces pain in humans under normal circumstances because of thermal, mechanical, chemical, or other irritants of nonneural tissues
Allodynia	Pain in a specific dermatomal or autonomous distribution associated with light touch to the skin; a stimulus that is not normally painful
Hyperalgesia	Increased sensitivity to stimulation (includes allodynia and hyperesthesia)
Hyperesthesia	Increased sensitivity to simulation (pain on response to a mild nonnoxious stimulus)
Sympathetic pain	Pain in the presence of or associated with overaction of sympathetic fibers; by definition, the pain is relieved by sympatholytic interventions
Hypoesthesia	Decreased sensitivity to stimulation
Hyperpathia	Abnormally painful reaction to a stimulus
Dysesthesia	An unpleasant abnormal sensation
Paresthesia	An abnormal sensation

From Gracely R, Price D, Roberts W, et al: Quantitative sensory testing in patients with complex regional pain syndrome (CRPS) I and II. In Janig W, Stanton-Hicks M, editors: *Reflex sympathetic dystrophy: a reappraisal*, vol 6, Progress in pain research and management, Seattle, 1996, International Association for the Study of Pain, pp 151–170.

important role in CRPS types 1 and 2. Nociceptive input is modulated via descending pathways, and both peripheral and central factors are required for the perception of pain (see Figure 53.2, *B*). Pain intensity is determined by the magnitude and extent of the initiating/ongoing event, afferent input, efferent modulation, and CNS interpretation. Conscious appreciation of nociceptive (painful) experiences is dependent on a complex interplay of afferent and efferent information modulated and balanced by physiologic adaptations. Vasomotor disturbances may result from a variety of mechanisms, including antidromic vasodilation, vasoparalytic dilation, normal somatosensory reflexes, and denervation super sensitivity.[28] Responses to nociceptive stimuli can vary significantly among individuals. The presence of nociceptive-induced inappropriate transmitter-receptor activity can affect peripheral microcirculatory control and, thereby, result in impaired nutritive blood flow[76,106,113] and may sensitize CNS pathways.[10,11,26,28,29,88,97,103]

Perception of Pain

By definition, CRPS does not exist in the absence of pain. Peripheral injury stimulates endogenous inflammatory mediators via nociceptive pathways. Repetitive trauma/injury may alter protective responses by producing earlier activation through sensitization. In addition to providing central input, local nociceptors initiate the direct release of peptides and neurotransmitters, control the inflammatory process, and promote tissue repair. Pain requires cognitive recognition.

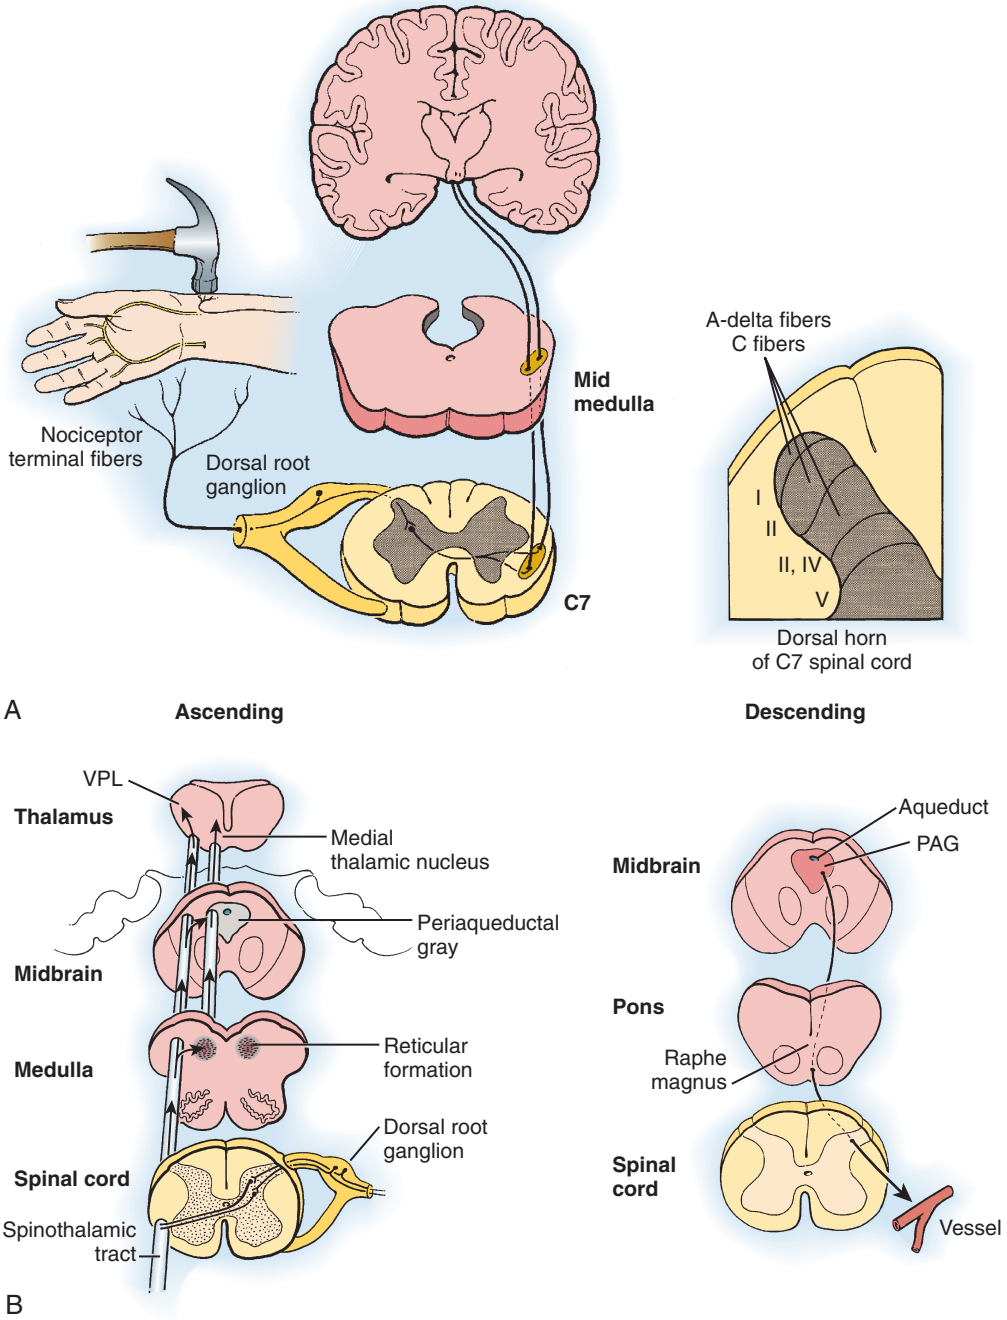

FIGURE 53.2 **A,** Abnormal central nervous system modulation of afferent sensory stimuli may contribute to the development of a dystrophic response after an injury that produces a peripheral nociceptive focus or "trigger." **B,** Ascending and descending pathways in the spinal cord and brain. *PAG*, Periaqueductal gray matter; *VPL*, ventral posterolateral nucleus. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

Pain Mediators and Receptor Control

A variety of nonneurogenic and neurogenic mediators participate in the transmission of information interpreted as pain. Nonneurogenic mediators include bradykinin, serotonin, histamine, acetylcholine, prostaglandins E_1 and E_2, and leukotrienes. Neurogenic mediators, which are biologically active peptides produced by primary afferent neurons, potentiate or inhibit nociceptive information. These mediators include substance P, vasoactive intestinal peptide, calcitonin gene–related peptide, gastrin-releasing peptide, dynorphin, enkephalin, galanin, somatostatin, cholecystokinin, γ-aminobutyric acid, dopamine, and glycine.

The role of α-adrenergic receptors and local blood flow in sympathetically maintained complex regional pain states is well documented,[31,60,109,111] and relief of pain after intravenous phentolamine, a mixed α_1- and α_2-antagonist, is considered pathognomonic for SMP (CRPS type 1).[109,110] Abnormal regulation of adrenoreceptor function or modulation (or both) in neural and

vascular structures is the major common control pathway supporting the concept that RSD (SMP) is a *receptor disease*.[36,109] Presynaptic and postsynaptic receptors are involved and affect nociceptive foci, blood flow, nutritional perfusion, and peripheral nerve excitability.[14,80,113] The pathologic mechanisms involved in the compromise of extremity blood flow and neural control include: (1) abnormal neurotransmitter release secondary to nociceptive foci, (2) abnormal receptor distribution, and (3) alterations in receptor sensitivity (e.g., upregulation or downregulation).

Gate Theory of Pain

The "gate theory" is an appropriate aid in the conceptualization of pain. The theory assumes that a finite amount of information can be received at the spinal cord or cortical level. The "gate" is the dorsal horn of the spinal cord. Thus, painful information displaced or modified by less noxious input cannot be processed through the gate. Although as yet unproven, certain general principles relating to pain processing can be conceptualized by using this theory.

Acute Versus Chronic Pain

Acute pain is initiated during tissue injury or destruction, and the presence of acute pain may be beneficial or harmful. Beneficial effects include physiologic responses for maintenance of blood pressure, cardiac output, intravascular volume, and appropriate homeostasis. Acute pain warns the host of danger, prevents inappropriate motion of an injured extremity, and may diminish additional harm from repetitive injury. Persistence of pain beyond the need for protective action is unpleasant and may induce hypertension, tachycardia, coagulopathy, hyperglycemia, anxiety, fear, and chronic pain. Chronic pain that occurs in the absence of ongoing tissue destruction or that provides an inappropriate reflection of the intensity, magnitude, or duration of the tissue damage/compromise is pathologic. Although the pathophysiology of chronic pain is incompletely understood, the following processes can contribute to its establishment: persistent mechanical irritation of peripheral neural structures, incomplete regeneration of peripheral nerves, abnormal neurotransmitter activity, nutritional deprivation secondary to abnormal arteriovenous shunting, and central imprinting.

After trauma or surgery, a transient period of dystrophic extremity function is normal. However, it is abnormal for hyperpathia (heightened pain for a given stimulus), allodynia (painful responses to normally nonpainful stimuli), vasomotor disturbances, and functional deficiencies to persist. If untreated, these conditions may progress to permanent compromise of the extremity. Posttraumatic alterations in extremity physiology follow a variable time course. Consequently, abnormal prolongation of these otherwise normal responses is pathologic, and over time, irreversible changes in anatomic structures or physiologic processes may occur (Figure 53.3). Therefore, *CRPS may be considered an abnormally severe or prolonged manifestation of a normal postinjury response.* Abnormally prolonged dystrophic events may damage or compromise the arteriovenous shunt mechanism,[77-79,106] produce arthrofibrosis,[77,78] cause excessive osteopenia,[16] alter neuroreceptor function,[109] or result in central pain imprinting or any combination of these sequelae.

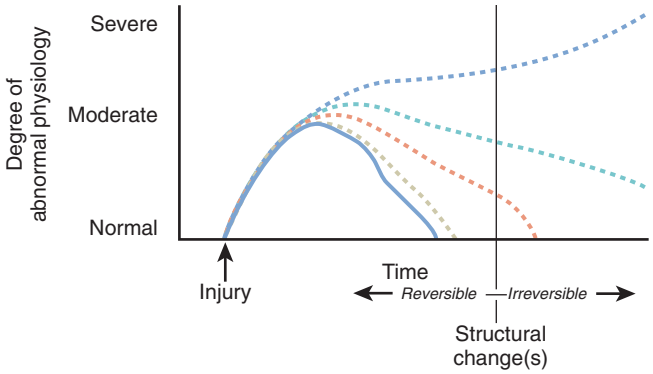

FIGURE 53.3 Abnormal physiologic events after trauma are "normal"; the majority of patients (*solid line*) recover spontaneously from the trauma. Abnormal prolongation of the intensity of these events and dystrophic pain of varying magnitude and duration (*broken lines*) are pathologic. Irreversible changes may occur and convert sympathetically maintained pain to sympathetically independent pain. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

Demographics of Complex Regional Pain Syndrome

In 2003, the incidence of CRPS in Olmsted County, Minnesota, was 5.46 per 100,000 person-years, with four times as many female as male patients.[119] From the electronic medical records of more than 600,000 patients listed in the Dutch Health Care System, the overall incidence rate of CRPS in the Netherlands was higher at 26.2 per 100,000 person-years, with females affected three times more often than males.[25] The mean age at onset was 46 years in the Minnesota study and 53 years in the Dutch study.[25,119] However, CRPS can also develop in children and adolescents.[147] The upper extremity is involved more frequently than the lower extremity, and fracture was the most common precipitating event.[25] The incidence of cigarette smoking is higher in RSD patients, and cigarette smoking is statistically linked to RSD.[4] Data suggesting a possible familial or genetic predisposition to RSD have also been presented but have not been confirmed.[47] A predisposition to CRPS type 1 has been suggested on the involved side of hemiplegic patients.[48] Eighty percent of patients in whom RSD was diagnosed within 1 year of injury will improve significantly,[77,78] and it is reported that 50% of patients with untreated symptoms lasting longer than 1 year will have profound residual impairment.[143]

Fracture of the distal end of the radius and ulna is one of the most *common* injuries associated with CRPS, and it complicates postinjury recovery in a measurable percentage of patients.[17] The natural history of CRPS after distal radius fractures includes finger stiffness or "poor function" at 3 months after injury and correlates with residual RSD at 10 years.[35] CRPS is more likely to occur after distal radius fractures in patients with tight casts[34] or after a nociceptive or neuropathic event such as compression of the median nerve, overdistraction, instability of the distal radioulnar joint, or ulnar fracture. Dystrophic pain after surgical release of the carpal tunnel is commonly encountered in referral centers.[77,78]

Common nerve injuries occurring during operative procedures that may precipitate CRPS include (1) injury to the palmar cutaneous branch of the median nerve during carpal tunnel surgery, (2) damage to the superficial branch of the

radial nerve during surgical approaches to the first and second dorsal compartments for tenosynovitis, and (3) trauma to the dorsal branch of the ulnar nerve during a surgical approach to the distal ulna.[77,78] The reports that CRPS may produce devastating consequences in association with simultaneous median nerve decompression at the wrist and partial palmar fasciectomy for Dupuytren contracture are not correct, and it may be performed safely.[84]

Psychological Factors and Effects

CRPS is not a psychogenic condition. Extensive reviews of the existing literature do not support a psychological causation or an associated personality disorder. However, chronic pain is known to play a role in psychological well-being, with 58% of 283 consecutive patients admitted to pain centers, regardless of cause, fulfilling the criteria for personality disorders.[37,140] Dependent, passive-aggressive, and histrionic personality disorders are common in those with chronic pain and are seen in patients with CRPS. Behavioral responses that reduce extremity use exacerbate edema and atrophy.

Psychological Problems Mimicking Complex Regional Pain Syndrome

The differential diagnosis of CRPS includes some psychological conditions, including conversion disorders and clenched fist syndromes.[48,132] A patient with SHAFT (sad, hostile, anxious, frustrated, and tenacious) syndrome is difficult to discern from a patient with CRPS without active suspicion.[46] A history of multiple operations, absence of consistent clinical findings, multiple treating physicians, a myriad of medications, psychiatric treatment, absence from work, disproportionate self-characterization and verbalization of symptoms, crying from pain, and a family history of disability are common factors. Misdiagnosis associated with abnormal postures is documented. Dysfunctional postures are defined, such as holding an upper extremity in a fixed posture. The typical posture of the hand of a patient with CRPS includes metacarpophalangeal (MP) and proximal interphalangeal (PIP) joint extension. MP and PIP joint flexion (clenched) is uncharacteristic of CRPS, and in such cases an alternative diagnosis is probable. Similarly, mild to moderate swelling is common; massive swelling or edema is rare, and alternative explanations (e.g., factitious symptoms) should be ruled out. Lack of objective findings (e.g., trophic changes, edema, osteopenia, radiographic or fixed contractures) suggests that other conditions are responsible for the symptoms.

Symptoms and Signs

The *pain* associated with CRPS is seen in a variety of clinical manifestations (see Table 53.3). The pain may be described as burning, throbbing, pressing, cutting, searing, shooting, or aching (or any combination of these descriptors). *Hyperalgesia*, or the perception of pain greater than would be expected, may be primary and affect the area of injury or secondary and affect nontraumatized surrounding areas or the entire limb. Identification of the zone of primary pain may aid in the localization of a *nociceptive* focus; however, diagnosis of the etiologic trigger event may not be possible until successful sympatholytic management of the secondary hyperalgesia is complete. *Allodynia*, or perception of pain initiated by normally innocuous stimuli, is a characteristic of sympathetically maintained CRPS. *Hyperpathia*, or pain produced by painful stimuli that appears with a delay, outlasts the initiating stimulus, and spreads beyond the normal neural distribution, is encountered frequently. It is important to differentiate *spontaneous pain* from stimulus-evoked pain. Difficulty sleeping because of burning pain is common and may be an early portent of progressive symptoms and signs.

Quantifying subjective complaints of pain with the use of standardized and validated instruments or questionnaires allows an objective analysis of symptoms.[77,78] Useful instruments to evaluate symptoms and health status include the visual analog scale (VAS) for pain,[96] the 36-item health status questionnaire (SF-36),[144] the McGill Short Form Pain Questionnaire,[96] and self-administered questionnaires designed to assess upper extremity symptoms/function.[13,83] The self-administered questionnaire used for assessment of the severity of symptoms and functional status for patients with carpal tunnel syndrome is applicable to dystrophic states caused by carpal tunnel surgery or injury to the median nerve at the wrist and allows the examiner to graphically follow the patient's health-related quality of life (Figure 53.4).[77,78,83] Cold intolerance, or pain on exposure to cold, may be analyzed by the McCabe Cold Sensitivity Severity Scale.[93] The importance of standardized physiologic testing and instruments is supported by the lack of reproducibility of isolated clinical evaluations. However, the use of published criteria and scoring systems for CRPS may be helpful.[44] The Budapest criteria facilitate the process.[57]

Trophic changes—stiffness; edema; osteopenia; atrophy of the hair, nails, or skin; hypertrophy of the skin (or hyperkeratosis); or any combination of these changes—may be present in patients with CRPS (see Figure 53.1). Changes in the skin, hair, or nails are seen within 10 days of onset in 30% of extremities with CRPS type 1 (RSD).[12] Despite treatment that reduces pain, cold intolerance, pain after use of the affected extremity, joint stiffness, nail and hair growth abnormalities, sensory disturbances, loss of finger extension/flexion, decreased grip strength, and shoulder stiffness are frequent and may persist.[150] Osteopenia is common, involves both cortical and cancellous (trabecular) bone, and requires significant demineralization for visualization on plain radiographs (Figure 53.5).[16] Objective analysis of bone demineralization requires dual-photon absorptiometry or quantitative scintigraphy.[7,16] Stiffness and atrophy of joints, muscles, and tendons may become apparent during endurance testing.[77,78] Movement disorders and dystonic posturing may also occur.[20]

Autonomic Function

The *autonomic nervous system* controls microvascular perfusion and sweat gland activity. Abnormalities in autonomic or vasomotor control, or in both, are seen during the course of CRPS in most patients, and loss of thermoregulatory control is common.[22,136] Affected extremities (hands) may be either "*hot*" or "*cold*," and significant differences in digital temperatures occur between the affected and unaffected extremities in 80% of patients.[12] Abnormalities in thermoregulation/vasomotion usually occur[76-78,105,106] and may vary depending on progression in the clinical stages of CRPS.[80] Autonomic control may be evaluated by assessment of total digital blood flow, which consists of both thermoregulatory and nutritional components,

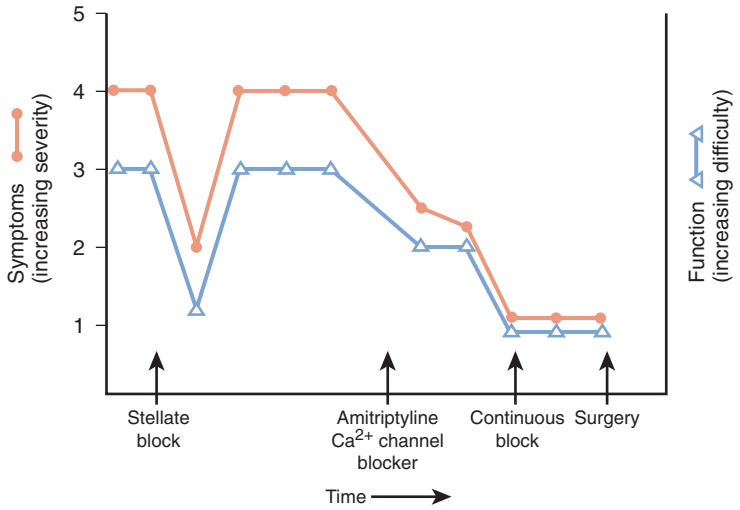

FIGURE 53.4 Symptoms and function in a dystrophic patient after carpal tunnel surgery may be monitored objectively with appropriate instruments. The self-administered carpal tunnel questionnaire contains 11 questions on hand/wrist symptoms and 8 questions on hand/wrist function; symptoms are rated numerically from none (1) to severe (5), and function is rated from no difficulty (1) to cannot do at all (5). A numerical score that reflects symptoms and function can be monitored over time, and the effects of intervention can be analyzed objectively. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

FIGURE 53.5 Plain radiograph of a patient with type 1 complex regional pain syndrome after fracture of the distal ends of the radius and ulna. The fracture line is visible. There is diffuse osteopenia in addition to juxtacortical demineralization and subchondral erosions and cysts. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

and by analysis of sudomotor activity—sweating and piloerection. A detailed history will reveal symptoms of autonomic dysfunction in 80% of patients.[12] Symptoms include abnormal sweating (excessive sweating or anhidrosis), vasomotor alterations, and heat or cold sensitivity (or both) (heat or cold intolerance). Vasomotor changes may be described as a reddish or bluish discoloration of the extremity either at rest or, more commonly, with the limb dependent. Evidence of autonomic dysfunction can be detected in 98% or more of patients by using sophisticated technology during the painful stages of CRPS.[77,78,80,106] Digital perfusion and its components can be analyzed by digital temperature measurements, laser Doppler fluxmetry, plethysmography, and vital capillaroscopy.[76-78] Sweating may be analyzed by resting sweat output, the quantitative sudomotor axon reflex test (QSART),[85] changes in galvanic skin response,[85] or asymmetry of somatosensory evoked potentials in the affected and contralateral extremities.

Sympathetic nervous system function, as reflected in laser Doppler fingertip blood flow and the vasoconstriction response to deep inspiration, varies by stage. Stage 1 patients exhibit increased blood flow but an unchanged vasoconstriction response, whereas stage 2 patients demonstrate decreased blood flow and stronger vasoconstriction.[62]

Functional impairment may be analyzed by using standardized assessments of hand function, such as the Moberg pickup test.[99] In addition, quantitative evaluation of extremity function before, during, and after stress with computerized equipment may detect subtle functional changes reflecting stiffness or atrophy. Thus, the use of standardized tests and various computerized systems can document functional impairment that may be difficult to quantify by traditional methods. The use of grip meters may be problematic. The utilization of standardized templates facilitates evaluation and documentation (Tables 53.3 and 53.4).

Physical Examination

The clinical characteristics of CRPS are related to altered extremity physiology. The magnitude of symptoms and signs is a reflection of the initiating event, postinjury response, inherent patient adaptability, interventional modalities, and time. The classic dystrophic progression from acute (<3 months) to dystrophic (3 to 6 months) to chronic (>6 months) occurs infrequently because of individual variability and the effects of

partial treatment. Patients with CRPS who are evaluated for a painful, hot, swollen, stiff hand are easily recognizable; however, the precipitating nociceptive trigger (e.g., contusion of the superficial radial nerve) may not be identified until the SMP is managed and the dystrophic manifestations are treated. Once allodynia and hyperpathia are alleviated, careful examination may delineate an underlying disorder that may be amenable to treatment.[77,78] Partially treated CRPS or variants of CRPS may be subtly manifested and can be labeled "poor results" or "noncompliant patients." In the postoperative or posttraumatic period, unusual swelling, stiffness, pain, and restlessness may represent a dystrophic response.

The physical examination of suspected CRPS patients should include a neurologic assessment and evaluation of the cervical and thoracic spine. The presence of cervical disease (either diskogenic or degenerative) may exacerbate CRPS, a form of "double-crush syndrome." Preexisting or acquired thoracic outlet or distant compression neuropathies may represent a "triple or more" crush syndrome. Cervical spine and shoulder range of motion should be recorded, and the brachial plexus should be evaluated. The arm should be assessed to rule out evidence of vascular or neurologic compression within the thoracic outlet. An adhesive capsulitis, or "shoulder-hand syndrome," is a frequent sequela that may be overlooked unless the shoulder is examined. Hypersensitivity, vascular adequacy, edema, sensibility, joint range of motion, motor function, grip, pinch, fibrosis, sweating, and vasomotor tone of the entire extremity must be evaluated. Grip is frequently abnormal and should be assessed carefully. Currently, there are no objective laboratory tests to aid in the diagnosis of CRPS.[32]

Mechanical Nociceptive Focus

Identification of nociceptive foci, which include peripheral nerve lesions and mechanical derangements, is important.

TABLE 53.4 Template for Evaluating Clinical Signs and Radiographic Signs of Complex Regional Pain Syndrome

Signs		0, None	1, Mild	2, Moderate	3, Severe	4, Very Severe

Evaluation before and after sympatholytic intervention may delineate "trigger events" that might have initiated or propagated the dystrophic symptoms.[77,78] Nociceptor input may be associated with SMP or SIP. However, early diagnosis plus prompt surgical correction of SMP associated with peripheral nerve injury is an effective management approach.

Diagnostic Testing

Pain Threshold Evaluation

Standardized evaluations and tests provide reproducible and objective information with regard to pain-pressure thresholds. Rubber-tipped algometers, dolorimetry, monofilaments, computer-controlled stimuli, or evaluations of thermal pain thresholds may be used to provide a quantitative measure of hyperpathia or allodynia. For example, perception of pain from a 2.83 Von Frey monofilament (normally not painful) in a specified area or dermatomal distribution defines the extent of allodynia. Success or failure of treatment can be assessed by repeated pain threshold evaluations. Monofilaments provide the most practical method for assessing and monitoring allodynia and hyperesthesia. Von Frey monofilaments are available in pocket kits, are inexpensive, and provide useful bedside sensibility and pain threshold data. Decreased pain after the use of a same-size or larger monofilament documents improvement, whereas persistent pain from the same-size or a smaller-diameter monofilament suggests ineffective management.

Radiography

Regional osteopenia can be seen on plain radiographs in approximately 80% of extremities affected by CRPS.[16,43,79] Significantly decreased mineralization is necessary for changes to be visualized on standard anteroposterior and lateral radiographs (see Figure 53.5). Classic Sudeck atrophy includes diffuse osteopenia with juxtacortical demineralization and subchondral erosions or cysts. Five radiographic patterns of resorption have been described: (1) irregular resorption of trabecular bone in the metaphysis creating a patchy appearance, (2) subperiosteal bone resorption, (3) intracortical bone resorption, (4) endosteal bone resorption, and (5) surface erosions in subchondral and juxtachondral bone.[43] Although osteopenia is easily visualized in metaphyseal areas, recent data confirm that the density of cortical and cancellous bone is affected equally in patients with CRPS.[7,16]

Functional Magnetic Resonance Imaging

In the future, functional magnetic resonance imaging may be valuable in evaluating the pathophysiology associated with CRPS and in monitoring patients' responses to interventions. Abnormalities in the size of the cortical representations of the affected hand on the primary and secondary somatosensory cortices have been reported, and "patterns of cortical reorganization in the primary somatosensory cortex seem to parallel impaired tactile discrimination."[104]

Bone Scan (Scintigraphy)

Three-phase technetium 99m bone scanning (TPBS) is performed commonly and has assumed a significant role in the diagnosis of RSD.[79,149] With TPBS, the first, or "dynamic," phase lasts 2 to 3 minutes and provides an assessment of digital perfusion; the second phase, or "blood pool image" or "tissue phase," allows an assessment of total perfusion over a 3- to 5-minute period; and the third phase, a standard bone scan, evaluates uptake of radiotracer in bony structures (Figure 53.6). In patients with CRPS, the use of a forearm or arm tourniquet or blood pressure cuff may affect accumulation of radiotracer in the hands or digits during phases I and II. Traditionally, scans have been considered "positive" if asymmetric flow is noted in phases I, II, or III.[79] However, more recent reports suggest that the diagnostic yield of phase III alone equals the diagnostic yield of the three-phase scan (Figure 53.7).[146] Mackinnon and Holder have stated that a "strictly interpreted" phase III scan with "diffuse increased tracer uptake in the delayed image is diagnostic for RSD."[59] Although a positive phase III scan provides specific corroboration of the clinical diagnosis of CRPS, the sensitivity of scintigraphy is insufficient to provide standalone criteria, and, therefore, it should be used to corroborate clinical suspicion. In the majority of studies, a "positive" scan has high specificity but poor sensitivity.[77-79,146] Quantitative scintigraphy provides useful physiologic data, allows quantitative assessment of regional bone loss associated with complex regional pain,[16] and adds useful diagnostic information.[3,15,77,78,118] However, bone scan data do not correlate with symptoms, do not provide prognostic information, and are unable to aid in the prediction of which interventional approaches might be successful.[77,78]

In the majority of patients, the abnormal bone turnover reflected in the TPBS is diffuse throughout the hand and wrist. The segmental distribution of RSD isolated to a digit, a single ray, or multiple rays can be evaluated by a bone scan to delineate the affected areas (Figure 53.8). Although TPBS is used frequently, there is no evidence to support (1) diagnostic accuracy

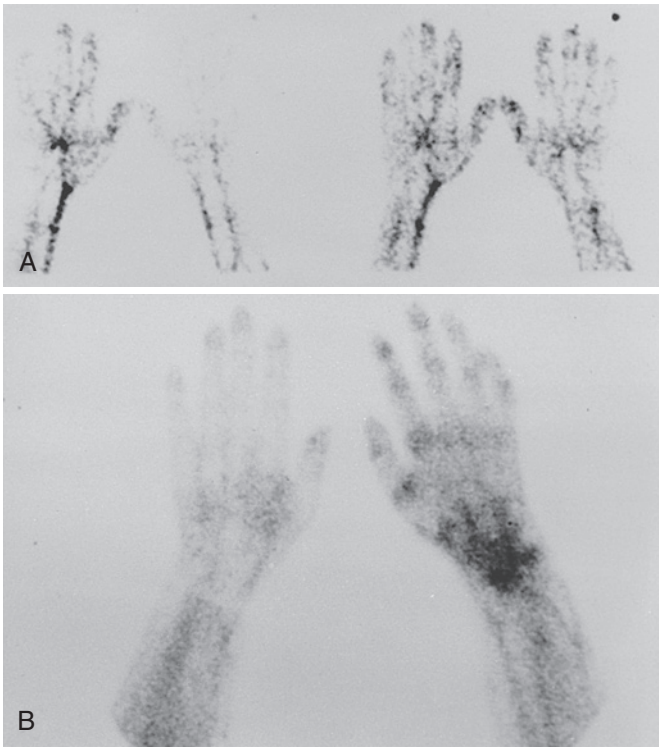

FIGURE 53.6 Three-phase bone scans. **A,** Phase I, a "dynamic phase," evaluates vascular perfusion by visual or quantitative analysis or by uptake of radiotracer after an intravenous injection. Each image represents a 3- to 5-second interval and allows assessment of flow dynamics. **B,** Phase II, a "blood pool" image, documents total tissue uptake of tracer during the first 3 to 5 minutes after injection. Phase III is a conventional bone scan (see Figure 53.7). (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

FIGURE 53.7 Abnormal (phase III) bone scan demonstrating increased periarticular uptake throughout the hand. This is a scan of the patient whose radiograph is seen in Figure 53.6. Notice the increased radiolucency at the fracture site. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

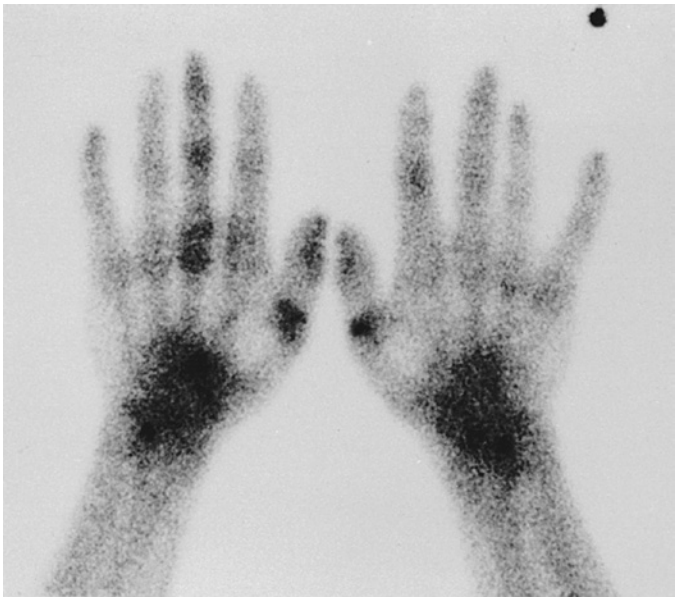

FIGURE 53.8 Segmental periarticular uptake confined to a digit in a bone scan of a patient with complex regional pain syndrome isolated to the long finger. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

in variant, partially treated, or late-stage CRPS[58]; (2) prognostic data that predict outcome[77,78]; or (3) value in determining management decisions.[58,77,78]

At this time, a "positive" phase III bone scan is not a prerequisite for the diagnosis of CRPS or SMP.[81] Bone scans do not correlate with traditional staging criteria for RSD, are not part of the diagnosis of SMP or CRPS,[81] do not predict recovery, and will not predict the potential for response to treatment.[77,78,146] However, the presence of a positive phase III bone scan provides objective support for the clinical diagnosis of CRPS.

Evaluation of Autonomic Control

Autonomic function controls sweating and microvascular perfusion. Evaluation of sympathetic control or, more specifically, the sympathetic dysfunction associated with characteristic pain from CRPS provides objective and sensitive methods to corroborate the clinical suspicion of CRPS.[134]

Regulation of Microvascular Flow

Under normal conditions, total digital blood flow is composed of 80 to 95% thermoregulatory flow and 5 to 20% nutritional flow; the distribution of nutritional versus thermoregulatory flow is governed by complex factors that control arteriovenous shunting.[33,76,105] Abnormal autonomic control of microvascular perfusion in patients with CRPS is reflected, in part, by ischemia secondary to inappropriate arteriovenous shunting and decreased nutritional flow.[64,76-78,80,92,105] The importance of nutritional flow in the pathogenesis of CRPS is supported by the segmental distribution of trophic events, the rapidity of action of successful sympatholytic interventions, and the similarity of pain patterns in patients with contrasting clinical findings. Abnormal arteriovenous shunting in bone has been documented in patients with CRPS. Nutritional deprivation may exist in both a "warm, swollen" hand with high total flow and a "cold, stiff" hand with low total flow. The common underlying finding in both clinical situations is nutritional deprivation resulting from inappropriate arteriovenous shunting (Figure 53.9). Pain relief in CRPS is not dependent on peripheral vasodilation (thermoregulatory flow) after spinal cord stimulation, thus suggesting the importance of nutritional flow.[69] In addition, there is growing evidence that physiologic subgrouping of CRPS patients, in contradistinction to staging based on timing, is important. For example, "warm" CRPS responds differently to intervention than "cold" CRPS does.

Total digital flow—both the thermoregulatory and nutritional components—may be analyzed by digital temperature measurements, laser Doppler fluxmetry, and vital capillaroscopy. *The use of a stressor to perturb physiologic homeostasis, by*

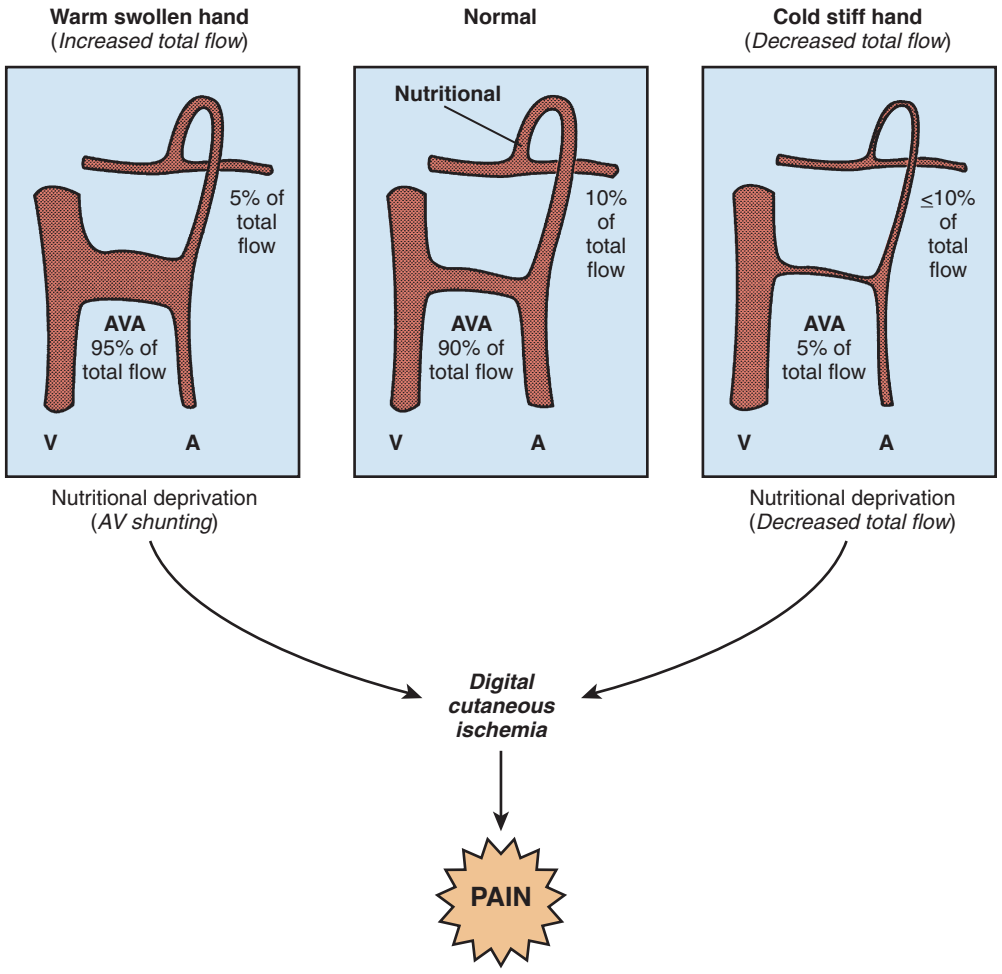

FIGURE 53.9 In a warm, swollen hand with increased total digital blood flow and in a cold, stiff hand with decreased digital flow, abnormal arteriovenous (AV) control through an arteriovenous anastomosis (AVA) may produce or contribute to abnormally decreased nutritional blood flow and pain. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

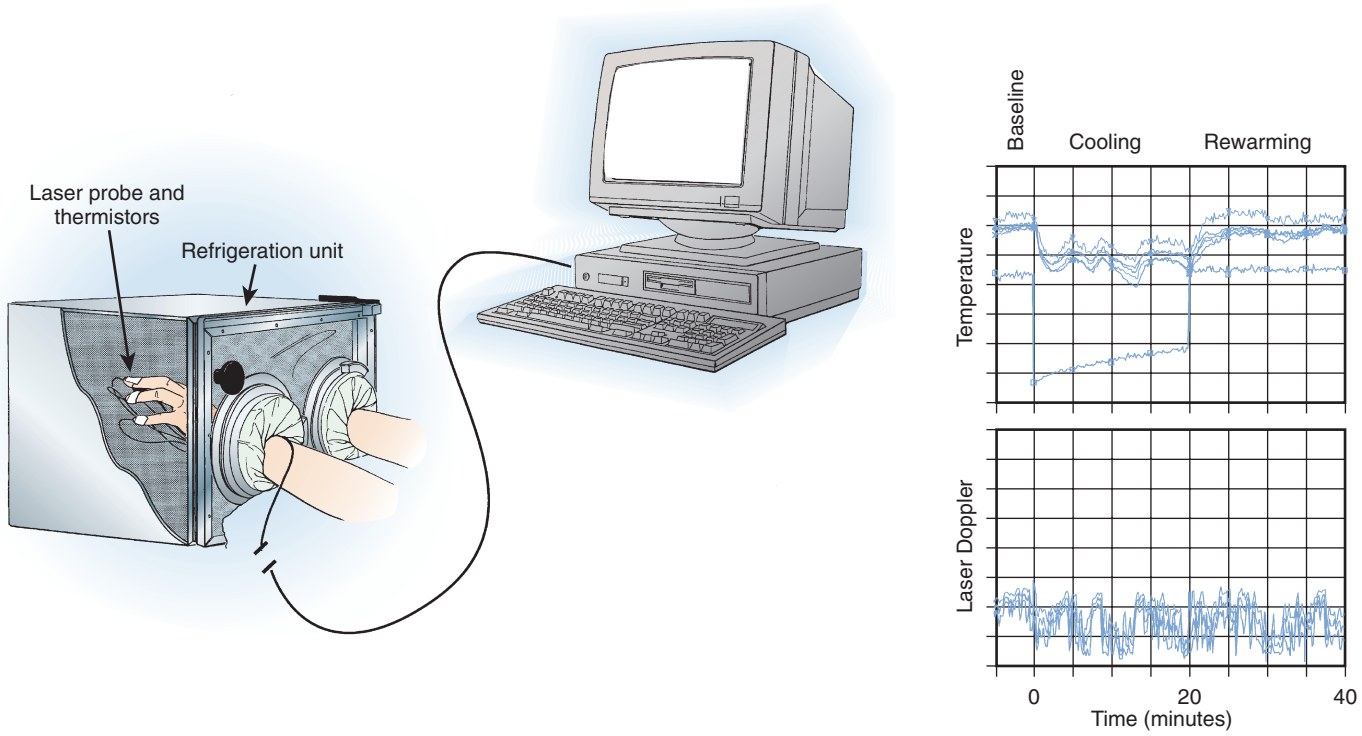

FIGURE 53.10 Digital microvascular physiology can be evaluated by using an isolated cold stress test combining digital temperature and laser Doppler fluxmetry measurements. Digital temperatures are monitored with thermistors attached to each digit of both extremities. Microvascular cutaneous perfusion is assessed with a laser Doppler probe attached to one digit of each extremity. Digital temperature and laser Doppler fluxmetry measurements are sampled with the use of custom computer software, and the results of the test are plotted for analysis. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

thermal, emotional, or ischemic methods, is necessary to obtain reproducible information, to evaluate dynamic response patterns over time, and to maximize sensitivity (Figure 53.10).[76,105] A technique that combines a stressor with a measurement technique is isolated cold stress testing.[76,105] In this procedure, total digital blood flow and microvascular perfusion may be evaluated by monitoring digital temperature and laser Doppler fluxmetry before, during, and after controlled thermal stress.[76] The heterogeneity of digital microvascular perfusion may be analyzed by laser Doppler techniques and is reflected in average pulp temperature readings. Nutritional flow may be measured directly by vital capillaroscopy (Figure 53.11).[76,113] Analysis of temperature, laser Doppler fluxmetry, microvascular perfusion, and nutritional flow permits an objective determination of autonomic vasomotor stability, as well as physiologic staging of autonomic sympathetic performance, defines the adequacy of nutritional flow, and provides an assessment of the effects of interventions.[76,78,85] For example, the effectiveness of sympathetic blockade may be assessed by analysis of digital temperature and microvascular perfusion during the application of a physiologic stress (Figure 53.12). Laser Doppler perfusion imaging provides an assessment of microvascular perfusion over a 12- × 12-cm area and may be used to evaluate the effects of sympathetic blockade on skin blood flow.[126]

Sudomotor Function

Sudomotor activity may be assessed by cumulative unstimulated resting sweat output, QSART,[85] galvanic skin response, combined temperature and peripheral autonomic surface potential reflex response,[75] and analysis of sympathetic skin response evoked by activation of sympathetic unmyelinated efferent fibers.[121] These techniques can be used to obtain quantitative measurements of sweat function, which can then be contrasted to contralateral or ipsilateral areas or normal controls (or both). When combined with microvascular perfusion indices of temperature or laser Doppler fluxmetry, these data supplement the clinical examination, document autonomic dysfunction, and provide objective evidence of the effects of intervention.[76,85]

Diagnostic Regional and Sympathetic Blockade

CRPS may be sympathetically maintained (SMP) or sympathetically independent (SIP). Relief after sympatholytic interventions defines SMP.[108,109] Pain relief after the administration of parenteral, oral, or topical pharmacologic preparations or after neural blockade confirms the influence of the sympathetic nervous system and supports receptor-mediated abnormalities.[108,109] Pain relief after an intravenous injection of phentolamine (a mixed α_1- and α_2-adrenergic blocking agent) is considered presumptive evidence of SMP,[109] or it may be considered diagnostic of SMP.[108] Phentolamine testing is compromised unless the drug is administered in conjunction with placebo injections.[109,110] Intravenous phentolamine may produce profound transient side effects, including headache and hypotension. Unlike other pharmacologic end-organ blockers (e.g., bretylium), phentolamine has no therapeutic indications and is used only as a diagnostic modality. Recent data indicate that adequate sympathetic blockade does not consistently correlate

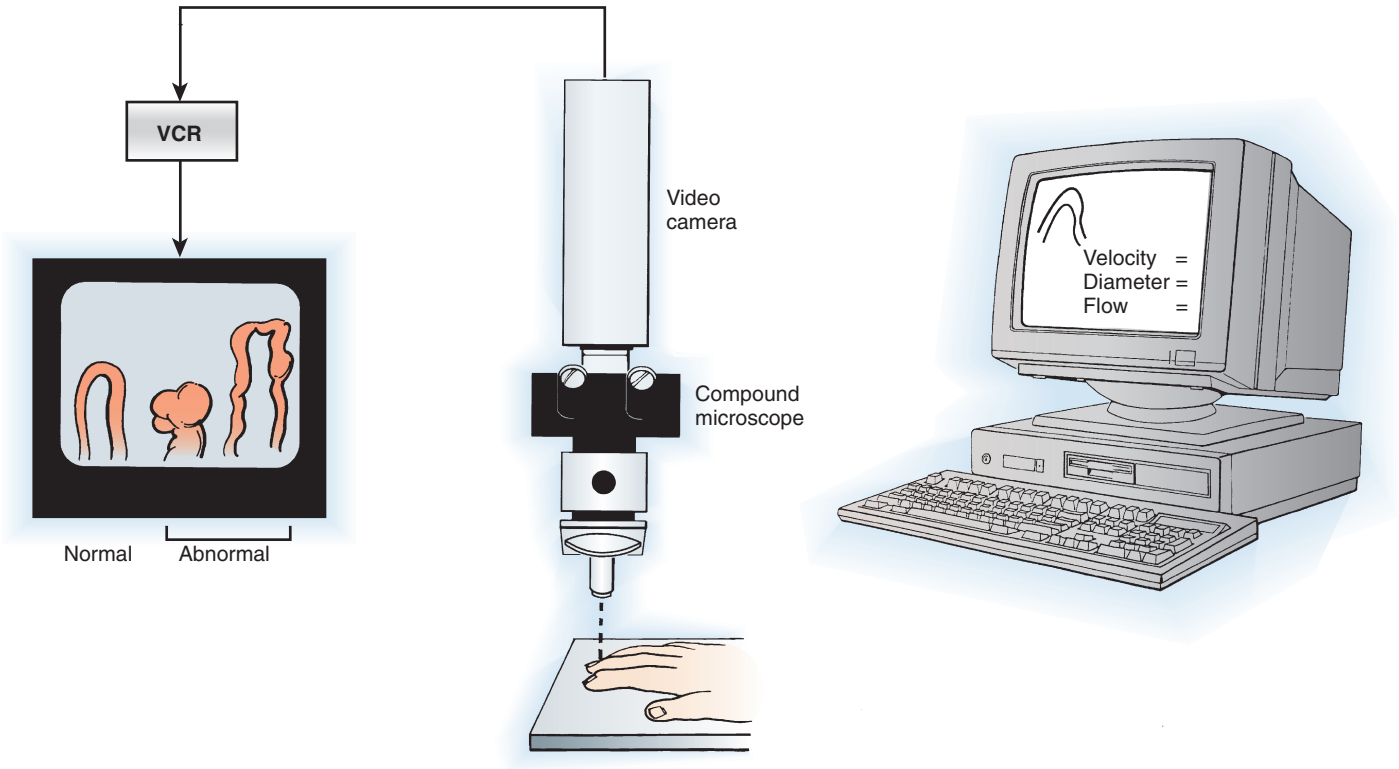

FIGURE 53.11 Nutritional capillaries may be visualized directly through a compound microscope, which provides visualization of red blood cell motion within the capillaries and permits the identification of normal and abnormal capillary morphology. Videotape analysis facilitates quantitation of the diameter of the capillaries and velocity of flow within the ascending and descending capillary loop. Abnormal morphology diagnostic of collagen vascular disease can be observed. *VCR,* Videocassette recorder. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

with the extent of pain relief and that the duration and density of the block may alter the clinical response.[137] The role of SMP may be evaluated by nerve blocks of the stellate ganglion, epidural space, brachial plexus, or peripheral nerves.[77,78] Diagnostic blocks are usually obtained with short-acting or intermediate-acting local anesthetics (e.g., lidocaine). Stellate ganglion blocks may be performed by injections administered at the transverse process of C6 (Chassaignac tubercle) or by a medial approach at C7. Injections of the stellate ganglion or sympathetic trunk that are adequate to induce sympatholysis are dependent on variations in patient anatomy, the presence or absence of scarring in or around the sympathetic chain, drug diffusion characteristics, and the ability and skill of the injector. Therefore, adequate interpretation of results requires verification of sympatholysis, which can be accomplished by the observation of indirect signs such as Horner syndrome, nasal congestion, or facial anhidrosis or by direct evidence of sympathetic nerve block such as an increase in temperature (≥3°C), venous engorgement of the hand veins, dry skin, changes in skin color, and characteristic laser Doppler changes.[77,78,90,106] Indirect "signs" of blockade are mediated by preganglionic fibers and can occur without sympathetic blockade. Consequently, it is imperative to have objective evidence of blockade before dismissing patients or declaring them to have SIP. Effective stellate ganglion blocks, even when administered by experienced anesthesiologists, occur in only 70 to 75% of cases. Therefore, objective determination of the adequacy/effectiveness of autonomic blockade is important. Furthermore, a patient who does not respond favorably to peripheral sympathetic blockade may achieve symptomatic relief with a continuous sympathetic block or from epidural blockade.[21]

Thermography

Thermographic techniques provide a large quantity of temperature data, allow comparison of both upper extremities, and permit rapid repeated measurements over time. However, peer-reviewed data do not support the use of thermography as a superior alternative to other conventional diagnostic modalities.[8] Recent data suggest that higher temperatures indicated by thermography do not correlate with skin surface flow in RSD[92] and that the use of temperature alone cannot distinguish RSD from "chronic upper limb pain." Thermographic data must be interpreted strictly to be effective. Misleading color-coded asymmetry patterns may be created by inappropriate sensitivity settings; that is, settings should exceed 0.5°C to 1.0°C per color band.[124] Repeated measurements over time from the same subject or subjects are reproducible and consistent, reflect skin blood flow, and correlate with symptoms in a variety of painful pathologic entities.[124] The use of a stressor strengthens thermographic data, which are a reflection of total skin blood flow,[52,76,105] and significantly improves the predictive and diagnostic value of telethermography.[52]

Endurance Testing

Objective evaluation of extremity function can be accomplished by using standardized tests and computerized analysis systems.

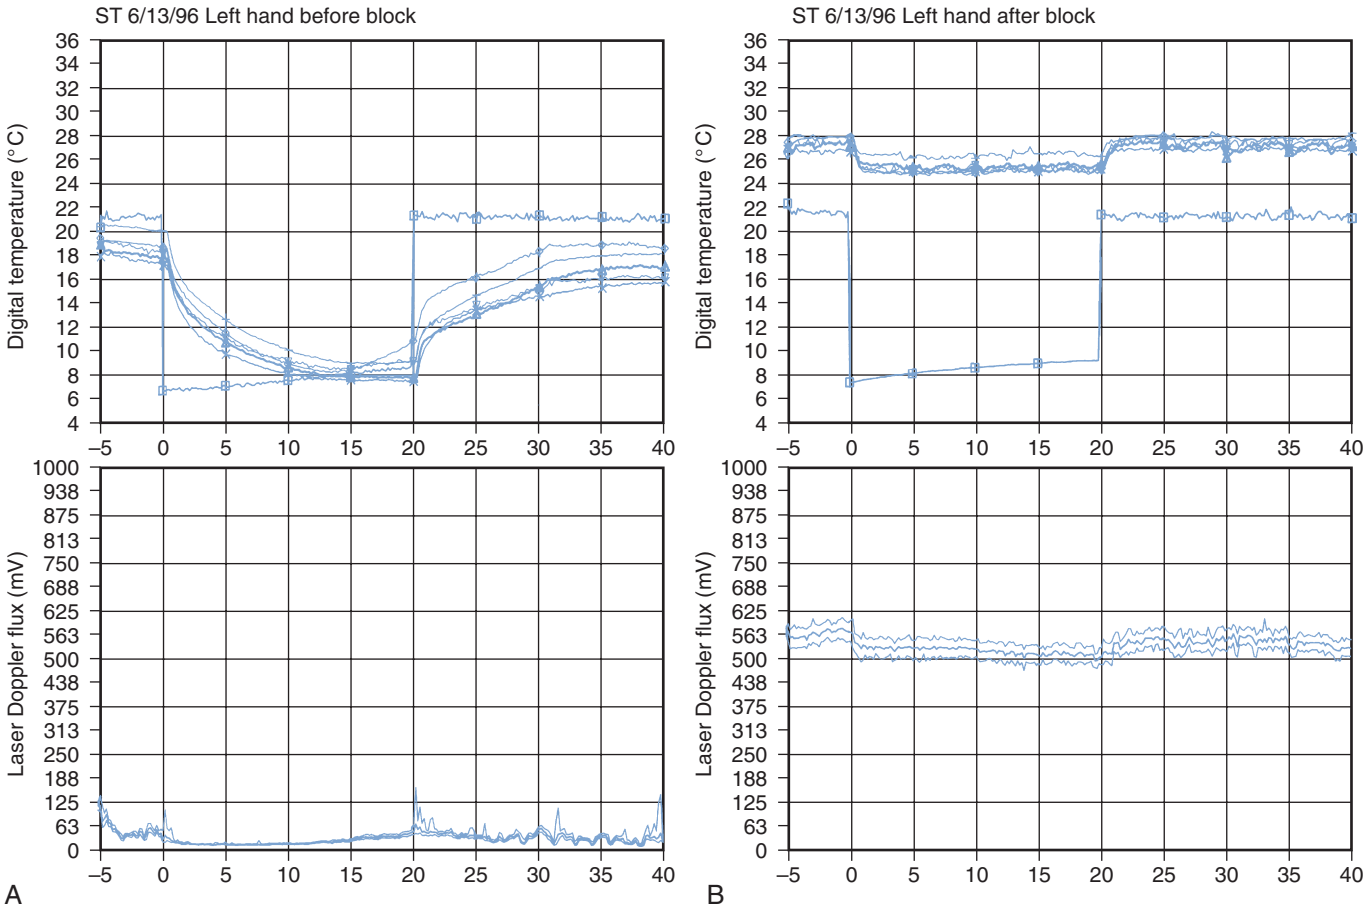

FIGURE 53.12 Laser Doppler fluxmetry in a patient with clinical RSD before **(A)** and after **(B)** sympathetic blockade. The temperature of all five fingers of the left hand and the environmental temperature (indicated by *squares*) are plotted in the upper portion of the graphs. Laser Doppler measurements were monitored with a probe placed on the left ring finger. Baseline temperatures and laser Doppler measurements were taken for 5 minutes. For the cooling phase, the hands were inserted into the refrigeration unit for 20 minutes. After cooling, the hands were removed from the unit and allowed to rewarm at room temperature for 20 minutes. After sympathetic blockade, digital temperatures were increased markedly during all phases of the testing procedure. The amplitude of laser Doppler flux was increased after the block, thus confirming modulation of sympathetic input (chemical sympathectomy). (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

These evaluations document overall functional capacity, verify gross and fine motor skills, and quantitate strength and endurance. Repeating these measures over time provides a sensitive and reproducible methodology that is capable of delineating subtle functional deficits, documenting the effects of intervention (management), and defining the magnitude of permanent impairment.[77,78]

Staging

As a practical guide to treatment, the concept of "acute stage" and "late-stage" CRPS may be helpful. The length of acute CRPS is variable and affected by the injury, patient coping mechanisms, and treatment. The acute stage encompasses treatment from onset to the development of atrophy and fixed contracture. Treatment of the acute stage is designed to alleviate pain, decrease abnormal arteriovenous shunting, manage edema, and correct nociceptive and/or neuropathic abnormalities. Management of late-stage patients is divided into (1) pain palliation using chronic medications (e.g., ketamine) or peripheral nerve or centrally implanted devices (e.g., dorsal column stimulators) and (2) correction of the fixed deformity or contracture.

Treatment

Patients with CRPS may have SMP or SIP. In general, patients with the latter have a poorer prognosis, do not respond as well to sympatholytic modalities, and may be more likely to progress to chronic pain and disability. The diagnosis of sympathetically independent CRPS should be reserved for patients:

1. Who have the clinical symptoms and signs of CRPS, that is, pain, atrophy, autonomic dysfunction, and functional impairment, and do not experience pain relief after sympatholytic intervention
2. With CRPS that was initially relieved by sympatholytic intervention that is no longer effective

If a nociceptive (dystrophic) focus, or trigger area, is identifiable, direct treatment of the abnormality may provide significant pain relief and reduce the need for prolonged use of medication. After a favorable response to oral sympatholytics, it may be possible to identify a specific cutaneous nerve injury, correct this underlying mechanical nerve problem, facilitate recovery, and improve functional outcome. By definition, patients with CRPS type 2 (causalgia) have an identifiable or documented peripheral nerve injury. Surgical interventions that

correct nerve damage or protect the nerve may decrease the incidence of nociceptive foci, lessen symptoms, and enhance function. Similarly, patients with CRPS type 1 (classic RSD) may have a nonneural or mechanical nociceptive focus, which if corrected will facilitate recovery of the extremity.

The choice of intervention may be influenced by physiologic staging, which in turn facilitates the selection of appropriate pharmacologic agents. The goal should be to correct the pathophysiologic manifestations of CRPS. Before selection of treatment, clinical or laboratory testing should be performed to determine (1) the extent of sympathetic tone (increased, normal, or decreased), (2) the presence or absence of edema, (3) the amount of total digital flow (elevated, normal, or decreased), and (4) the status of nutritional flow (decreased or normal).

If sympathetic tone is increased (based on clinical judgment or objective testing), sympatholytic medications aimed at correction of neural or vascular adrenergic tone should be used. On occasion, the only manifestation of abnormal tone may be inappropriate arteriovenous shunting with decreased nutritional flow. Edema should be managed with physical modalities or specific pharmacologic treatment. Estimates of total blood flow and the components of flow may also guide treatment decisions. In summary, *treatment of CRPS is complex and may involve simultaneous or sequential use of multiple treatment modalities.*

Multidisciplinary Approach to Management

Although CRPS can be managed effectively by a single physician, a multidisciplinary team approach is often advisable to optimize patient outcomes. Input from a surgeon, primary care practitioner, psychologist, hand therapist, case worker, or psychiatrist (or any combination of these professionals) is often beneficial. Inclusion of a rehabilitation specialist, case worker, or workers' compensation coordinator may also be beneficial. The lead member of the team is determined by the circumstances of the pain process. For example, management of the acute phase of CRPS type 2 after a distal radius fracture and median nerve injury is often best coordinated by a hand surgeon. Under other circumstances, a primary care physician, anesthesiologist, or psychologist might be the most appropriate individual to coordinate care (e.g., in a patient with CRPS type 1 and persistent symptoms after more than a year of active treatment). Pain clinics are a valuable resource and should be incorporated into management plans. However, they should not be used as a patient "dumping ground." Continued involvement of the initial treating physician throughout the process optimizes patient management. After the dystrophic process is quiescent, one or more mechanical foci may be evident that would not be apparent to an isolated practitioner. A physician who understands the injury process and is knowledgeable about the diagnosis and management of upper extremity disorders should be involved in the ongoing management of the patient.

Pharmacologic Interventions

On the basis of empirical, theoretical, and documented modes of action, a variety of oral, topical, and parenteral pharmacologic interventions are and have been used to treat CRPS.[82] Theoretical mechanisms of drugs that control pain associated with dystrophic or causalgic responses include membrane stabilization (e.g., anticonvulsants, local anesthetics), competitive inhibition of the neurotransmitter receptor blockade (e.g., terazosin), blockade of the end-organ effects of sympathetic stimulation (e.g., nifedipine), and desensitization of central pain-signaling neurons (e.g., α_1- and α_2-blocking agents). Some of these drugs may exhibit more than one mode of action. Few of the drugs used in the management of CRPS are listed for "pain management" in the accompanying package insert approved by the U.S. Food and Drug Administration (FDA). Rather, their use is based largely on empirical data and assessment of the risk-benefit ratio. *Before using the drugs discussed in this chapter, each practitioner should be familiar with the pharmacology, side effects, potential complications, indications, and contraindications for each* (see accompanying tables).

Vitamin C

Although the mechanism is unknown, four randomized controlled trials support the efficacy of 500 mg of vitamin C as a preventive intervention to decrease CRPS after trauma or surgery. The relative risk after treatment with 500 mg or more of vitamin C daily after surgery or injury is 0.22.[125]

Oral and Topical Medications

Antidepressants

Antidepressants are frequently used in the management of chronic pain, although there is no clear evidence that they are effective,[32] and the evidence that is available is anecdotal.[114] Antidepressants have been used in patients with CRPS because they have been shown to effectively relieve pain in those with diabetic neuropathy and postherpetic neuralgia.[20] Originally, antidepressants were used empirically to relieve posttraumatic depression; however, they also provide analgesia and modulate sympathetic hyperactivity in the peripheral nervous system and CNS.[24,86,145] Antidepressants used for CRPS include tricyclic antidepressants, tetracyclic antidepressants, atypical antidepressants, and selective serotonin reuptake inhibitors.

Tricyclic antidepressants have been in use since the early 1960s and are some of the most common agents used for the management of CRPS. A decrease in SMP is based on the drugs' interference with postganglionic reuptake of amines, downregulation and desensitization of presynaptic α_2 and serotonergic receptors, and reduction of the synthesis and release of norepinephrine. The variation in the biogenic amines in these antidepressants produces differential receptor affinity and accounts for the differences in clinical response. This explains why one antidepressant may prove efficacious in one patient and not in another. The most commonly used tricyclic antidepressants include imipramine, amitriptyline, doxepin, desipramine, nortriptyline, and protriptyline (Table 53.5).[24]

Drug selection should be individualized to account for potential side effects, drug interactions, comorbid conditions, previous response to the drug, and patient age. The most common side effects of tricyclic antidepressants are anticholinergic, cardiovascular, and CNS effects (see Table 53.5). Long-term treatment with these drugs is tolerated; however, abrupt drug discontinuation should be avoided because of the potential adverse side effects. Chronic treatment with this class of drugs requires physician monitoring.

The *tetracyclic antidepressant* maprotiline (Ludiomil) is pharmacologically similar to imipramine and blocks the

reuptake of norepinephrine more than that of serotonin. The anticholinergic properties of this drug are significant and may complicate its use (see Table 53.5).

Trazodone (Desyrel), an *atypical antidepressant*, can be used to treat CRPS. Its mechanism of action includes preferential blocking of the reuptake of serotonin and binding to adrenergic (α_1 and α_2) receptors. Once-per-day dosing is possible; however, the effects of β-adrenergic blockade are often difficult to tolerate and include tremor, hypertension, bradycardia, dizziness, and sedation.

The use of *selective serotonin reuptake inhibitors*, or second-generation antidepressants, has increased significantly over the past decade. These drugs include fluvoxamine (Luvox), paroxetine (Paxil), fluoxetine (Prozac), and sertraline (Zoloft) (Table 53.6).[98,139] Selective serotonin reuptake inhibitors bind preferentially to the presynaptic serotonin carrier in the CNS and thereby inhibit reuptake of serotonin. Side effects, which may be significant, tend to diminish after 1 to 2 weeks. Even though the efficacy of the selective serotonin reuptake inhibitors used for treating chronic pain is not well defined, these agents are used frequently for that purpose. Selective serotonin reuptake inhibitors are commonly prescribed in conjunction with low-dose tricyclic antidepressants; the use of both drugs has a synergistic effect in many patients. Tricyclic antidepressants produce the most pronounced sympatholytic effects and should be used before or in addition to selective serotonin reuptake inhibitors.

TABLE 53.6 Selective Serotonin Reuptake Inhibitors Used in Management of Complex Regional Pain Syndrome

Anticonvulsants

Anticonvulsants were first used to treat hyperpathic pain and later to treat CRPS.[95] Although their mechanism of action is unknown, it is postulated that these compounds stabilize excitable nerve membranes, limit neuronal hyperexcitability, and inhibit transsynaptic neuronal impulses in the CNS.[86] Anticonvulsants are often used in combination with other medications (e.g., tricyclic antidepressants). Phenytoin (Dilantin), carbamazepine (Tegretol), valproic acid (Depakene), and gabapentin (Neurontin) are the most commonly used anticonvulsants in managing CRPS (Table 53.7).

Membrane-Stabilizing Agents

The oral use of local anesthetics provides a new approach to the management of CRPS. Local anesthetics selectively depress neuronal activity within the spinal cord, decrease C fiber polysynaptic conduction, reduce alpha motor neuron reflexes, and diminish noxious thermal and chemical reflexes.[24] However, the exact mechanism by which local anesthetics reduce pain is unclear. The development of oral membrane-stabilizing agents was based on the observation that lidocaine, when used intravenously, provided relief from chronic pain. Tocainide (Tonocard) and mexiletine (Mexitil) are available as oral medications (Table 53.8). Unfortunately, side effects with tocainide are common (40% to 80% of patients experience adverse effects) and include serious idiosyncratic reactions such as interstitial pneumonitis, psychosis, encephalopathy, neutropenia, lupus-like syndrome, agranulocytosis, anemia, hepatitis, and convulsions. Mexiletine is less commonly associated with severe complications, but known drug reactions associated with its use include lupus-like syndrome, abnormal liver function, blood dyscrasias, and impotence. Therefore, the use of these drugs in patients with CRPS is limited to severe or refractory cases.

Adrenergic Compounds

The role of α-adrenergic receptors and transmitters is well documented in CRPS with SMP (Table 53.9).[6,24] Adrenergic agents useful in the management or diagnosis (or both) of SMP

TABLE 53.8 Comparative Characteristics of Intravenous and Oral Local Anesthetic Agents Used for Chronic Pain: Membrane-Stabilizing Agents

	Lidocaine	Mexiletine (Mexitil)	Tocainide (Tonocard)
Dosage	3 mg/kg (range, 2-6 mg/kg). Test dose over period of 20-30 minutes	10 mg/kg/day	20 mg/kg/day
Cardiovascular side effects	Bradycardia, hypotension	Palpitations, chest pain, syncope	Hypotension, ventricular arrhythmias
Central nervous system side effects	Dizziness, nervousness, apprehension, euphoria	Dizziness, tremor, headache	Dizziness uncommon: encephalopathy and psychosis
Other side effects		Nausea, vomiting	Blood dyscrasias, pulmonary fibrosis, nausea, rashes
Contraindications		Cardiogenic shock, second- or third-degree atrioventricular block (if no pacemaker)	Second- or third-degree atrioventricular block in the absence of a pacemaker, heart failure

TABLE 53.9 Adrenergic Agents Used in Management of Complex Regional Pain Syndrome

	Phentolamine (Regitine)	Phenoxybenzamine (Dibenzyline)	Prazosin (Minipress)	Terazosin (Hytrin)	Clonidine (Catapres)
Administration and dosage	IV infusion: 25-30 mg/100 mL saline in 20 minutes	PO: 5-120 mg/day	PO: 1 mg once at bedtime up to tid	PO: 1 mg qid	Topical, intrathecal, or PO: 1 mg/hour by patch weekly; 1 mg PO tid initially
Action/mechanism	Postsynaptic α_1-antagonist Presynaptic α_2-antagonist	Postsynaptic α_1-antagonist Presynaptic α_2-antagonist $\alpha_1 > \alpha_2$	Postsynaptic α_1-antagonist	Postsynaptic α_1-antagonist	Presynaptic α_2-agonist
Side effects	Hypotension, cardiac arrhythmias, weakness, nausea, dysrhythmias	Orthostatic hypotension	Orthostatic hypotension	Orthostatic hypotension	Dry mouth, drowsiness

From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.

and variant forms of CRPS include α_1-antagonists, α_2-antagonists, combined α_1- and α_2-antagonists, and α_2-agonists (see Table 53.9).[6,63,108,109]

Phentolamine (Regitine), first introduced as a diagnostic test for RSD, produces nonselective, competitive α-adrenergic blockade by affecting postsynaptic α_1 receptors and presynaptic α_2 receptors.[6,108,109] Theoretically, the resulting chemical sympathectomy induces peripheral vasodilation, increases nutritional blood flow, and decreases non–microvascular-mediated adrenergic sensitization. Decreased pain or pain relief after intravenous phentolamine (25 to 30 mg) is pathognomonic for adrenergically driven SMP.[109] Patients with a positive response to intravenous phentolamine are likely to respond to other forms of sympatholytic intervention. The use of phentolamine as a definitive test for CRPS is hindered by the presence of false-negative results and the absence of placebo controls.[107]

Nonselective oral adrenergic medications include phenoxybenzamine (Dibenzyline), which is an irreversible postsynaptic α_1-antagonist and a presynaptic α_2-antagonist. Unfortunately, the drug is poorly tolerated by many patients; however, the pain relief that it provides may be dramatic. Prazosin (Minipress) and terazosin (Hytrin) block postsynaptic α_1 receptors selectively without significantly affecting presynaptic α_2 receptors and may diminish symptoms such as allodynia and vasospasm.[128]

α_2-Adrenergic agonists may also be effective. Clonidine (Catapres), a selective presynaptic α_2-agonist in the CNS, is used clinically in three divided doses or as a continuous transcutaneous patch. In patients with edema and hyperalgesia, dramatic improvement may result from α_2-agonist stimulation (Table 53.10).[24]

Calcium Channel Blockers

Calcium channel blockers have been demonstrated to decrease symptoms in selected patients with CRPS (Table 53.11). Although their mechanism of action in the treatment of CRPS is unclear, calcium channel blockers decrease sympathetic tone by preventing release of calcium after stimulation of adrenergic receptors. Nifedipine (Adalat, Procardia) and amlodipine (Norvasc) are the most commonly used.[24] By inhibiting extracellular calcium passage through L-channels in the vascular smooth muscle membrane, the effects of adrenergic agents are blocked and vasoconstriction is diminished. Use of these drugs often results in significant diminution of pain, which may correlate with increased nutritional perfusion and decreased abnormal arteriovenous shunting.[76,77,109,110]

Corticosteroids

High success rates have been reported with the use of corticosteroids for the management of CRPS.[20,32,114] The exact

TABLE 53.10 Parenteral Medications Used in Management of Complex Regional Pain Syndrome

	Methods of Administration and Usual Dosage	Mechanism of Action	Major Short-Term Disadvantage or Side Effects	Contraindications
Bretylium	IV regional: 100-200 mg	Norepinephrine-reuptake-blocking agent; depletion of terminal vesicle of norepinephrine		No longer available
Clonidine	Continuous epidural: 10-40 mg/hour	Diminishes regional sympathetic outflow by direct action at the spinal cord (see Table 53.9)	Hypotension, transient sedation (see Table 53.9)	Advanced renal insufficiency, first-degree atrioventricular block, concurrent agonists or α-antagonist (see Table 53.9)
Phentolamine	IV injection: 5-15 mg	α-Adrenergic blocker	Hypotension	Coronary artery disease
Cortisone	IV injection: 5-15 mg	α-Adrenergic blocker	Hypotension	Coronary artery disease
Reserpine	IV injection: no longer available in the United States	Norepinephrine inhibitor	Orthostatic hypotension	Depression

TABLE 53.11 Calcium Channel Blockers and Corticosteroids Used in Management of Complex Regional Pain Syndrome

	Nifedipine (Adalat, Procardia)	Amlodipine (Norvasc)	Corticosteroid
Dosage	10-30 mg PO tid or 30-90 mg qid sustained	2.5-5 mg/day	10 mg/day PO
Mechanism of action	Blockade of calcium channels on vascular smooth muscle cells	Blockade of calcium channels on vascular smooth muscle cells	Decreases inflammation, unknown
Common side effects	Headaches, peripheral edema, postural hypotension	Headaches, postural hypotension	Multiple, including edema, circulatory problems, paresis, dermatologic effects, cataracts

From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.

mechanism of action of these agents in dystrophic pain has not been elucidated, although they are believed to stabilize membranes. A high starting dose (e.g., 60 mg of prednisone) rapidly tapered over a period of 5 to 10 days is commonly used. Long-term use of low doses (2 to 5 mg) is also advocated.[49] The use of corticosteroids remains controversial because of their potential side effects, complications, and variable benefits. Side effects include adenohypophyseal suppression, hirsutism, and abnormal fat deposition. Complications include avascular necrosis of osseous structures (i.e., the femoral head). Corticosteroids have also been infused regionally in a Hannington-Kiff protocol as an intravenous bolus distal to a proximal tourniquet.[55]

Neuromuscular Blocking Agents

Botulinum A and B toxins have been used for the management of acute and chronic pain. These agents are injected into muscle or skin with reported relief of muscle spasm, dystonia, and skin hypersensitivity through incompletely delineated mechanisms that include inhibition of substance P and decreased muscle overactivity.[5,18,73,74,116,117]

Bisphosphonates

Bisphosphonates have been shown to be effective for CRPS in multiple clinical trials.[114,141] A variety of bisphosphonate compounds and routes of administration have been used, including intravenous clodronate and alendronate.[39,114] The mechanism of action of this class of drugs is to decrease inflammation and provide analgesia by preventing bone resorption.[20,114] Clodronate has been shown to act on inflammatory mediators, including interleukin-1, interleukin-6, lactic acid, and tumor necrosis factor-α.[114] The analgesia produced by bisphosphonates is attributed to modulation of inflammatory cytokines and systemic factors such as prostaglandin E_2 and subsequent nociceptor desensitization. However, to date, no studies have compared the efficacy of the different bisphosphonate compounds.[114]

Calcitonin

Salmon calcitonin (Miacalcin) delivered either by intramuscular injection or intranasal spray has been used for CRPS (Table 53.12).[32] Several studies evaluating the pain relief provided by calcitonin have shown that it is superior to placebo for the relief of CRPS pain. However, the degree of pain relief is probably similar to that associated with therapies such as a combination of physical therapy and analgesics.

Ketamine

Ketamine, an NMDA receptor antagonist, has been studied in animal models of pain (see Table 53.9).[9,32,45,102,115,122] Ketamine is believed to have a peripheral effect on opioid, sodium, and potassium channels.[41] Pain relief, improved mobility, and a reduction in autonomic symptoms are reported after intravenously infused ketamine.[32] However, the use of intravenous ketamine is associated with a high incidence of side effects. Intravenous ketamine must be administered by appropriately credentialed professionals with access to patient monitoring

TABLE 53.12 Other Medications

	Mechanism of Action	Dosage	Common Side Effects
Salmon calcitonin (Miacalcin)	Decreased bone resorption	200 IU by nasal spray	Rhinitis, fatigue, back pain, hypertension, epistaxis, hepatitis, headache, depression, possible allergies
Bisphosphonates: alendronate (Fosamax)	Decreased bone resorption Decreased serum Ca^{2+}	800 mg bid PO 300 mg IV for 2-5 days for problems	Abdominal cramping, exacerbation of kidney problems
Dissociative anesthetics: ketamine hydrochloride (Ketalar)	Anesthetic NMDA receptor blocker (blocks Na^+/K^+ channels	2 mg/kg (IV), 2-3 mg/kg (IM), topical	Severe physiologic reactions, respiratory depression, must be administered by an anesthesiologist with monitoring
Vitamin C	Unknown	500 mg/day PO	Minimal

From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.

and resuscitation equipment. Ketamine gel has also been used in a limited number of patients to treat neuropathic pain.[32]

Free Radical Scavengers

Free radical scavengers have been proposed to treat CRPS type 1 based on the assumption that an exaggerated inflammatory response to injury produces toxic oxygen-free radicals that cause pain.[32] Dimethyl sulfoxide (DMSO): 50% concentration showed favorable results in a randomized controlled trial in "warm" CRPS type 1 and *N*-acetylcysteine (NAC) in "cold" CRPS. Both groups—DMSO and NAC—were more effective if patients were treated early.[101] DMSO has not been approved by the FDA for use in human patients.

Other Treatments

Other additional oral and topical medications used to treat CRPS include capsaicin,[129] transdermal nitroglycerin,[61] and prostaglandin E_1 ointment.[91] Ketanserin, a selective S_2 serotonergic antagonist, has been documented to provide relief of RSD pain in a double-blind, placebo-controlled crossover study.[54] However, further clinical trials with these medications are necessary to determine their safety and efficacy in patients with CRPS.

Some of the newer proposed treatments of CRPS include thalidomide (Thalomid), which is believed to affect cytokines that might play a role in CRPS.[114] Several drugs that have been used successfully to manage neuropathic pain have also been suggested for use in CRPS patients.[114] An example is tramadol (Ultram), which has a dual action on μ-opioid receptors and serotonin/norepinephrine reuptake.[114] Intrathecal baclofen has been used to treat CRPS patients with dystonia.[20]

Parenteral Medications

Intravenous Regional Infusion

Infusion of drugs into an isolated extremity for analgesia was described by Bier in 1908, and intravenous drug infusion for dystrophic pain was used first in the 1970s by Hannington-Kiff.[55] The latter's protocol, with or without minor modifications, is still used by many anesthesiologists and pain specialists to deliver intravenous drugs to patients with CRPS. The most common pharmacologic agents used with this technique are bretylium tosylate and corticosteroids (see Table 53.10).[32,38,55,60,65] Tourniquet-induced analgesia may be involved in the short-term pain relief observed after the Hannington-Kiff protocol. Although guanethidine was used in the past, evidence suggests that when compared with placebo, it does not produce any decrease in pain.[20,39] Guanethidine and reserpine are no longer available commercially in the United States and, in general, are not indicated clinically in the management of CRPS type 1 or 2. The use of intravenous corticosteroids in the management of CRPS is not supported by any controlled clinical trials. Bretylium tosylate (Bretylol) is the only drug approved and labeled by the FDA as an intravenous competitive blocking agent. Bretylium produces a transient release of norepinephrine from postganglionic sympathetic nerve endings, followed by blockade of norepinephrine uptake. It is well tolerated and appears to be effective in selected patients.[38,60] Bretylium or corticosteroids may be used in conjunction with regional anesthesia for surgical procedures in patients requiring reconstructive procedures or to facilitate mobilization of stiff joints by manipulation under anesthesia.[142] In rare cases, lasting relief may be obtained after a single intravenous infusion of a sympatholytic drug or corticosteroid; however, in many cases, sequential blocks (three to five) are required. Intravenous regional droperidol, an α-adrenergic antagonist, has been evaluated in a double-blind, placebo-controlled crossover study.[72] Effectiveness of intravenous ketorolac and lidocaine has been reported.[131] Intravenous regional phenoxybenzamine "appeared" to produce long-term relief in five patients.[89]

Diagnostic Intravenous Infusion

Intravenous infusions are used for diagnostic purposes; there are no current treatment programs that involve the use of such infusions.[127] Intravenous phentolamine is used to determine the presence of α-adrenergically mediated sympathetic pain,[6] and intravenous lidocaine may be used to assess the potential efficacy of oral membrane-stabilizing agents.[24]

Epidural Agents

Epidural corticosteroids and clonidine have been used and may provide relief in selected patients.[31,111]

Percutaneous Neural or Ganglionic Blockade

Neural blockade of the stellate ganglion, brachial plexus, or spinal cord/nerve roots is effective in relieving CRPS in some cases (see the earlier section "Diagnostic Regional and Sympathetic Blockade"). A series of blocks performed at 3- to 14-day intervals is often necessary to achieve adequate sustained relief.

Continuous Autonomic Blockade

The use of prolonged blockade or continuous sympathetic blockade (or both) for the management of chronic pain has been established. Sympathetic blockade may be achieved by continuous infusion of a local anesthetic over the area of the stellate ganglion or paravertebral ganglia, along the brachial plexus, or within the epidural space. Specific blocks include anterior scalene, axillary, and brachial (Figure 53.13). Epidural blocks have been used successfully in the lower extremity and provide an alternative method to achieve sympathetic blockade in the upper extremity.[21] Blocks should be performed by experienced physicians with access to resuscitation equipment and ventilatory support. Epidural blocks may be effective in patients who demonstrate no improvement after peripheral sympathetic blockade,[21] and brachial plexus blocks may provide relief in patients unresponsive to stellate ganglion blocks.[30] Complications include complete or temporary motor and sensory blockade, which may compromise respiration, as well as bleeding, and nerve irritation.

Biofeedback and Acupuncture

Self-hypnosis or biofeedback (or both) may be useful in the management of properly selected patients.[40,51] Acupuncture (using electrodes or transdermal needles, or both) has also been advocated for the management of CRPS.[81] These techniques should be used judiciously.

Implantable Devices

Peripheral Nerve Implants

Implantable electrical stimulators have been placed on painful peripheral nerves throughout the nervous system. These include stimulators for gray matter, the dorsal column, the spinal cord, and peripheral nerves. Currently available devices allow various options, including placement of multiple electrodes on peripheral nerves, use of long-lasting implantable pulse generators, and use of remote programming. Single peripheral nerve stimulation can result in pain relief, improve sleep, decrease the use of addictive pain medication, and improve health-related quality of life.[23]

Implantable Spinal Cord Stimulation

Spinal cord stimulation (SCS) in selected patients relieves pain, improves the health-related quality of life, and is more effective and less expensive than standard treatment.[71,138] Selected patients who respond to a trial of SCS are candidates for SCS.[100] Analysis of spinal cord stimulators at 5 years after a randomized controlled trial documented a high complication rate in the implant group and results similar to physical therapy alone for pain relief and other measures.[70] Despite diminishing effectiveness over time, 98% of the SCS group would repeat the procedure.[70] Because of the invasive nature of SCS, it should not be used early in the treatment protocol; however, SCS is a potential intervention that can be used after careful patient selection.[20]

Central Nervous System Ablative Techniques

CRPS has been treated by bilateral anterior cingulotomy with only short-term palliation.[120]

Level of Evidence for Treatment of Complex Regional Pain Syndrome

A review of the randomized placebo-controlled trials on the treatment of CRPS type 1 identified 26 studies, 18 randomized, placebo-controlled trials, and 8 randomized, actively controlled trials.[39] Based on this review, there is limited to no evidence for the efficacy of sympathetic blocks (stellate ganglion or regional intravenous sympathetic blocks), free radical scavenging, prednisolone treatment, acupuncture, or manual lymph drainage.[39] However, promising results were observed with drugs regulating calcium[39,114] and qigong.[39] Vitamin C was identified as being useful in preventing CRPS type 1 after distal radius fractures (see Table 53.12). Authors have attributed the lack of high-quality evidence for the efficacy of lumbar sympathetic blocks, intravenous regional blocks, and stellate ganglion blocks to studies with small sample sizes, lack of control treatment groups, inadequate methodology to rate the response to interventions, and lack of data on the duration of response.[100] The only pharmacologic intervention that has been shown to be effective in multiple controlled trials is treatment with bisphosphonates.[114]

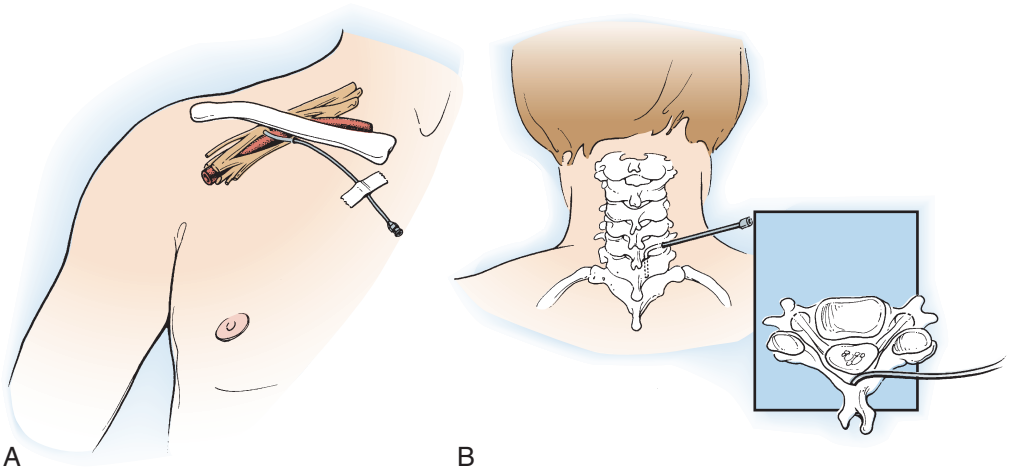

FIGURE 53.13 Placement for continuous blockade with a brachial plexus catheter **(A)** and continuous cervical epidural blockade **(B)**. In both cases a small Silastic catheter is introduced percutaneously and continuous blocking agents or other medications are infused via a pump mechanism. (From Koman LA, Pochling GG: Reflex sympathetic dystrophy. In Gelberman RH, editor: *Operative nerve repair and reconstruction*, Philadelphia, 1990, Lippincott, pp 1497–1524.)

❖ AUTHORS' PREFERRED METHOD OF EVALUATION AND TREATMENT

The manifestation of CRPS is quite variable, and the classic finding of a mildly to moderately swollen, painful hand is not always present. Difficulty sleeping and burning pain may be harbingers of escalating symptoms and signs. Commonly, the patient's condition is thought to represent a "poor" result after surgery or minor trauma. However, examination reveals subtle, yet retrospectively more obvious, symptoms and signs of a dystrophic process. The time course of CRPS may vary considerably, with mild symptoms preventing recovery without pathognomonic findings. Variability in the course of the syndrome is common. Many patients with undiagnosed CRPS recover spontaneously; others "smolder" in the early stage of CRPS for prolonged periods. Occasionally, within a short period patients progress rapidly from painful extremities that are hot and swollen to painful, cold, and stiff extremities and then to stiff and painless extremities. CRPS can affect a single digit, an isolated peripheral nerve distribution, or an entire limb. *Early diagnosis is aided by a high index of suspicion and the recognition that CRPS can occur after any traumatic event.*

Diagnosis

Because successful treatment of CRPS is positively influenced by the rapidity of diagnosis and treatment, early clinical recognition of this syndrome is crucial. A dystrophic process should be considered in all patients experiencing pain that is out of proportion to the traumatic or surgical insult and that is inappropriately influencing function or outcome. High-risk groups for CRPS include patients who sustain peripheral nerve injury, distal radius and ulna fractures, or crushing trauma; however, CRPS may affect any person with an injury. In the postoperative period, painful and excessive swelling combined with vasoconstriction or vasodilation suggests CRPS. The diagnosis of CRPS is clinical, and symptoms must include pain, trophic changes, autonomic dysfunction, and functional deficits. If a diagnosis of CRPS is suspected, instruments to quantitate pain (e.g., McGill Short Form Pain Questionnaire and VAS for pain),[96] overall symptoms and function (e.g., self-administered carpal tunnel questionnaire),[83] and Disabilities of the Arm, Shoulder, and Hand (DASH)[13] are administered. Objective measures of hyperpathia/allodynia are preferred, if possible, and responses to measured stimuli such as monofilament testing are quantifiable. Edema is estimated or measured by volumetric analysis. Function is assessed by questionnaires or verified by standardized methods (or both) (e.g., grip, pinch, Moberg pickup test, computerized instrumentation). The use of standard instruments, appropriate questionnaires, and reproducible objective tests assists in confirming the diagnosis and aids in monitoring the efficacy of interventions.

Physiologic staging of autonomic function is determined by analysis of temperature and laser Doppler fluxmetry before, during, and after a cold stress.[76,105] Nutritional capillary perfusion is assessed by vital capillaroscopy. Temperature and laser Doppler fluxmetry data provide reproducible and sensitive information that can give an estimate of physiologic function, document pathophysiology, and guide treatment decisions. Although not used routinely, phase III bone scans provide confirmative information when combined with clinical prerequisites. Intravenous phentolamine, stellate ganglion blocks, epidural injections, and somatic nerve blocks are used to verify the presence of SMP and predict the efficacy of oral sympatholytic drugs. The location of any identifiable nociceptive foci can be identified after the use of oral or parenteral sympatholytic medications.

Multidisciplinary Team Approach

Our management protocol involves a pain control clinic, as well as anesthesiologists, psychologists, case workers, and therapists. In acute, active phases of the dystrophic process, diagnostic testing and treatment decisions are coordinated through our offices in concert with a hand therapist and case manager. Direct referrals for specific evaluations or treatments are made as needed. If blocks are required, referral is made to an anesthesiologist-directed pain clinic in which resuscitative equipment and skilled personnel are available to perform invasive interventions. The choice of intervention is discussed with the physician administering the block or blocks, and follow-up is coordinated in both offices. In more chronic cases, patients are referred for either primary management or consultation, depending on the circumstances.

Hand Therapy

The use of physical therapy in the management of CRPS is well supported.[53,77,78] Therapeutic regimens should address treatment of the entire limb. For example, restricted shoulder motion resulting from secondary adhesive capsulitis is often insidious in onset and debilitating over time. Therefore, maintenance (or restoration) of shoulder motion is necessary to optimize recovery and may have a profoundly positive impact on health-related quality of life. If present, limited elbow motion may also be debilitating. Joints in close proximity to the area of trauma and the small joints of the hand and wrist are most frequently involved with arthrofibrosis and resultant restricted hand and wrist range of motion. Prevention of arthrofibrosis is important because once it is established, it is difficult to manage. Although physical therapy modalities alone may provide dramatic improvement, many patients require concomitant pharmacologic intervention and adaptive therapies[77,78] or surgery (or both).[53] *The mainstay of therapy should include active and passive joint range of motion, including stress-loading activities, transcutaneous electrical nerve stimulation (TENS) desensitization techniques, or sensory reeducation, or any combination of these therapies.*

Adaptive Modalities

Adaptive therapeutic modalities include TENS techniques, contrast baths, continuous passive motion, intermittent positive pressure with pneumatic pumps, and hydrotherapy.[112] TENS units are theorized to decrease pain by blocking nociceptive input and have been shown to increase extremity blood flow.[112]

Patient Expectations

Nonoperative treatments are a valuable adjunct in the management of CRPS; however, patient tolerance of these treatments differs. Expectations regarding the events taking place during traditional therapeutic modalities, the physiologic consequences of these interventions, and the time course until recovery should be discussed in detail with patients before treatment is initiated.

Details of the type of therapy to be used, such as active range of motion, splinting, or contrast baths, should be outlined. In addition, possible adverse effects, such as swelling and transiently increased pain, should be discussed and the variability in the potential responses detailed. Possible adjustments to the treatment regimen, including the addition of blocks and oral medications, and the side effects/consequences of these treatments should be discussed before treatments are initiated.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Oral Medications

Drug selection should be based on physiologic staging of the CRPS and should address the symptoms. In patients with SMP, an estimate of total flow, nutritional flow, edema, and reported symptoms may guide the decision-making process. Combination drug treatment is used frequently, often in conjunction with hand therapy (i.e., stress loading), adaptive therapy, and TENS. Various combinations of drugs may be used; two drugs from separate classes are often more effective than two drugs from one class. For example, patients with SMP, high total blood flow, and nutritional shunting without edema may be given amitriptyline and phenytoin in combination with a stress-loading program. If treatment is successful, total flow will be decreased by minimizing arteriovenous shunting, nutritional flow will increase, and pain will be relieved.

In patients with pain associated with a cold, stiff, atrophic hand, evaluations usually indicate compromised nutritional flow. The use of a calcium channel blocker combined with a serotonin reuptake inhibitor should increase nutritional flow and thereby relieve the symptoms. TENS may also increase nutritional flow by inhibiting smaller nociceptive fibers.[112] Hyperalgesia with significant edema is managed initially by transdermal clonidine in conjunction with a tricyclic antidepressant or a serotonin reuptake inhibitor (or both). Corticosteroids are seldom used because of fear of avascular necrosis. Patients should be monitored carefully with the use of objective data (e.g., pain scales, functional instruments, physiologic testing) when possible. In the absence of clinical improvement, oral medications should be altered or augmented by parenteral interventions.

Treatment Expectations and Complications

The natural history and potential side effects associated with oral medications should be outlined before initiation of the treatment. The fact that drugs prescribed for CRPS are often used for "off-label" indications should be mentioned, and the potential side effects of each drug should be discussed. It is helpful to emphasize to patients that certain classes of drugs are not always used for the package insert indications. Because side effects of drugs are dose related, patients should understand that the doses used for managing the symptoms of CRPS are often less than the doses that are commonly prescribed for other conditions. It should be explained that several drugs used to manage the pain associated with CRPS were originally developed to treat psychological issues or seizures. For example, when using an antidepressant or antipsychotic medicine, it is prudent to tell patients that you are not prescribing the drug because they have psychological issues or because they are having seizures. Instead, you are prescribing the drug because of its effects on the nervous system that facilitate pain management. For phenytoin (Dilantin), patients should be informed that short-term use does not cause gingival hypertrophy.

Expected Outcomes of Drug Therapy

The expected outcomes of drug therapy are relief of pain, decreased swelling, and diminished hypersensitivity to touch.

Drug therapy is frequently combined with other therapies because drugs often provide incomplete relief without additional interventions in 80% of patients.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Parenteral Medications

The administration of intravenous medications via variations of the Hannington-Kiff technique or serial stellate ganglion blocks should be guided by controlled protocols, and their continuation should be based on documented and progressive improvement in pain management. We prefer continuous autonomic blocks (e.g., epidural blocks) for 3 to 7 days. The effectiveness of the block may be verified by stress testing after 24 to 36 hours of blockade. It is important to monitor the patient closely by objective criteria, and courses of "blocks" should be based on the attainment of prospective goals within a predetermined time frame.

We have found continuous autonomic blockade to be efficacious in selected patients; it may attenuate the dystrophic process, thereby allowing identification of a nociceptive focus. Furthermore, its use for 3 to 5 days may alleviate symptoms, may allow the patient to return to a satisfactory functional level, or may prevent recurrence or exacerbation of pain after surgical intervention. Biofeedback may be used in conjunction with psychological support in selected patients who demonstrate appropriate psychological profiles established by objective testing (e.g., Minnesota Multiphasic Personality Inventory).

Treatment Expectations and Complications

Parenteral interventions are administered primarily by anesthesiologists. Nevertheless, providing patients with a description of the procedures used to administer parenteral drugs and an explanation of the expected outcomes is helpful. We advise patients that although serial blocks may result in transient benefits, the cumulative effects of repeated serial blocks or continuous blocks may decrease pain in 50% to 80% of patients. The major common side effects of parenteral interventions are pain associated with injection of the drug and bruising at the injection site. Patients should also be informed that a small percentage of patients will have increased symptoms after blocks.

Expectations for Parenteral Treatment

Few patients are affected negatively after parenteral interventions (<5%). Eighty percent of patients experience at least a 50% or greater decrease in pain and other symptoms. Pain during drug injection and injection site tenderness are common.

Surgical and Ablative Therapies

Chemical Sympathectomy

Chemical sympathectomy achieved by the injection of phenol or other agents along the sympathetic trunk provides clinical efficacy in selected patients. For this procedure, diluted phenol (3-7%) is injected into the nerve or ganglia with computed

tomography being used for needle localization. This allows a reversible axonotmesis with recovery in 3 to 6 months. Theoretically, chemical sympathectomy produces pain relief without complete transection of the nerves and diminishes the possibility of delayed hypersensitivity from receptor upregulation. The use of peripheral sympathectomy to increase perfusion after arterectomy, including resection of sympathetic fibers on peripheral blood vessels, was first described by Leriche.[66] Although resection of major blood vessels is not recommended for CRPS, the role of sympathectomy continues to be evaluated and has been reported anecdotally as being effective.

Surgical Sympathectomy

Surgical sympathectomy has been reserved for patients with refractory CRPS because the results are variable. Short-term effectiveness is common, and success after sympathectomy has been reported after failure of other treatment modalities. Successful surgical sympathectomy requires complete sympathetic denervation of the appropriate limb fibers from the stellate ganglion to T2 and T3. Thoracoscopic ganglionectomy is currently being used with satisfactory sympathectomy success rates[123]; however, the effects of proximal sympathectomy on distal sympathetic tone (as reflected by increased blood flow) are transient and last from 6 to 24 weeks. The cause of the loss of efficacy is postulated to be secondary to upregulation of distal receptors, which may produce supersensitivity to circulating or endogenous catecholamines and prompt recurrence of symptoms. However, in some patients, the pain relief after sympathectomy is sufficient to break the dystrophic cycle, and the improvement persists. Patients occasionally experience an increase in pain and symptoms after sympathectomy. Therefore, temporary (3- to 6-month) chemical sympathectomy of the autonomic sympathetic nervous system may be preferable to transection of neural structures. When chemical sympathectomy is used, nerve regeneration will occur and receptor upregulation either does not take place or is diminished. Radiofrequency ablation of the cervicothoracic ganglion has also been recommended.[148] Recently, intrathecal or epidural administration of drugs such as clonidine has been advanced.[111]

Surgical Outcomes and Complications

Deterioration in the patient's condition after surgery occurs infrequently in patients who have responded positively to preoperative sympathetic blocks. In addition, patients benefit from appropriate sympatholysis initiated during the postoperative period to control symptoms. Exacerbation of symptoms occurs transiently in 50% of patients; however, few patients (<5%) continue to experience these symptoms 3 months after surgery. A 50% or greater decrease in pain and other symptoms is observed in 75 to 80% of patients if (1) nociceptive or neuropathic foci are appropriately identified and (2) perioperative sympatholytic management techniques are used. *These observations can be extrapolated to all surgical interventions used in CRPS patients except dorsal column stimulation.*

Summary of the Role of Sympathectomy

Critical analysis of the peer-reviewed literature to assess the effects of both chemical and surgical sympathectomy for neuropathic pain concluded that this clinical practice "is based on poor quality evidence, uncontrolled studies, and personal experience. Furthermore, complications of the procedure may be significant…"[87,130] and "denervation super-sensitivity of blood vessels and intense vasomotion may be associated with recurrence of pain."[12,100] These findings are in agreement with observations by the authors, although some investigators report success with stellate ganglion ablation.[68]

Management of the Neural Dystrophic Focus

If a nociceptive (dystrophic) focus, or trigger area, is identifiable, direct treatment of the abnormality may provide significant pain relief. Nociceptive foci, identifiable in less than 50% of patients, may be mechanical or neural. If diagnosed, the underlying focus may be managed by conventional procedures after maximal pharmacologic control is achieved. If symptoms persist, surgical correction of the defect/deformity may be helpful. The most common neural diagnoses contributing to CRPS are neuroma, neuroma-in-continuity, and secondary compression neuropathies.

Diagnosis and Management of Structural Neural Problems

Neuromas develop in 30 to 40% of patients with significant nerve injuries and may precipitate a dystrophic response, complicate clinical management, and interfere with health-related quality of life. A partial nerve injury, when complicated by a neuroma-in-continuity, is characterized by allodynia, hyperpathia, and vasomotor abnormalities; sudomotor changes are common and cold sensitivity may be significant. Compression neuropathies are frequently seen in patients with CRPS[50,77,78] and may either be the precipitating causal event or occur secondarily. Most frequently, the median nerve is involved within the carpal canal; involvement at the elbow is less frequent. The ulnar nerve at the cubital tunnel or within the wrist may also be involved. The posterior interosseous branch of the radial nerve may be compressed above or within the supinator (radial tunnel syndrome).

Physical examination after sympatholytic intervention may be required to verify the clinical suspicion of neuroma, neuroma-in-continuity, or compression neuropathy. Local anesthesia of the suspected nerve proximal to the suspected injury may be helpful and provides confirmation of clinical suspicion.

Surgical Management of Neural Injury in Complex Regional Pain Syndrome

Surgery on neural structures compromised by neuromas, neuroma-in-continuity, or compression is indicated if symptoms persist after nonoperative modalities, including sympatholytic medications, and if the symptoms can be controlled medically in the perioperative period. An acute dystrophic flare-up of quiescent CRPS is possible in the postoperative period; however, exacerbation of symptoms may be managed effectively with oral medications or a continuous block. Surgical options include neurolysis, neurorrhaphy, or neural relocation. Environmental modification is also an option as is a combination of surgical procedures and environmental modification.

If a neural insult is identified and is correctable surgically, the nerve is explored via an extensile incision. All adhesions are released, and the nerve is evaluated under magnification, with an operating microscope if necessary. The appropriate treatment option depends on the clinical findings, the location and

type of nerve (i.e., motor, sensory, or mixed), the preoperative nerve function, the location of the injury, the quality of the neural bed and its environment, and the general needs and condition of the patient. With a complete nerve transection or a neuroma-in-continuity, the following general principles apply:

- Avoid tension on the repair site or sites by performing nerve grafts from the sural nerve or, for small nerves, a branch of the medial or lateral antebrachial cutaneous nerve.
- Manage adhesions between the skin and nerve by "Z"-plasty local flaps or distant flaps.
- If excessive scarring or adhesions develop, modify the neural bed with the use of autologous fat, rotational muscle flaps, pedicled muscle or fascial flaps, free muscle transfer, autologous or allograft venous wraps, or nerve conduits.[67]
- Minimize internal neurolysis.
- Include sympatholytic intervention (e.g., continuous autonomic blockade), pharmacologic palliation, physical therapy, and early active and passive range of motion in the postoperative care.
- Establish hemostasis to prevent hematoma formation.
- Avoid constrictive postoperative dressings.

For the treatment of compression neuropathy, the dystrophic response is managed by sympatholytic medications or autonomic blockade, or both, and the nerve is evaluated clinically. If symptoms are sufficient to justify intervention, location of the compression neuropathy is confirmed by peripheral nerve conduction velocities or interstitial pressure measurements. Complete release of the involved nerve is important. If there is damage to the neural bed or the neural bed is compromised, modification of the neural environment is appropriate. The patient may be treated postoperatively with appropriate sympatholytic oral medications or continuous autonomic blockade (or both) to minimize postoperative pain and prevent a dystrophic flare-up. Postoperative management of CRPS patients is dependent on the type of surgical procedure. However, sympatholytic intervention with parenteral or oral agents is important, and exacerbation of symptoms is rare. Patients should expect prolonged rehabilitation, continued use of oral nonnarcotic agents for 3 to 6 months, and residual disability. For example, surgical release of the intrinsics by myotomy or tenotomy of the MP or PIP joints will decrease "stiffness" but will not restore full range of motion (50% improvement is average).

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Common Nerve–Related Complex Regional Pain Syndrome

Surgical Technique for the Management of Injury to the Superficial Branch of the Radial Nerve Complicated by Complex Regional Pain Syndrome

The superficial radial nerve may be injured traumatically or during surgical release of the first or second dorsal compartment of the wrist. Options for treatment include proximal transection of the nerve in normal tissue beneath the brachioradialis muscle, exploration with neurolysis, or repair.

The nerve should be approached through an extensile incision that incorporates the previous scar, if necessary. The nerve may be adherent to the tendons, the tendon sheath, or overlying skin; regional fat necrosis is common. To facilitate dissection, the nerve should be identified proximally and distally in an unoperated or uninjured area while working toward the area of injury. While working from normal to abnormal tissue, the nerve is isolated to expose existing lesions. A decision is then made regarding management of the injury. If repair is selected, microscopic dissection plus repair of injured fascicles is performed end to end or with a nerve graft. If the nerve is to be transected, it may be resected to a level of surrounding normal tissue or relocated to an unscarred area (Figure 53.14). Either a sural nerve or a forearm nerve is harvested from a separate incision to accomplish nerve grafting. Based on experience in six patients with injured superficial radial nerves and CRPS, our preference is to use the sural nerve to avoid a potential nociceptive focus in the same extremity. During preoperative assessment, donor nerves may be blocked proximally so that the patient appreciates the degree of potential numbness in the donor nerve field that will be experienced after the surgery. The sural nerve is harvested through a separate lateral incision in

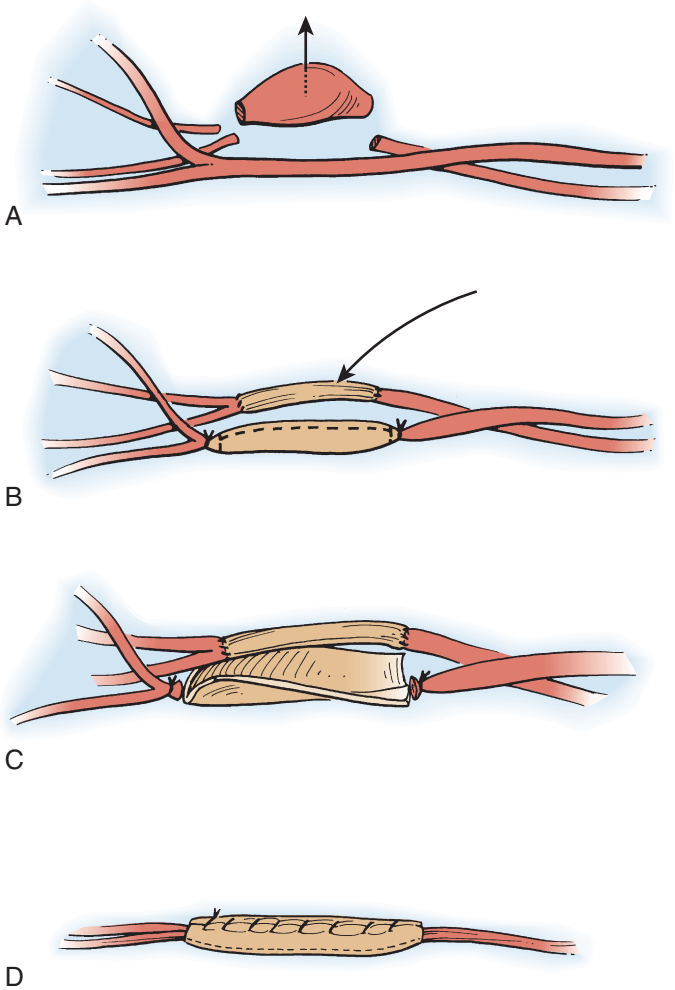

FIGURE 53.14 Authors' preferred treatment of a neuroma of the superficial branch of the radial nerve. **A,** Resection of the neuroma. **B,** Repair with a sural nerve graft and ligation of the cephalic vein. **C,** Longitudinal split in the resected segment of vein. **D,** Cephalic vein wrapped loosely around the nerve repair. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

the leg. The grafting is then completed with 8-0 or 9-0 nonabsorbable suture under the operating microscope.

Excessive scar-related attachment of the nerve to underlying tendon structures or to overlying skin requires environmental modification. Although this may be achieved by a variety of means, we prefer covering the nerve with a section of the adjacent cephalic vein or harvesting a separate vein from the leg or arm. Alternatives include nerve conduit grafts, local or free fat grafts, and free muscle transfer.[67] After repair, the tourniquet is deflated, bleeding is controlled, and a drain is placed to prevent hematoma formation. Subcutaneous tissue is closed with absorbable suture, and the skin is approximated with nonabsorbable suture or staples, or both. Postoperative reactivation of the dystrophic process is a major concern, but it may be minimized by maintaining a continuous autonomic blockade for 3 to 5 days after surgery.

CRITICAL POINTS *Management of Patients With a Painful Median Nerve and Complex Regional Pain Syndrome*

Indications
- Quiescent or stable sympathetically maintained CRPS with mechanical pain
- Previous neurolysis with scar and decreased nerve mobility

Preoperative Evaluation
- Demonstrate painful nerve gliding.
- Evaluate peripheral nerve conduction velocities.
- Do not perform surgery unless sympatholytic intervention reduces the pain significantly.

Pearl
- Have an anesthesiologist perform a continuous autonomic block before surgery for intraoperative and postoperative pain management (2 to 5 days).

Technical Points
- Perform an extensile neurolysis.
- Excise any synovitis, if present.
- Mobilize the nerve.
- Cover the nerve with fat, a muscle flap, vein, synthetic conduit, or free tissue transfer.

Pitfalls
- Failure to confirm potential control of postoperative pain with oral or parenteral drugs or continuous field or nerve blocks
- Incomplete mobilization of the involved nerve
- Inadequate interposition of soft tissue or other material between skin-nerve and nerve-tendon interfaces

Postoperative Care
- Initiate early range-of-motion exercises of the fingers and wrist.
- Maintain adequate pain management for 3 to 7 days with parenteral or oral agents, or both.
- Note that continuous blocks are helpful for pain relief. Allow unrestricted motion when the patient is comfortable.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Revision of Carpal Tunnel Surgery

Persistent mechanical pain associated with dystrophic symptoms after release of the transverse carpal ligament or neurolysis of the median nerve is a difficult problem. The nociceptive focus may result from internal or external scarring, neuroma-in-continuity, or transection of a nerve branch (e.g., the palmar cutaneous branch of the median nerve). When SMP is associated with a demonstrable peripheral nerve lesion, surgical intervention/correction of the underlying lesion may provide significant palliation. If external adhesions or mechanical problems are contributing to the nociceptive focus, environmental modification may be necessary.

The nerve is approached through an extensile excision and identified proximally and distally in "normal" tissue. The nerve is then traced distally to the "takeoff" of the palmar cutaneous branch, which is dissected separately and protected unless already damaged. Dissection in a distal to proximal direction is performed while avoiding injury to the nerve branches. The entire nerve from the distal portion of the forearm in normal tissue to the terminal proper and common digital nerves and motor branches should be identified. The superficial palmar arch should be identified and protected. Internal neurolysis should be avoided, if possible. If a *neuroma* or *neuroma-in-continuity* is encountered, it may be dissected under the operating microscope and either repaired or grafted, and placed in a protected environment. All sensory branches and recurrent motor branches are identified.

If there is significant scarring between the nerve and the surrounding subcutaneous tissue, tendons, skin, or synovium, the neural environment should be modified. Options include placing a local or distal autologous flap, using local pedicle muscle flaps (e.g., abductor digiti quinti, palmaris brevis, pronator quadratus), using forearm fascia, transferring distal free tissue (i.e., fascia, omentum, muscle), or wrapping the scarred nerve with an autologous or allograft vein, usually the saphenous vein (Figure 53.15). If venous wrapping is selected, either autogenous saphenous vein or allograft may be wrapped directly around the median nerve with a space left through which the palmar cutaneous branch can exit (Figure 53.16).[67] The palmar cutaneous branch, if scarred or injured, may be wrapped separately with a small vein from the forearm, or an allograft may be placed around the nerve. If autologous vein is used, it can be wrapped around the nerve in "barber pole" fashion. The saphenous vein is seldom large enough to fold around the median nerve itself but will wrap easily around the branches. The graft should be sutured proximally and distally with a 5-0 or 6-0 nonreactive suture. *Chromic suture should be avoided because chemicals released from the suture can create a nociceptive neural focus.*

Injury to the palmar cutaneous branch of the median nerve is common. If this branch is injured, the branch may be resected and moved to an unscarred area or repaired by using end-to-end anastomoses or an interposition nerve graft. For grafting, we prefer, when possible, to use a short branch of the medial or lateral antebrachial cutaneous nerve. This graft may be harvested through a separate oblique incision in the forearm. Nerve repair is accomplished under the operating microscope with 9-0 to 10-0 nonabsorbable suture on 75- to 130-μm needles.

Before completion of the procedure, the tourniquet is released, bleeding is controlled, and a suction drain is placed. Postoperatively, the limb is protected from pain and dystrophic flare-up by the use of continuous autonomic blockade. Motion of the affected extremity is initiated in a controlled active

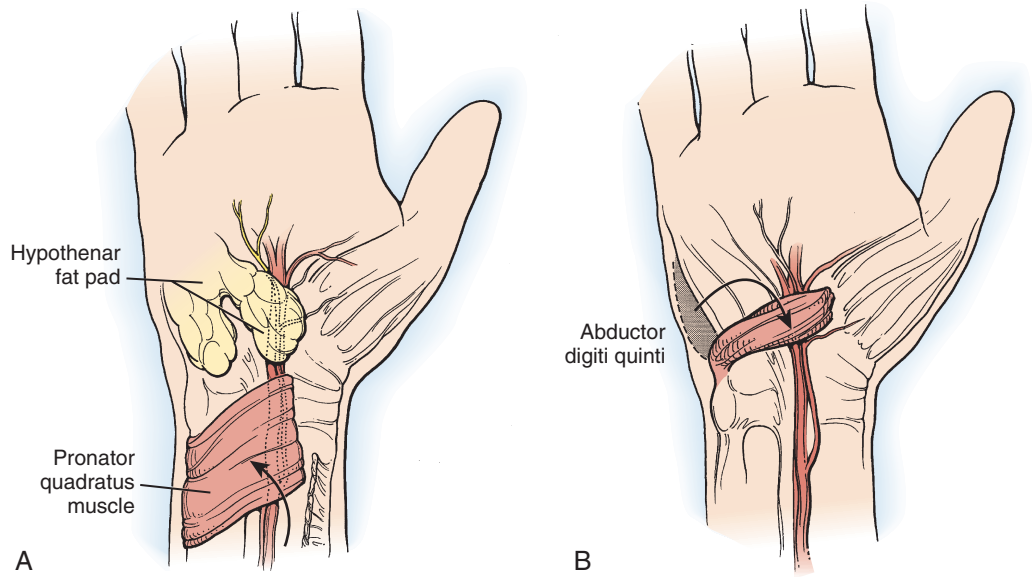

FIGURE 53.15 Options for modifying the environment surrounding an injured median nerve at the wrist include transposition of **(A)** pedicled hypothenar fat, the pronator quadratus muscle, or **(B)** the abductor digiti quinti muscle. therapy program or by using continuous passive motion over the 3- to 5-day period of hospitalization for the continuous blockade.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Metacarpophalangeal and Proximal Interphalangeal Joint Contractures (Late-Stage Treatment)

Surgical management of any chronic deformity that may occur after CRPS is possible and appropriate. However, reexacerbation of a dystrophic response is a potential risk with any surgical intervention for these deformities. This risk is minimized by attention to the principles discussed in this chapter. Perioperative pain control with continuous epidural or peripheral catheters is prudent and should be maintained for 3 to 5 days after surgery. Alternatively, continuous field block catheters may be used for pain control.

Surgical correction of secondary joint deformities from arthrofibrosis may be necessary after CRPS. Fixed contractures of the MP joints in extension and the PIP joints in flexion or extension are common. In addition, the shoulder, elbow, and wrist may have restricted motion.

Early management of CRPS will diminish the development of contractures; manipulation under sympatholytic blockade has been advocated to prevent such contractures. However, disuse and segmental ischemia of the extremity may produce arthrofibrosis despite active intervention. Surgery on contracted joints should not be initiated until maximal nonoperative improvement has been achieved. In general, the waiting period should be a minimum of 3 to 6 months after successful elimination of the active dystrophic pain. This policy is in contradistinction to early intervention for identifiable peripheral nerve injuries, which should be dealt with as soon as it is safe in terms of dystrophic symptoms.

When nonoperative improvement has reached a plateau, and symptoms warrant intervention, release of the MP or PIP joints

(or both) can be achieved. Indications for surgery are joint pain without diffuse dystrophic symptoms and arthrofibrosis that interferes with functioning. Persistence of MP and PIP joint contractures is devastating because it prevents adequate hand function and interferes with the health-related quality of life. If necessary, all four MP joints and all four PIP joints can be released in a single operation. It is important for the patient and physician to understand that this is a salvage procedure and that improvement in gross hand function, reduction in pain, and improved quality of activity are both the long-term and the short-term goals; restoration of full flexion or extension, or both, is not a reasonable goal or expectation. Surgery is performed to allow the hand to achieve improved function, to facilitate MP joint motion, and to make active grasp and release less cumbersome and painful. The range of motion achieved intraoperatively rarely persists postoperatively.

Operative Technique

After placement of an epidural or brachial plexus catheter, adequate surgical anesthesia is obtained. The MP and PIP joints are approached through oblique dorsal incisions. The extent of adhesions in the extensor mechanism and the degree of arthrofibrosis are identified. Major findings in the MP joint in the presence of an extension deformity include contracture and thickening of the collateral ligaments, adhesions of the volar plate and metacarpal neck, dorsal capsular tightness, and intrinsic muscle contracture. PIP joint motion is limited by contracture of the extensor mechanism, as well as by the collateral ligaments and volar plate adherence. Tendon-splitting incisions are avoided by approaching the MP joints from the radial side and moving the extensor tendon ulnarly. The joint capsule is opened and the collateral ligament identified. Frequently, erosions are present beneath the collateral ligament, which is invariably hypertrophied and contracted. The true and accessory collateral ligaments are released from the metacarpal head on the radial and ulnar sides; a small elevator is used to mobilize the volar plate without detaching it from the phalanx. Transection of the volar plate is rarely necessary. After release of the collateral ligaments and freeing of the volar plate, the MP joints should move from neutral to greater than 90 degrees of flexion without subluxation (Figure 53.17).

If necessary, the PIP joint is approached through a dorsal incision. Tendon splitting is avoided with the extensor mechanism retracted after releasing both transverse retinacular ligaments. The lateral band and central slip may be moved radially or ulnarly to allow ready access to the joint. The joint is dissected, the collateral ligaments are released, and the volar plate is freed (see Figure 53.17).

The intrinsics are tested after sequential release of the MP and PIP joints. If an intrinsic contracture exists, intrinsic release is performed. Once these procedures are completed, all these joints should move through a satisfactory range of motion of 170 degrees or greater, and the joints should be stable. If stability is in question, the MP joint is pinned in full flexion and the PIP joint in 35 to 45 degrees of flexion. Continuous passive motion or an active and passive range-of-motion program is used postoperatively.

The results of MP joint release are gratifying, and usually 80% to 90% of the intraoperatively achieved range of motion is maintained. However, release of the PIP joint is less satisfactory. Although patients report significant symptomatic relief and improved health-related quality of life, joint range of motion averages approximately 50% of that observed intraoperatively.

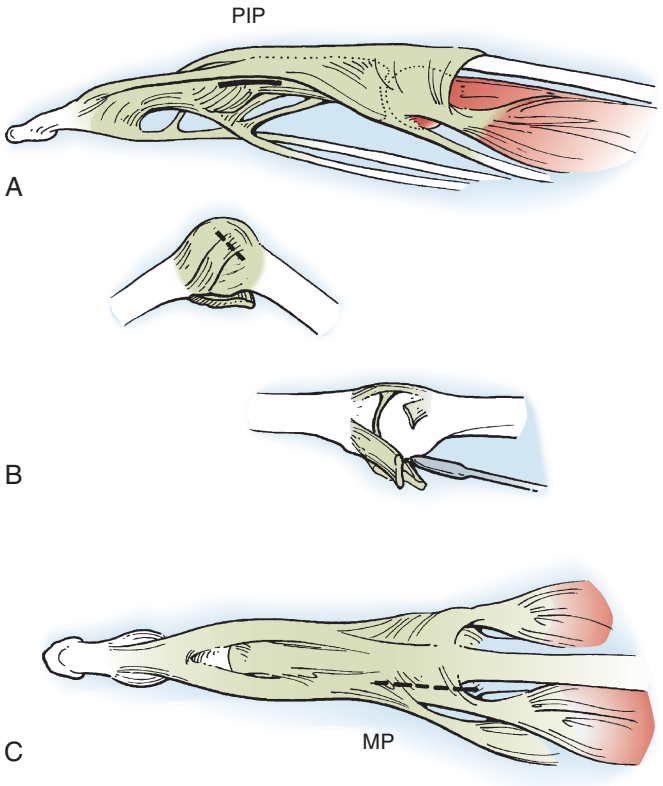

FIGURE 53.17 Release of the metacarpophalangeal (MP) and proximal interphalangeal (PIP) joints. **A,** Through an oblique dorsal incision, the PIP joint is exposed by elevating the extensor mechanism after release of the transverse retinacular ligament. **B,** The capsule is incised and the collateral ligament released. Dorsal adhesions may require lysis. **C,** The MP joint is approached by incising a portion of the sagittal bone, reflecting the extensor tendon ulnarly, and incising the capsule. The collateral ligaments are then released. (From Koman LA, editor: *Bowman Gray orthopaedic manual*, Winston-Salem, NC, 1996, Orthopaedic Press.)

Amputation

Amputation is reported as a course of last resort in a small number of patients with CRPS. Indications for amputation of the affected limb are recurrent infection and massive edema, as well as improvement in function; however, even after amputation, patients are rarely symptom free, prosthesis use is rare, recurrence of CRPS is frequent,[19,27] and psychosocial dysfunction persists.[133]

If necessary, amputation of limbs affected by CRPS requires perioperative sympatholytic treatment with oral medications and sympathetic blockade. Immediate prosthetic fitting is advisable and psychological support is helpful.

Factitious Disorders

Dean S. Louis and Morton L. Kasdan

Occasionally, a patient will have symptoms or physical findings that do not coincide with recognizable disease patterns. The symptoms may be out of proportion to the physical findings, or the physical findings may not make sense based on the historical record or when compared with our previous experience. When this happens, the examining physician should consider the possibility that the patient's agenda may be something other than wellness.[3,8,13,15,18]

A variety of terms have been used to describe these findings, including *malingering*, *factitious disorders*, and *conversion reactions*.[2,7,9,20,29,30] These are only a few of the various and often confusing designations that apply and that the hand and upper extremity surgeon must recognize. The complexities of the psychiatric diagnoses are not pertinent here but are referenced elsewhere.[8,16,20]

The majority of the diagnoses that we have seen fit into one of the major categories just listed. There are some recognizable patterns of clinical findings that should instantly alert the evaluating physician. Current psychiatric thought in this area has been summarized by LoPiccolo and colleagues[16] as follows: "While malingering[12] represents a *conscious* intent to deceive for the purpose of obtaining an easily identifiable goal (secondary gain), it should not be confused with factitious disorders. Factitious disorder is also defined as an *intentional* production of symptoms, but differs from malingering in that it is always considered pathological, and in that its goal is an internal rather than an external incentive, i.e., to assume the sick role."[4,20] Previous thought had denied attribution to personal motivation and referred to unconscious mechanisms to explain the observed behavior. Both malingering[12] and factitious disorders may be detected by either direct observation of situational behavior or by videotaped surveillance. The former would occur when an individual was observed in the workplace, social environment, or inpatient facility by staff to be performing contrary to any self-described limitations. Secondary surveillance involves direct videotaping from a concealed location of the individual performing a task or tasks that the individual claims to be unable to do because of a specific condition (examples would involve observed gripping or fine motor skills when the individual denies being able to do them). Although malingering and factitious disorders are "first cousins," they have a major difference. A malingerer is *feigning* illness, whereas a person with a factitious disorder is *causing* illness.

RECOGNIZABLE FACTITIOUS DISORDERS

Factitious Lymphedema

Patients with factitious lymphedema[10,17,19,23,26,27] usually have a history of the mysterious appearance of painless swelling of the limb and denial of any knowledge of the cause of the problem. It is usually attributed to occupational activities. The site of the edema is at a defined point anywhere from the shoulder distally (Figure 54.1). It is probable that the condition formerly called Secretan's disease was a form of factitious lymphedema.[11]

Once it is recognized, treatment may be effective. Hospitalization of the patient and controlled elevation will result in a rapid decrease in the edema. If it persists with constant elevation, late night rounds may reveal a tourniquet somewhere about the limb. An alternative outpatient technique is the application of a shoulder spica cast. Psychiatric or psychological consideration, or both, should be sought. There is no indication for surgical intervention.

Factitious Ulceration

Patients with factitious ulceration usually have a history of trivial trauma, with lesions subsequently developing that will not heal (Figure 54.2). The easiest way to confirm that the lesion is factitious is to cover the area with a cast so that the patient cannot manipulate the wound.[22] Healing under such circumstances helps confirm the diagnosis. Be aware that even with the application of a cast, some patients may still attempt to aggravate the wound with something as simple as a wire hanger.

Dysfunctional Postures

There are a host of nonfunctional hand postures that patients assume.[6,17] They have some common characteristics and are usually associated with a claimed inability to use the hand (Figures 54.3 to 54.5). In the classic position of the clenched fist,[25] the ulnar three digits are held in a flexed position while the thumb and index fingers are fully mobile and functional. There are many variations on this theme, including but not limited to an adducted thumb, extension of the digits, and combinations of all possible positions.

We are aware of a case in which the examining physician was sued for performing a vigorous passive examination that the patient claimed hurt her and worsened her condition. In such circumstances, it may be prudent for the physician to merely

FIGURE 54.1 Thirty-seven-year-old woman with a history of mysterious swelling of her left hand. There is an obvious area of tourniquet compression just distal to the elbow flexion crease. This was the initial manifestation of a long-involved and convoluted series of events that ended with severe flexion contracture of all fingers.

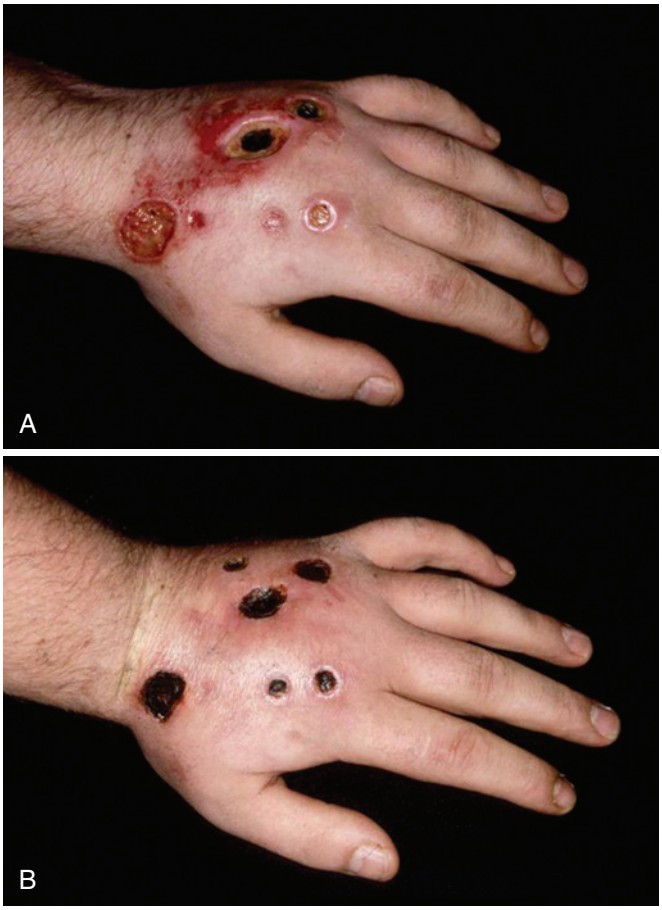

FIGURE 54.2 **A,** This young man sustained a trivial injury to the dorsum of his hand while at work. There was no break in the skin initially. While recovering from the initial condition, multiple circular areas resembling burns appeared as noted here. **B,** It was presumed that the areas seen in the previous picture represented self-inflicted cigarette burns. A cast was applied for 2 weeks and the wounds healed as seen here. After cast removal, an exacerbation of the wounds occurred.

observe and record active motion when patients say that they cannot move from a certain position.

DIFFERENTIAL DIAGNOSIS OF FACTITIOUS DISORDERS

There are many clinical patterns that may be factitious,[1] but those illustrated here are the most common ones observed in two separate practices over a 30-year period. The assumption inherent in this chapter is that all recognized medical conditions have been excluded and that the evaluating physician is now trying to figure out what is really going on. Recognition of the entities mentioned will make them a part of "recognized medical conditions."

Recognizing Factitious Illness and Avoiding *Mistaken* Diagnoses

There are several warning signs of factitious illness seen by a hand surgeon. Such signs may include

- Seeking treatment at many health facilities without a clear diagnosis after multiple tests and operations
- Severe symptoms that are not consistent with what seems to be a minor incident or injury
- Multiple wounds or scars
- Symptoms, such as swelling or stiffness, that are reported to be changing and worsening without apparent cause
- A desire and willingness for further testing and treatment that has little, if any, justification

Factitious illness is frequently underdiagnosed, misdiagnosed, and therefore incorrectly treated. Because of the patient's role and psychological condition, factitious illness is seldom suspected at the onset of care unless the treating physician is aware of such patterns and includes this condition as a possibility. Factitious illness is also difficult to prove because concealment and denial by the patient are central to the condition itself. Not surprisingly, treatment of a variety of conditions, *except* factitious illness, often begins and compounds the disorder, thereby creating new problems. The most common misdiagnosis is complex regional pain syndrome (CRPS) type 1 (see Chapter 53), or reflex sympathetic dystrophy.[28] Once labeled as having CRPS, the patient often proceeds through multiple levels of the health care system—from primary care physicians to advanced surgical specialties. Patients who indeed have a factitious condition (psychologically needing to be ill) begin to accept the fact that they have a real disease. Multiple stellate ganglion blocks, surgical nerve decompression, and intensive physical therapy are often undertaken over a period of months or years with no improvement and the usual

FIGURE 54.3 This woman, with an initial diagnosis of factitious lymphedema, as seen in Figure 54.1, was lost to follow-up for 6 months and returned with the classic posture of a clenched fist with severe excoriation of the palmar skin. The flexion deformities became permanent with fixed flexion contracture.

FIGURE 54.4 When first seen in June 1995, this 23-year-old man claimed that he had been injured in 1994 when a heavy object struck the dorsum of his right hand. At the time of his evaluation, he held his right upper extremity in a fixed posture and claimed that he was unable to use the right upper extremity for anything. Reflex sympathetic dystrophy had been diagnosed, and he had undergone multiple blocks and insertion of a dorsal column stimulator. Bilateral radiographs documented symmetric and normal mineralization of the bones. Video surveillance clearly revealed full active and strenuous use of the entire upper extremity. The grand jury returned a true bill of indictment for felony fraud. He pleaded guilty to a lesser charge of making a false sworn statement.

consequence of intensifying and solidifying the psychological disorder.

Because these patients accept and expect to be ill and disabled, the misapplication of treatment of CRPS results in the nocebo effect.[5,11,14,24] In contradistinction to the placebo effect, the patient's symptoms actually *worsen* with treatment despite the lack of noxious side effects of the various treatments and interventions, however misguided. Despite these dismal results, these patients are surprisingly willing to undergo further testing, imaging, and treatments. This feature of factitious illness adds weight to the imperative for proper diagnosis as early as possible.

MANAGEMENT OF PATIENTS WITH FACTITIOUS DISORDERS

There are neither easy solutions nor uniformly applicable paradigms for dealing with these difficult patients. Most patients with factitious disorders have a need to be injured or disabled, usually without seeking financial gain. Instead, they may have personality disorders or be seeking attention from a parent, spouse, or family member. Others may have a more obvious source of financial gain if disabled.

It is the hand surgeon's responsibility to recognize these patterns of factitious disease and refer or suggest referral for psychiatric evaluation, if possible. The act of referral itself is a delicate matter that requires a level of trust and frequently family support. This is not always the case. Unfortunately, family members are often unwittingly enabling and abetting the factitious illness and are hostile to the suggestion that there is not an operation or test that will cure the problem. Nonetheless, if possible, it is best to refer these patients to a psychiatrist who is willing to help them. Unfortunately, not all psychiatrists are willing to accept these patients, and finding sympathetic treatment may be extremely difficult.[7,8]

Editor's note (DPG): Some readers may think it inappropriate to have a chapter on factitious disorders in a book on operative surgery. Everyone would agree that the patients described in this brief chapter are clearly those in whom we should want to avoid operative intervention, but an accurate diagnosis in such patients is not always clearly apparent and virtually never easy to prove. It is precisely because these patients do constitute a pitfall for the unsuspecting hand surgeon that the editors deemed it necessary to include the chapter.

FIGURE 54.5 When first seen in 1989, this 53-year-old man claimed that he did not have good use of his left hand. He was a diabetic and was noted to have diffuse neuropathy. The patient had a full range of active motion but would immediately return his hand to the stiff, extended position. The significance of the black glove that he wore at each visit was not clear. He was drawing disability benefits.

55.1 Metacarpophalangeal arthroplasty in rheumatoid arthritis.

Reconstructive hand surgery has been established as an effective component in the overall management program of a patient with rheumatoid arthritis. However, it should be understood that hand reconstruction does not restore normal function to rheumatoid hands. Pain may be alleviated, severe deformity prevented or corrected, and appearance and function improved, but motion and dexterity still will be limited, and weakness will remain a significant disability.[129] Because of the difficulty in consistently restoring or improving function, careful judgment must be used when recommending reconstructive surgery. Fortunately, disease-modifying medical therapy has decreased the need for reconstructive hand and upper extremity surgery. Nonetheless, the skilled hand surgeon should have a working knowledge of rheumatoid hand and wrist deformities and their treatment.

The purpose of this chapter is to describe the surgical techniques used to correct rheumatoid hand deformities. However, an understanding of these techniques is only one requirement—the surgeon must also appreciate the natural history of the disease and its deformities. In addition, he or she must understand the functional needs and limitations of each patient to make appropriate judgments regarding the indicators for surgical treatment.[22] By working closely with the rheumatologist; orthopedic surgeon; and physical, occupational, and hand therapists, the hand surgeon will have a better understanding of an overall treatment program and thereby provide the best care possible for these patients.

SURGICAL CONSIDERATIONS IN THE ARTHRITIC PATIENT

The care of a hand affected by rheumatoid arthritis differs in many respects from that of a hand affected by trauma. In a rheumatoid patient, an ongoing process of joint and tendon destruction can persist for many years. Involvement of one joint affects adjacent joints. Involvement of neighboring joints or recurrent disease can nullify the effects of previous surgery. The manifestations of the disease vary for each patient. Cooperation between the rheumatologist and the surgeon is essential to provide appropriate surgical recommendations for each individual.[62,117]

Rheumatoid arthritis is a systemic condition that affects synovial tissue. All deformities, joint destruction, and pathologic anatomy that occur in patients with rheumatoid arthritis are the result of the way in which the diseased and hypertrophied synovial tissue alters its surroundings. Rheumatoid synovium destroys articular cartilage by a poorly understood enzymatic reaction, invades subchondral bone, and stretches the soft tissues that support the involved joint. It also surrounds and invades the flexor and extensor tendons. The result is disruption of the normal architecture of the hand and wrist and loss of the normal delicate balance of flexor and extensor forces across adjacent joints of the hand–wrist unit. Nearly all the surgical procedures performed on the rheumatoid hand and wrist fall into one of five groups: synovectomy, tenosynovectomy, tendon surgery, arthroplasty, and arthrodesis.

Judgment regarding the type and timing of surgical procedures for reconstructing the rheumatoid hand and wrist requires experience. An individual treatment plan must be formulated for each patient based on the status of the hand and the patient's needs, as well as the surgeon's expertise and experience. The presence of deformity is not, in and of itself, an indication for surgery because many patients maintain good function despite significant deformity. We believe that reconstructive rheumatoid hand surgery is not for the physician who occasionally performs hand surgery.[29,119]

Good rapport with the patient is essential because the reconstructive program usually spans many months and often years. The patient's disease pattern affects the surgical approach in rheumatoid reconstruction. In general, synovectomy is indicated for patients with mild disease controlled by drugs who experience persistent synovitis in one or two joints. However, synovectomies are contraindicated in patients with rapidly progressive joint disease. In these patients, frequent observation is required so that reconstructive surgery can be performed before the development of severe deformities. Early tenosynovectomy may be required for patients with progressive disease to prevent tendon rupture. With the advent of antitumor necrosis factor (anti-TNF) therapy, communication between the rheumatologist and hand surgeon is especially important for patients with aggressive disease. Before embarking on surgical treatment, an optimal medical regimen should be established.

Better results are possible when reconstruction is performed before severe fixed contractures occur and before significant subluxation or dislocation develops. After the capsule and supporting ligamentous structures have stretched, the lack of adequate soft tissue support makes maintenance of joint alignment and function more difficult. Caution must be used when considering reconstructive surgery for patients with mild deformities who are basically healthy and active but are frustrated because of general loss of function. They want to pursue their avocations or sports activities but may not have the strength or endurance to do so. Hand surgery cannot restore full function in these patients and may weaken the hand even further; therefore, it is not indicated because it would not produce the desired or expected end result. Such patients need to understand their disease and modify their activities. A hand therapist can be helpful in this situation.

Hand surgery can also lead to disappointing results in patients with significant destruction of multiple joints but who have minimal pain and function relatively well despite their disease. Unless surgery can provide either significant pain relief or a dramatic change in function, the patient's expectations for reconstructive surgery may not be fulfilled. Patients' expectations should match the surgeon's goals and anticipated results. They must know that some deformity, especially at the metacarpophalangeal (MP) joints, is likely to recur after surgery. There is no substitute for in-depth preoperative discussion between the surgeon and patient.[24]

MEDICAL CONSIDERATIONS IN THE RHEUMATOID PATIENT

Certain factors should be considered in rheumatoid patients scheduled for hand surgery. A careful evaluation prior to the scheduled surgery will alert the surgeon to these, and appropriate consultations can be obtained ahead of time if needed.[112]

Cervical spine involvement may be subtle. However, with the increased use of brachial plexus block technique, and options for general anesthesia, which minimize cervical manipulation in rheumatoid patients with limited cervical extension (i.e., laryngeal mask airway, video scope, or fiber-optic scope intubation), formal preoperative evaluation of the cervical spine rarely is necessary unless symptoms are present. If the patient has a history of numbness or paresthesias with cervical motion, imaging studies and neurological consultation should be obtained preoperatively.

Temporomandibular joint involvement may compromise intubation, and the anesthesiologist should be aware of this so that adequate plans can be made for nasotracheal or fiber-optic intubation if necessary. Pulmonary involvement can result from the disease itself (i.e., pulmonary rheumatoid nodules or interstitial fibrosis) or as a consequence of antirheumatic therapy. Felty syndrome (splenomegaly and neutropenia), although rare, can cause a profound decrease in the white blood cell count and thereby increase susceptibility to infection.

Drug therapy must be taken into account when planning surgery.[48] The medications currently used to treat patients with rheumatoid arthritis include nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, naproxen, diclofenac, piroxicam, and etodolac; corticosteroids; nonbiologic disease-modifying antirheumatic drugs (DMARDs), such as methotrexate, leflunomide (Arava), sulfasalazine (Azulfidine), and hydroxychloroquine (Plaquenil); and biologic DMARDs. The latter interferes with the action of tumor necrosis factor (TNF-α), interleukin 1 or 6 (IL-1, IL-6), and T-cell costimulation or depletes B lymphocytes such as infliximab (Remicade), etanercept (Enbrel), adalimumab (Humira), anakinra (Kineret), tocilizumab (Actemra), abatacept (Orencia), and rituximab (Rituxan). Systemic corticosteroids and penicillamine can delay wound healing. Methotrexate can affect liver function, which may affect the choice of anesthesia.

There have been conflicting reports on infection rates in patients taking methotrexate who undergo surgery for rheumatoid arthritis.[18,44,54,115] We have not noticed an increased incidence of infection in patients undergoing reconstructive hand surgery, however, and the recent literature supports continuing the use of methotrexate during the perioperative period.

Some studies have reported twice the infection rate in rheumatoid patients taking biologic DMARDs and undergoing major joint arthroplasty compared to osteoarthritic patients who are not taking these medications. In spite of this, the overall postoperative infection rates remain low, in the 1 to 2% range. Again, we have not had an increase in infection rate in our rheumatoid patients undergoing hand and wrist reconstruction, the majority of who are taking DMARDs.

Detailed discussions and recommendations regarding withholding and restarting various antirheumatoid medications in the perioperative period are available in the literature. While specific recommendations may vary, we have found the following general guidelines for the length of time to withhold various medications preoperatively useful:

- ASA: 5 to 7 days
- NSAIDs: 3 half-lives (varies with each drug)
- Methotrexate and hydroxychloroquine: do not withhold
- Cyclophosphamide, azathioprine, sulfasalazine: several days
- Leflunomide (Arava): 2 weeks
- Biologic DMARDs: two treatment cycles

However, it is important to consult with the patient's rheumatologist before making a final decision. Postoperatively, we take the precaution of withholding biologic DMARDs until wound healing is complete (2–3 weeks) and all temporary pins placed during surgery have been removed.

STAGING HAND SURGERY

One of the difficult tasks in rheumatoid surgery is formulation of a plan for systematic reconstruction of the hand. Although there are no hard-and-fast rules, some general principles can be outlined. The priorities for hand surgery in rheumatoid patients are to (1) alleviate pain, (2) improve function, (3) retard progression of the disease and/or prevent loss of function, and (4) improve appearance. Appropriate decisions are made more easily if each of these priorities is considered for each patient. Relief of pain is the foremost goal. The indications for surgery to relieve pain are clear and predictable; fusions and arthroplasties accomplish this goal.

Pain may be the most important factor in determining a rheumatoid patient's ability to work. Many with severe deformities can work because they are able to adapt to their functional limitations. In contrast, patients with much less deformity but with significant pain are less able to continue gainful

employment. A painful wrist or thumb usually takes precedence over dislocated MP joints of the fingers. Acute carpal tunnel syndrome or proliferative dorsal tenosynovitis with a single-tendon rupture is allocated high priority to prevent permanent loss of median nerve function or more tendon ruptures.

Loss of function is not synonymous with deformity, and careful evaluation and discussion are needed before any surgery to improve function is undertaken. Patients with adequate function, despite deformity, may not benefit from surgery. Carpal tunnel syndrome can be aggravated by any surgical procedure in the hand. Therefore, carpal tunnel release should be considered before or in conjunction with other surgical procedures on the volar aspect of the wrist.

Each joint must be evaluated both individually (Table 55.1) and as part of the whole hand. We usually correct MP joint deformities before treating proximal interphalangeal (PIP) joint ones.[86,95] An exception to this approach is a severe boutonnière deformity, which should be corrected before or at the same time as the MP joint because a severe flexion deformity at the PIP joint compromises the result of the MP joint surgery. Conversely, an extension deformity of the PIP joint concentrates flexion at the MP joint and enhances MP motion. Therefore, extension deformities at the PIP joint can be corrected at a later time.

PIP joint deformity is often the result of a primary MP joint deformity. Treating the MP joints first may simplify treatment of the PIP joints. Just restoring MP joint alignment and motion can provide significant improvement in hand function, even with imperfect PIP joint function. The converse is not necessarily true; reasonable PIP joint motion does little to improve hand function if the MP joints remain fixed in flexion (Figure 55.1).[77]

If extensor tendon reconstruction is required in addition to MP joint surgery, we reconstruct the MP joints before the extensor tendons are treated. This facilitates postoperative rehabilitation because MP extension can be provided with a dynamic splint. Extensor tendon reconstruction can be done at a second stage without compromising the previous MP joint surgery.

Most patients have bilateral hand problems that require surgical treatment. We encourage the patient to help us decide on which hand to operate first. During the rehabilitation period, the nonoperated hand must perform additional work, and this can induce a flare of synovitis. It may be prudent to operate on the less-involved hand first, especially with an apprehensive patient. This approach can prevent progressive deformity, provide a better overall result, and allow the patient to assess the potential benefits of further reconstruction.

We prefer to perform preventive surgery, such as synovectomy, dorsal tenosynovectomy, and even median nerve decompression, before considering reconstructive surgery. It is best to begin a reconstructive program with surgical procedures that are predictable in their outcome and effect and to progress in stages to procedures that are less predictable. Thus, procedures such as thumb MP joint fusion, distal interphalangeal (DIP) fusion in the fingers, and wrist fusion can be performed first, followed by distal ulnar excision and MP joint arthroplasty.

The effect of proximal joint function on the wrist and hand must be considered in preoperative planning. Shoulder or elbow reconstruction (or both), if indicated, should be done before hand reconstruction so that rehabilitation of the hand after surgery is not impeded by more proximal problems. The proximal and distal joints must be evaluated before any surgery because they can affect the type of surgery to be performed. If elbow flexion is limited, for example, the ability of the hand to get to the mouth may be compromised if the wrist is corrected into a more extended position. Therefore, the wrist should be fused in a neutral or slightly flexed position, or elbow flexion should be increased.

Occasionally, it is necessary to consider hand deformities and upper extremity limitations in view of the patient's lower extremity problems. If a painful or deformed hand prevents the use of ambulatory aids, such as crutches or walkers, it may be necessary to perform upper extremity surgery before lower extremity surgery. In general, patients with a rheumatoid wrist problem require fusion to allow the use of ambulatory aids.

TABLE 55.1 Stages of Rheumatoid Joint Involvement

Stage	Description
1	Synovitis without deformity
2	Synovitis with a passively correctable deformity
3	Fixed deformity without joint changes
4	Articular destruction

OTHER CONNECTIVE TISSUE DISEASES (RHEUMATOID VARIANTS)

Psoriatic arthritis, systemic lupus erythematosus (SLE), and scleroderma are three uncommon arthritic diseases that superficially resemble rheumatoid arthritis, but they are different and may require an unusual surgical approach. These diseases frequently involve the hand and wrist and thus are significant to the hand surgeon. Each of these diseases has distinct features affecting the types of deformities seen and the treatments needed to adequately care for the patients. The specifics of the surgical techniques are discussed in the corresponding section on rheumatoid arthritis.

Psoriatic Arthritis

Psoriatic arthritis is a rheumatoid variant that is classified as one of the seronegative spondyloarthropathies, along with Reiter's syndrome, ankylosing spondylitis, and the arthritis of inflammatory bowel disease. The classic finding in psoriasis is a scaly, erythematous rash. Approximately 5% of patients with psoriasis have some type of inflammatory arthritis. The skin lesions precede the arthritis-associated changes in most cases, but in 15 to 20% of patients the skin lesions develop after the onset of arthritis. This rash may be extensive or localized to small patches on the scalp, face, or extremities. Direct skin involvement can occur on the hand and complicates surgical treatment because of the enhanced risk for infection.

Staphylococcus aureus has been cultured from psoriatic skin. The psoriatic rash improves with ultraviolet light, which is one of the main treatments of this condition. Because the skin condition often improves during the summer, this factor should be taken into account when scheduling elective surgery on a hand with a significant psoriatic rash.[7] The diagnosis of psoriasis can

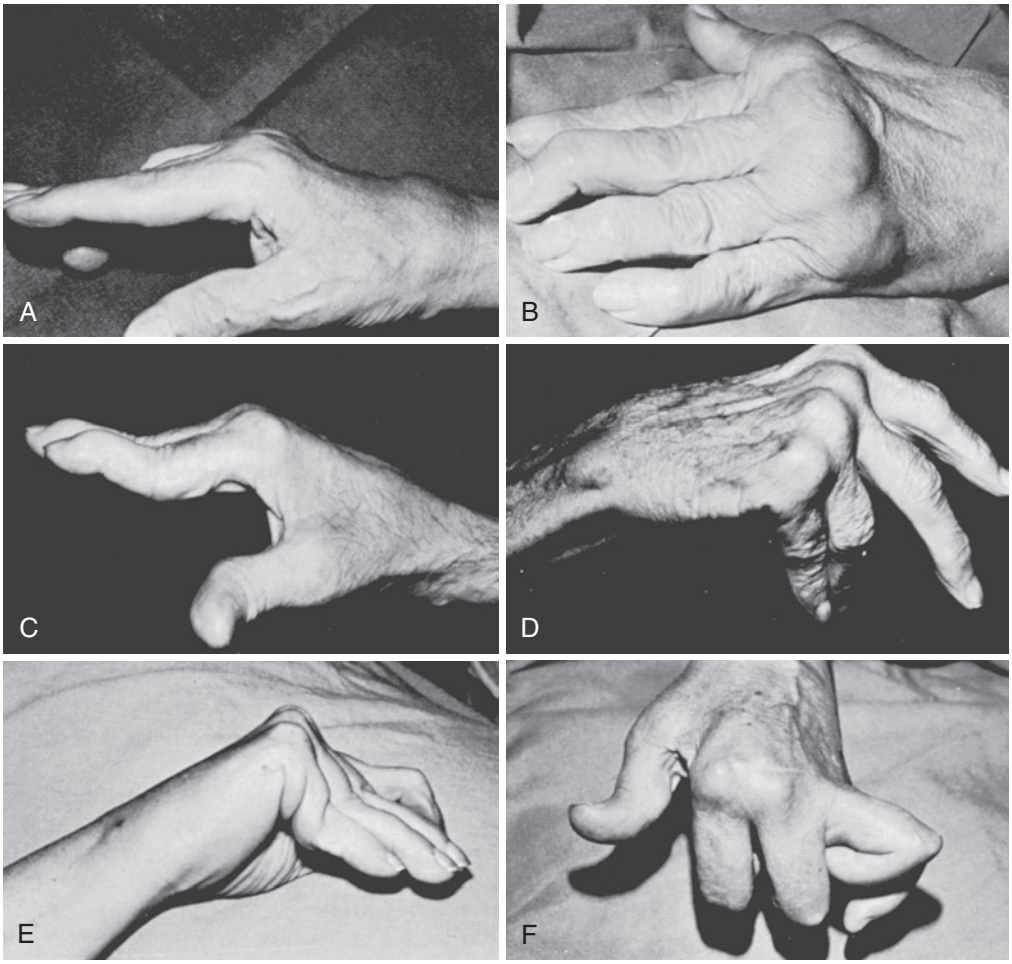

FIGURE 55.1 Examples of stages of rheumatoid hand deformities. **A,** Stage 1: early metacarpophalangeal (MP) joint synovitis without deformity. Note the early dorsal tenosynovitis. **B,** Stage 2: moderate MP joint synovitis without dislocation of the MP joints and without marked bone destruction. **C,** Stage 2: early MP joint subluxation with a swan neck deformity. Both these deformities are correctable passively, and there is no cartilage or bone destruction. The patient is a candidate for intrinsic release, synovectomy, and extensor tendon relocation. **D,** Stage 3: classic example of MP joint dislocation without proximal interphalangeal (PIP) joint involvement. Note the absence of wrist joint subluxation and minimal subluxation of the distal end of the ulna. Extensor tendon function is intact. **E,** Stage 3: fixed dislocation of the MP joints with a secondary swan neck deformity. Note the mallet deformity of the distal interphalangeal joint in the index finger. **F,** Stage 4: severe hand deformity with fixed dislocation of the MP joints and fixed-flexion contractures of the PIP joints. The patient had previously undergone synovectomy. Salvage surgery includes PIP joint arthrodeses and MP joint arthroplasties. (From Millender LH, Nalebuff EA: Evaluation and treatment of early rheumatoid hand involvement. *Orthop Clin North Am* 6:697–708, 1975, with permission.)

also be made by characteristic changes in the nails. It has been stated that 80% of patients with psoriasis have nail changes, but this finding is present in just 15% of those with arthritic involvement. Psoriasis of the nails alone without overt evidence of cutaneous disease is infrequent. The most common nail finding is pitting, which represents involvement of the proximal matrix. Other nail findings include leukonychia and crumbling nails.

The pattern of joint involvement in psoriatic arthritis varies widely: 95% of such patients have peripheral joint involvement; 25% have a polyarthritis similar to rheumatoid arthritis; and 5% have classic DIP joint disease with erosion of the terminal phalanges, DIP joint destruction, nail pitting, and onycholysis. Osteolysis is common, with destruction of bone and ultimate widening of the joint spaces. Bone proliferates along the margins of the bone on the distal side of the joint. The proximal bone tapers and, when associated with distal bone changes, leads to a "pencil-in-cup" appearance.

Osteolysis most commonly affects the DIP joints but can involve all the finger joints and result in digital shortening. In its full-blown stage, these patients have arthritis mutilans. Because of collapse of the digits, the condition has been called "opera-glass hand."[91] Collapse of the fingers can also occur in rheumatoid patients but is more frequently seen in those with psoriatic arthritis. Although osteolysis is the most frequent radiographic finding in a psoriatic hand, spontaneous ankylosis can also occur. In digits with spontaneous or surgical fusion, digital length is maintained.[91] It is common for the distal joints to fuse spontaneously, but this can also occur at the PIP level. Most patients with hand involvement have combinations of osteolytic and fused joints. In our experience, ankylosis of the digital MP joints does not occur. Inflammation of the periosteum, tendons, and tendon insertions may be a factor in the fusiform swelling of digits in this disease—the so-called sausage swelling or psoriatic dactylitis with significant soft tissue

swelling around the joints. Radiographs readily show the periarticular soft tissue enlargement that explains the clinical appearance. Fusiform swelling of the digits is best treated by medical means.

Psoriatic arthritis causes hand deformities similar to those seen in rheumatoid arthritis, with several typical differences, including psoriatic skin lesions. There is a much lower incidence of tenosynovitis and tendon rupture than noted for rheumatoid arthritis.[132] Therefore, tenosynovectomy and other tendon surgery are uncommon in patients with psoriatic arthritis. The subcutaneous nodules associated with rheumatoid arthritis are not found in this condition. Unlike rheumatoid disease, which tends to be symmetric, patients with psoriatic arthritis usually have asymmetric involvement of the hands. This asymmetry is also present within the hand, with apparently unaffected digits adjacent to involved fingers that are short or demonstrate significant deformity.

Although individual patients can have both osteolysis and ankylosis, one of these characteristics is usually more prominent than the other, thus making it possible to categorize patients into various groups, which helps determine treatment choices. We now use a modification of the Moll and Wright classification, which is based directly on the radiographic and clinical changes seen in these hands. In psoriatic arthritis there can be (1) spontaneous fusions that maintain digital length, (2) osteolysis with bone loss, or (3) joint stiffness with rheumatoid arthritis–like deformities. It is important to stress that the degree of bone loss can vary from mild to extensive. Spontaneous ankylosis can also involve single or multiple joints.[7,90]

Digital Deformity

The most common deformities seen in a psoriatic hand are flexion deformities of the PIP joints without the corresponding distal joint hyperextension characteristic of the boutonnière deformity.[106,132] As a consequence of the flexed PIP joint, the MP joints are often hyperextended and ultimately become stiff. Severe fixed-flexion deformities are best treated by fusion rather than arthroplasty. Swan neck deformities, which are common in rheumatoid arthritis, occur occasionally in psoriatic arthritis but often result from a distal joint mallet deformity rather than originating at the PIP level.

In contrast to rheumatoid arthritis, patients with psoriatic arthritis tend to have MP joint extension contractures rather than flexion contractures. Postoperative motion after MP arthroplasty may be limited in comparison to that usually obtained for rheumatoid patients. If arthroplasties are performed, more bone should be resected to allow adequate space for the implant. Experience with MP arthroplasties has found that the risk for infection is higher in this group.[74] Fixed-flexion deformities of the MP joints appear in patients with stiff or extended PIP joints. These patients have difficulty grasping large objects because of the limited MP extension frequently associated with a contracted thumb web space.

The DIP joints are involved frequently but rarely need treatment because they tend to fuse spontaneously. Arthritis mutilans, which results in severe loss of bone stock with collapse and shortening of the digit, is not uncommon and must be treated early and aggressively by joint fusions and bone grafting to restore digital length (Figure 55.2).[106]

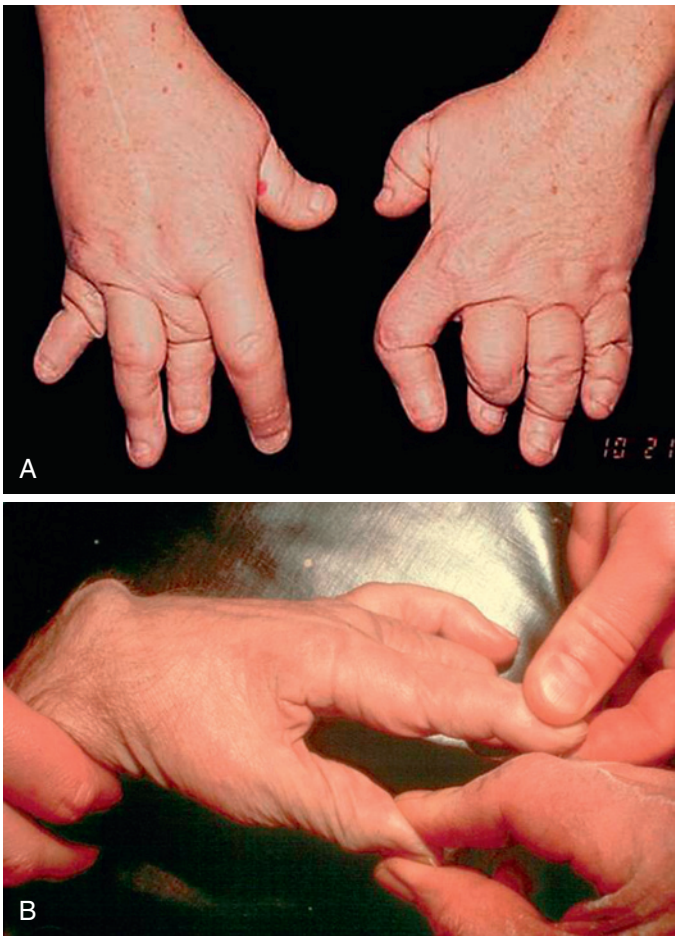

FIGURE 55.2 **A,** Arthritis mutilans with typical "opera-glass" hand deformities. **B,** Traction on the collapsed digits restores the soft tissue envelope to length. This allows restoration of pinch function by fusion of the affected joints using bone graft.

Thumb Deformity

Each of the three thumb joints can be involved in psoriatic arthritis. As noted for rheumatoid arthritis, the most common deformity includes MP joint flexion and interphalangeal (IP) joint hyperextension. Hyperextension deformities of the MP joint are rare in this group. Stiffness at the carpometacarpal (CMC) joint level does develop in these patients and greatly reduces thumb function. Surgical procedures should include MP or IP fusion, or fusion of both joints. It is advisable to pronate the thumb as part of the fusion to improve thumb–index finger pinch. At the basal joint, to restore or maintain thumb motion, we prefer resection arthroplasty with ligament suspension,[13] as used for osteoarthritis.[90]

Wrist Deformity

Wrist involvement is common in psoriatic arthritis.[132] Presently, we limit wrist surgery in patients with psoriatic arthritis to fusion and excision of the distal ulna.[92] The techniques are the same as those used for rheumatoid arthritis. Spontaneous intercarpal fusion can alleviate the need for additional wrist surgery if the alignment is good and motion is not painful. We do not recommend wrist arthroplasty for patients with psoriatic arthritis.

Systemic Lupus Erythematosus

SLE is a multisystem disease with frequent joint and hand involvement. It can involve many major organs of the body such as the heart, lungs, and kidneys.[107] Pericarditis is the most common heart problem, and pleuritis affects pulmonary function. It has been reported that 50% of lupus patients have clinical manifestations of renal disease. Skin lesions occur in 85% of them, with a typical erythematous blush in the butterfly area on the cheeks and across the bridge of the nose often being noted after sun exposure. Another common rash is an erythematous maculopapular eruption on the fingers and palm that also can occur after sun exposure.[107]

Systemic lupus erythematosus is frequently diagnosed initially as rheumatoid arthritis or "nonspecific" arthritis.[107] In children, the most common initial diagnosis is rheumatic fever. At present, the generally accepted means of diagnosing SLE is based on the American Rheumatism Association's preliminary criteria. A patient needs to have 4 of 14 criteria, either simultaneously or serially, to make the diagnosis of SLE. Some of them are LE cells, arthritis, Raynaud's disease, facial erythema, pleuritis, pericarditis, and uremia.[107]

Lupus patients are predominantly young women, with a female-to-male ratio of 9:1.[107] This condition is more common in black women than in white women, with an average age at onset of between 15 and 25 years.[107] Hand involvement can include symmetric joint swelling, tenderness, pain with motion, and morning stiffness. Raynaud's disease is common. Joint deformities are the most predominant hand manifestation of SLE. Although the deformities can appear similar to those seen in rheumatoid arthritis, ligamentous and volar plate laxity, as well as tendon subluxation leading to joint imbalance, are the hallmarks of this disease rather than joint destruction.[30]

The joint deformities occur without the erosive destruction of the articular cartilage seen in other forms of arthritis. The wrist, digits, and thumb are the most frequent sites of involvement, and the ankles, elbows, and shoulders are least often affected.[30] The deformities occur without the erosive destruction of the articular cartilage seen in other forms of arthritis. Radiographs show deformity, but with normal-appearing joint spaces (Figure 55.3). Tenosynovitis can occur and may be present without joint involvement.

Patients with SLE are best managed by a team approach. They may have serious medical problems that take priority over hand and wrist deformities. A rheumatologist or internist should carry out the medical treatment of this condition. Patients without major organ involvement are usually treated symptomatically with NSAIDs.[107] In more serious cases, corticosteroids are indicated. With regard to specific wrist and hand involvement, a cooperative effort between a hand therapist and surgeon is ideal.

The initial treatment of passively correctable deformities, which are the hallmark of SLE, is best handled by exercises and splinting. We do not believe that the common deformities of SLE will be permanently corrected by these methods, but it is possible to maintain function for an extended period, thereby delaying surgery. Patients can be taught to stretch tight ulnar intrinsics caused by digital ulnar deviation at the MP joint level. Wrist splints are helpful to maintain wrist alignment. Resting splints at night are useful to keep the fingers in proper alignment at the MP joint level. For passively correctable swan neck deformities of the fingers, patients can wear Silver Ring or Oval-8® splints, which resemble jewelry and are well accepted by patients. Commercially available LMB Wire-Foam™ and Soft-Core Foam™ splints are useful for early boutonnière deformities. The risk of "conservative" nonoperative treatment may be progression to fixed deformities that alter the treatment options for the surgeon. Therefore, the surgeon's role is to determine when it is appropriate to modify the course of the disease by surgical intervention.

FIGURE 55.3 Lupus causes deformities similar to those seen in rheumatoid arthritis but without joint destruction. Note the ulnar deviation and volar subluxation of the metacarpophalangeal joints, the secondary radial deviation of the metacarpals, and the scapholunate dissociation in the absence of joint space narrowing, periarticular erosions, and cyst formation.

Wrist Deformity

Deformities can often be corrected passively, but attempts to reconstruct the deformities by soft tissue procedures are associated with a frustratingly high recurrence rate. Thus, arthroplasties or fusions, or both, may be necessary, even though the joints have been preserved and look uninvolved on radiographs. Surgery in lupus patients should be performed before fixed deformities occur. With regard to the wrist, the most useful surgical procedures are limited to total wrist fusions. For complete wrist dislocations, total wrist fusion is the procedure of choice.[92] For ulnar translocation of the carpus, wrist realignment should be performed along with either radiolunate or radiocarpal fusion to maintain midcarpal motion.[92] In our opinion there is no place for arthroplasty in the lupus wrist. Total wrist replacement is not advisable because stability and soft tissue balance are so critical to success. The lax ligaments characteristic of lupus do not provide the essential support to

prevent recurrent deformity. Realignment of the wrist reduces the risk for secondary finger deformities. However, most of the deformities at the MP joint level are primary as a result of soft tissue changes at the local level.

A common wrist problem is carpal supination, which results in prominence of the distal end of the ulna. In addition to being unsightly, causing pain, and restricting wrist rotation, it can cause attrition extensor tendon ruptures.[30,89] Dorsal wrist tenosynovitis is uncommon in SLE. When tendon ruptures do occur, they are generally the result of attrition. A Darrach procedure is useful in lupus. Stabilization of the remaining ulna with a portion of the extensor carpi ulnaris (ECU) tendon or the ulnar carpal ligaments should be performed to prevent dorsal migration.[64] It is important to bevel the dorsal lip of the resected ulna to minimize subsequent attrition tendon ruptures over a sharp bone edge.

Digital Deformity

The characteristic finger deformity at the MP joint is ulnar deviation and volar subluxation.[30,89] The patients demonstrate excellent finger flexion with loss of active extension while maintaining passive extension. With time, they gradually lose passive extension. The sequence of pathologic findings is as follows: subluxation of the extensor tendon ulnar to the metacarpal head occurs and, as this support is diminished, the proximal phalanx subluxes volarly. The joint capsule becomes thinned, and a defect in the dorsal capsule occurs. With increasing ulnar deviation, the ulnar intrinsic muscle shortens, with subsequent hyperextension deformity at the PIP level. At first, the deformity is passively correctable, but gradually this mobility is lost. Despite the MP deformity becoming fixed, the articular cartilage is preserved.

In a previous review of this subject, we noted that soft tissue realignment of the extensor tendons did not maintain correction in 21 of 30 digits.[30,89] In each of these fingers, the deformity recurred and often became fixed. Swanson arthroplasties were performed either for fixed-MP joint deformities or for digits in which soft tissue correction had failed. We concluded that arthroplasty with a silicone implant was indicated even though the metacarpal head was intact, with normal-appearing articular cartilage.[30,89] Zancolli reported success in maintaining MP joint alignment in patients with rheumatoid arthritis by attaching the extensor tendon to the proximal phalanx, which minimized recurrent tendon subluxation.[141] Wood and associates, using the same technique, corrected recurrent extensor tendon subluxation in a large group of patients that included two with SLE.[140]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

We have attempted to restore MP alignment and function by soft tissue surgery, including extensor tendon relocation and tenodesis. In patients with full passive correction, we approach the joint dorsally. A central defect in the joint capsule is repaired, and the extensor tendon is relocated to the dorsum of the joint directly on the bone, as described by Wood and associates.[140] As part of the soft tissue rebalancing, the contracted ulnar sagittal fibers are released and the radial sagittal fibers are reefed in an attempt to rebalance support of the extensor tendon directly over the joint. The aim is to restore full MP extension when direct traction is applied to the extensor tendon.

Although the ulnar intrinsic was released completely in many patients, there have been complications later. In a few fingers, we noted late radial deviation with tightness of the radial intrinsic. For this reason, we now believe that complete ulnar intrinsic release is not without risk and prefer, instead, to step-cut and lengthen the ulnar intrinsic. We believe that the intrinsic transfers that are useful in correcting severe ulnar deviation in rheumatoid arthritis are particularly dangerous in SLE. All the soft tissue surgery that we perform is designed to restore alignment and balance to the joint. It may be foolhardy to think that restoration of local anatomy can withstand the tissue changes in SLE. We believe, however, that the deformities can be corrected and the need for joint replacement thereby delayed or avoided. These same soft tissue repairs are indicated for patients with fixed-MP joint deformities requiring prosthetic replacement.

Prolonged postoperative splinting is required after MP surgery regardless of whether implants are used. The joints are held in good alignment for 6 weeks before motion is initiated. Once MP motion is begun, the fingers are splinted together as a unit to maintain alignment and concentrate flexion at the MP level. Dynamic splinting is also used to support extension and maintain digital alignment during the early healing stage.

Occasionally, we have treated SLE patients who also demonstrate excessive finger MP joint hyperextension. In this situation, the "lasso procedure" described by Zancolli for ulnar nerve palsy[141] is combined with dorsal soft tissue balancing. In this procedure, the sublimis tendon is detached from its insertion and passed around the A1 pulley to restrain MP joint hyperextension.

Proximal Interphalangeal Joint Deformity

Finger IP joints can have hyperextension, flexion, or lateral deformities that occur as a result of stretching of the supporting tendons, collateral ligaments, and volar plate mechanism. With mild and early deformities, the soft tissue procedures useful for rheumatoid arthritis can be carried out. Unfortunately, these deformities frequently become severe and fixed, thus making arthrodesis the treatment of choice. Restoration of IP alignment, even by fusion, is essential if the MP joint corrections are to be maintained long term.

Thumb Deformity

The thumb is commonly involved in SLE. It is often the first place where hand deformities occur.[30,89] A frequent primary manifestation is lateral subluxation of the distal joint. However, the distal joint deformity can be a secondary response to primary deformity at the MP level. With MP joint hyperextension, the distal joint rapidly assumes a flexed position, whereas the reverse occurs with MP flexion deformities.[85] The treatment of choice is surgical fusion, which restores thumb stability and function. In addition, correction of the IP joint deformity decreases the chance of reciprocal deformity at the more proximal MP joint.[85]

The thumb MP joint can also be the primary site of deformity. Subluxation of the extensor tendons is common in SLE, and the thumb is no exception. As extensor pollicis longus (EPL) support diminishes, the MP joint assumes a flexed position.[85] Lateral instability can also occur in long-standing cases as a result of laxity of the collateral ligaments. Initially, passive

correction is possible, but later the deformity becomes fixed. As a response to the severe flexion, the metacarpal assumes an abducted position and the distal joint hyperextends, thereby producing the typical type I thumb deformity.[85]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

If passive MP joint extension is possible, there are two surgical approaches that we have found useful: EPL rerouting[85] and MP joint arthrodesis. EPL rerouting is preferred if the thumb IP joint requires fusion to provide stability. This procedure restores active MP extension while maintaining mobility, thereby relieving some strain on the CMC joint. However, certain modifications are in order, including reefing the collateral ligaments for lateral support and postoperative splinting for 6 weeks. Temporary Kirschner wire fixation is important to maintain the corrected position. Joints in SLE patients ordinarily do not get stiff after immobilization. The typical range of postoperative flexion is about 40 degrees and is usually achieved even with 6 weeks of immobilization.

When the flexed MP joint cannot be passively corrected or is hyperextended or if the CMC and IP joints are good, arthrodesis is the procedure of choice. The joint should be fixed in 15 to 20 degrees of flexion. Arthroplasty of the MP joint with a flexible implant might be considered, but experience with this approach in SLE patients has not been as successful as in those with rheumatoid arthritis. SLE patients tend to regain excessive motion and fracture the prosthesis, with recurrent deformity. If both the MP and IP joints are fused, it is imperative that motion at the thumb CMC joint be maintained.

Primary subluxation or dislocation of the thumb CMC joint also occurs in lupus. If the MP and IP joints are well aligned and stable, fusion of the CMC joint can be performed to provide general improvement in thumb alignment and function.[30,89] It is important to stabilize the CMC joint with the metacarpal in a slightly abducted position. However, excessive metacarpal abduction must be avoided because it may lead to excessive MP joint flexion and dislocation, with a further reduction in thumb function. A prosthetic replacement is not indicated.

An alternative to CMC fusion is soft tissue stabilization, which is essential if the MP and IP joints are fused. Realignment of the metacarpal with the flexor carpi radialis (FCR) tendon is effective in maintaining stability with[10] or without[31] resection arthroplasty. Temporary Kirschner wire fixation can be used.

Scleroderma

Scleroderma (systemic sclerosis) is a generalized disease with involvement of the skin, gastrointestinal tract, kidneys, lungs, heart, and often the hands. It is more frequent in females than males. Although the etiology of this condition is unknown, it is thought to be a disorder of small blood vessels and connective tissues that leads to fibrosis. Fibrosis of the skin affects primarily the face and hands; it alters the patient's appearance and leads to severe finger deformities and subsequent loss of hand function. The facial involvement contracts the skin around the mouth, thereby reducing the patient's ability to open the mouth. Scleroderma patients tend to look alike.

A common early manifestation is Raynaud's phenomenon, with intermittent vasospasm and reduced digital circulation. During these episodes, the fingers become white, then turn blue and finally reddish. The reduced digital circulation can lead to skin ulcers, gangrene of the fingertips, and ultimately digital amputations. The acronym CREST has been used to describe the common features of systemic sclerosis: calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia. The term *overlap syndrome* is used for scleroderma patients with associated findings characteristic of lupus, dermatomyositis, or rheumatoid arthritis.

There are two forms of systemic sclerosis: (1) a type with limited and localized skin involvement and (2) a more common diffuse type. Patients with the diffuse type more frequently exhibit finger joint contractures and digital deformities. Subcutaneous or intracutaneous calcinosis can occur within a single digit and cause painful hard areas at the fingertip, or it may be widespread within the hand and arm. The skin can break down over these areas and discharge a white toothpaste-like or chalky material. The term *sclerodactyly* is used to describe the appearance of the fingers, which become slender with thin, shiny, and sclerotic skin.

Digital Deformity

The deformity patterns seen in scleroderma are diverse, but certain combinations are common. The most frequent deformity is the progressive development of PIP flexion contractures (Figure 55.4). The patients gradually lose the ability to actively extend the PIP joints, and then flexion contractures develop and become severe and fixed. The extensor mechanism over the joints thins and ultimately ruptures. The skin blanches and eventually breaks down, thereby exposing the underlying tendon or the open joint. The danger of joint infection or osteomyelitis is real. Therefore, keeping areas of skin breakdown clean before surgical correction is critical. As increasing flexion of the PIP joint develops, patients compensate by hyperextension at the MP joint level. Initially, the MP joints maintain active flexion, but over time, the collateral ligaments, joint capsule, and overlying skin contract and severely limit MP joint flexion.

The development of PIP joint hyperextension is also encountered in scleroderma but is infrequent. This deformity is secondary to the development of MP joint subluxation in flexion, similar to patients with rheumatoid arthritis. The prominent metacarpal head can erode the overlying skin. The skin and muscles of the first web space often shorten, and a contracture

FIGURE 55.4 Scleroderma typically causes severe proximal interphalangeal joint contractures that result in compensatory hyperextension of the metacarpophalangeal joints.

develops. This reduces thumb mobility and diminishes the ability to grasp large objects between the thumb and index finger.

Surgery on a scleroderma patient's hand is usually performed to improve function and relieve pain. It is unlikely that splinting and exercises can stop progression of the deformity. Scleroderma poses distinct problems for the hand surgeon. The deformities encountered are similar to those seen in rheumatoid arthritis; however, the altered circulation and skin changes associated with this disease adversely affect surgical options and treatment. Wound healing is compromised, and surgical exposure is limited because of the tight skin and poor circulation, thus complicating the surgery options.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

Increasing deformity with loss of function, the development of skin breakdown, and extrusion of calcific material are frequent indications for surgical consultation. The most common indications for surgery are vascular insufficiency with digital ulceration, calcinosis, and finger and thumb deformities.

Ulceration

Ulceration at the tips of fingers is the result of poor circulation and may be extremely painful. The ulceration is often slow to heal. Skin breakdown at the PIP or MP level results from a combination of decreased circulation and pressure from underlying bone prominence secondary to the joint deformity. Such open wounds can progress to deep infection, but with splinting and good wound care they often heal. They require frequent dressing changes, occasional debridement, and protective splinting. Range-of-motion exercises should be curtailed to protect the underlying joint because the risk for joint sepsis or osteomyelitis is real.

At the fingertips, the underlying phalangeal tufts can be resorbed, and if gangrene ultimately develops, autoamputation can occur or surgical amputation will be needed. These ulcerations are best treated with local topical antibiotics such as silver sulfadiazine. Wound cultures usually reveal *S. aureus*, and appropriate antibiotics are used if an infection is present. Resection of a bony prominence or joint fusion may be the only way to heal open wounds over the MP or PIP joints. With patience, however, many open areas heal spontaneously and therefore should be treated conservatively initially.

Calcinosis

Calcinosis can be intracutaneous or subcutaneous. According to Jones and associates, its frequency is 15% in the diffuse type of scleroderma and 44% in the limited cutaneous variety.[57] Calcium deposits can occur within a single digit or be widespread throughout the hand. They cause symptoms when close to the surface and result in local skin breakdown. The deposits are quite firm and produce tender areas in finger pulp that interfere with the patient's ability to pick up objects. They can spontaneously extrude calcific material, which can be removed surgically from the distal pulp. In areas with digital nerves in close proximity, only limited removal is carried out. Usually, a curet is used rather than a scalpel. This is a particularly common approach in the thumb.

Irrigation with saline solution is also used to safely remove as much material as possible. Occasionally, after removing the calcium deposits the fingertips are left open to allow spontaneous healing rather than placing sutures through compromised skin. In most cases, partial removal or debulking may be enough to relieve the patient's symptoms.[57] Isolated calcific masses in the forearm can be surgically excised without any risk for circulatory or nerve problems.

Deformity of Digital Joints

Surgery at the DIP joints usually consists of either amputation or fusion. Amputation may be required if gangrene, osteomyelitis of the distal phalanx, or a septic DIP joint develops. Such surgery is best done under regional anesthesia with release of the tourniquet before closure to check for adequate circulation. The skin flaps are closed loosely to avoid any compromise of the skin. However, any surgery at the distal level is risky as a result of diminished circulation. Therefore, the surgeon must proceed cautiously because of the possibility of postoperative gangrene and subsequent amputation.

The Proximal Interphalangeal Joint

At the PIP joint level, the most common deformity is fixed flexion. Skin blanching or breakdown is frequently present, along with exposure of the extensor mechanism. In late cases, there may be complete sloughing of the extensor mechanism and exposure of the PIP joint. Hand function decreases as the fixed-flexion deformity increases. To improve grasp, patients compensate with MP joint hyperextension, which itself becomes fixed unless an attempt is made to maintain motion. The circulation at the PIP level is better than in the distal part of the finger. Thus, it is possible to operate with less risk at the PIP joint, even with infected or exposed joints.

In our opinion, fusion is the procedure of choice for the common fixed-PIP joint flexion contracture. The bone resection as part of the fusion procedure, combined with skin resection, makes it possible to achieve primary healing. The overall functional result of a PIP joint fusion is determined in large part by the range of motion of the MP joints. With good MP function, the PIP joints can be fused in less flexion. If MP motion is reduced, it should be regained surgically by either capsulotomy or arthroplasty before proceeding with PIP joint fusion. With severe flexion contractures, there may be an intraoperative circulatory problem as the digit is straightened. In this situation, it may be necessary to either accept less correction than usual[57] or perform digital sympathectomy to improve the circulation and preserve the correction. Sympathectomy is not usually performed at the same time.

Some surgeons have reported using Swanson flexible implant arthroplasties at the PIP joint level. However, the ultimate gain in motion in reported cases has been small.[98] In addition, the amount of bone resection required for insertion of the implant can lead to considerable digital shortening. This approach is not recommended.

The Metacarpophalangeal Joint

At the MP level, the circulation approaches normal levels. The area is warm to palpation, and therefore the surgeon has the ability to carry out more extensive surgery with normal wound healing. However, tight skin poses a significant problem when one tries to achieve additional flexion. Although it is possible to insert flexible prosthetic implants at this level, the risks are

increased over resection arthroplasty, which can also restore satisfactory motion. With shortened dorsal skin and fixed MP hyperextension, however, the situation changes. When faced with this dilemma, the surgeon can safely approach the metacarpal heads using a palmar approach and carry out wide resection of the metacarpal heads to restore flexion.

For patients with fixed-MP hyperextension and severe fixed-flexion of the PIP joints, it is imperative that the PIP flexion contractures be corrected by fusion before restoring MP flexion by resecting the metacarpal heads through a volar incision. We have noted considerable remodeling of the metacarpal heads after resection, which makes this technique a viable alternative to implant surgery for some patients. In patients with MP flexion deformities, a standard dorsal approach is used.

First Web Contracture

Another area treated surgically in patients with scleroderma is a tight first web space between the thumb and index finger. Opening the space and releasing the tight deeper structure may require release of the adductor attachment to the thumb and the addition of a skin graft. Selected fusion of the IP or MP joint of the thumb is also helpful when thumb deformities reduce the ability to achieve adequate thumb–index finger pinch. In some patients, resection of the trapezium may be required to restore thumb metacarpal abduction.

Vascular Insufficiency

Surgical approaches to improve digital circulation have focused on attempts to decrease the sympathetic innervation of the digital vessels. Several authors, including Flatt,[39] have described various techniques to strip the adventitia of the common digital arteries in the palm. Each of the techniques has resulted in temporary improvement in digital blood flow, with increases in skin temperature and improvement in the healing of fingertip ulcers. Jones and coworkers investigated digital circulation in scleroderma patients by several methods, including digital plethysmography, cold stress testing, and intraarterial digital subtraction angiography.[58] Cold stress testing involves measurement of digital temperature, pulse volume readings, or laser Doppler flow values of the digits before and during exposure of the hands to a cold environment and during subsequent rewarming.

At surgery, the entire superficial palmar arch is inspected to look for segmental occlusions and determine the need for interposition vein grafts. The surgeon also inspects for constrictive fibrous tissue around the small vessels that can be excised. Jones and colleagues call this surgical approach "decompressive arteriolysis." Unfortunately, patients undergoing these various techniques often continue to have pain, and recurrent ulceration develops within 2 years. However, it is an exciting new approach to the management of diminished distal circulation in patients. For further information, please see Chapter 60.

RHEUMATOID NODULOSIS

Subcutaneous nodules are common in patients with rheumatoid arthritis and are seen occasionally in those with SLE. These nodules occur frequently in the olecranon areas (Figure 55.5) and on the extensor surfaces of the forearms. They can be tender and a source of discomfort to the patient if they are large. The nodules can develop on the dorsal aspect of the hand (see Figure 55.5, *A*), where they are unsightly, or on the palmar surface of the digits, where they may interfere with hand function because of pressure sensitivity or compression of digital nerves. They can cause erosion of the overlying skin and can form a draining sinus from necrosis of the central core of the nodule. Nodules that form in subcutaneous areas on the volar surface of the digits can interfere with function because pressure during grip or pinch causes discomfort.

Symptomatic nodules can be resected. Meticulous hemostasis should be obtained, particularly in the region of the olecranon. The use of a drain (brought through normal skin) usually prevents or minimizes the postoperative formation of hematoma or seroma. On the palmar surface of the digits, care must be taken to protect underlying structures, particularly the neurovascular bundles, and to maintain sufficient skin to allow primary closure. If the wound cannot be closed, skin grafts should be used.

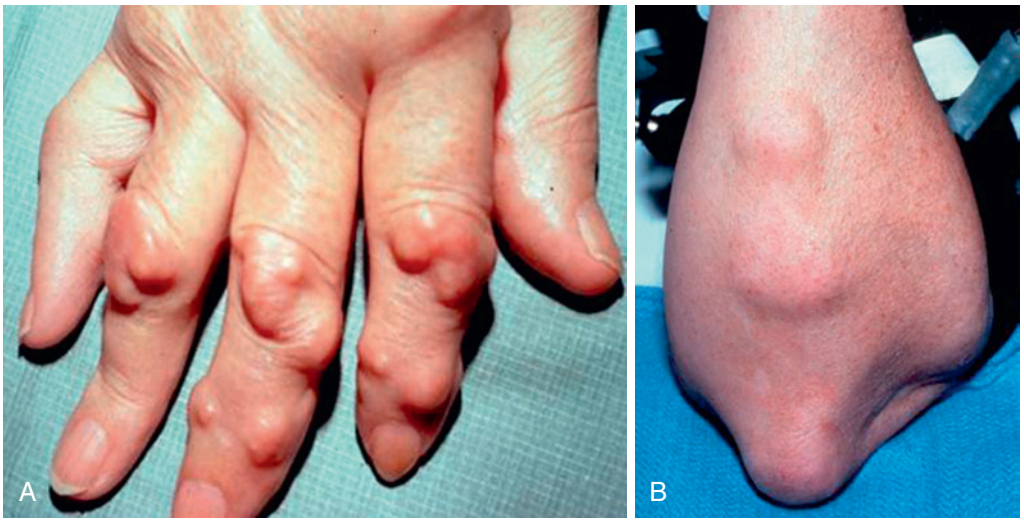

FIGURE 55.5 **A,** Rheumatoid nodulosis on the fingers' dorsal aspects. **B,** Rheumatoid nodules on the posterior aspect of the forearm and in the olecranon region can cause considerable discomfort. Resection of these nodules is accomplished through longitudinal incisions.

Rheumatoid nodulosis has been described as a separate clinical entity (rheumatoid variant); it is characterized by multiple subcutaneous nodules, usually on the hands, and is associated with intermittent polyarthralgia, absent or minimal joint involvement, subchondral cystic radiolucencies, and positive rheumatoid factor. Involvement of the hands by prominent subcutaneous nodules, often in clusters, can be extensive. When unsightly, resection of multiple nodules can dramatically improve the hand's appearance. There is some tendency for these nodules to recur after excision.[40,69]

RHEUMATOID ARTHRITIS

Tenosynovitis

Rheumatoid arthritis is a disease of the synovium. The synovium-lined sheaths that surround many of the tendons about the hand and wrist can be affected by proliferative synovitis in the same way as the synovium-lined joint spaces. Tendon sheath involvement is common and may occur months before the symptoms of intraarticular disease are noted.[97]

The three common sites of tendon sheath involvement are (1) the dorsal aspect of the wrist, (2) the volar aspect of the wrist, and (3) the volar aspect of the digits (Figure 55.6). Rheumatoid tenosynovitis can cause pain, dysfunction of tendons, and ultimately tendon rupture after invasion of tendons by the proliferating synovium. Treatment can relieve the pain and, if instituted before secondary changes in the surrounding structures and before tendon ruptures have occurred, can prevent both deformity and loss of function. For this reason, dorsal, volar, and digital tenosynovectomies are often the first surgical procedures indicated for rheumatoid patients.[97] Of patients with tenosynovitis, 50 to 70% have been found to have infiltration of the tendon by proliferative tenosynovium at the time of prophylactic tenosynovectomy.[73]

ANATOMY OF THE TENDONS AND TENDON SHEATH

On the dorsal aspect of the wrist, the deep fascia thickens to form a band approximately 3 cm in width. This dorsal retinaculum functions as a pulley for the extensor tendons that run in compartments directly beneath it. Six separate compartments are formed by vertical septa that run from the volar surface of the retinaculum to the dorsal surface of the radius and ulna; they are referred to numerically:

1. Contains the most radial tendons, abductor pollicis longus (APL) and extensor pollicis brevis (EPB)
2. Contains the extensor carpi radialis longus (ECRL) and extensor carpi radialis brevis (ECRB) tendons
3. Contains the EPL tendon
4. Contains the extensor digitorum communis (EDC) and the extensor indicis proprius (EIP) tendons
5. Contains the extensor digiti quinti (EDQ) tendon
6. Contains the ECU tendon

Each of the tendons within these compartments is surrounded by tenosynovium, which begins just proximal to the proximal edge of the retinaculum and continues distally to the level of the metacarpal bases. The tendons distal to this area are covered by paratenon rather than by tenosynovium.

On the volar aspect of the wrist, the flexor tendons of the fingers and thumb and the median nerve pass into the hand under the transverse carpal ligament (flexor retinaculum). This thick ligament extends across the volar aspect of the carpus attached to four "pillars"—the trapezium and the scaphoid on the radial side of the wrist and the hamate hook and pisiform on the ulnar side—to form the roof of the carpal canal. Just before the finger flexors enter the carpal canal, a common sheath of tenosynovium surrounds them. The flexor pollicis longus (FPL) tendon runs in a separate tendon sheath.

The tendon sheaths of the index, middle, and ring fingers extend from midpalm to the DIP joints. The sheaths of the thumb and little finger continue proximally into the carpal

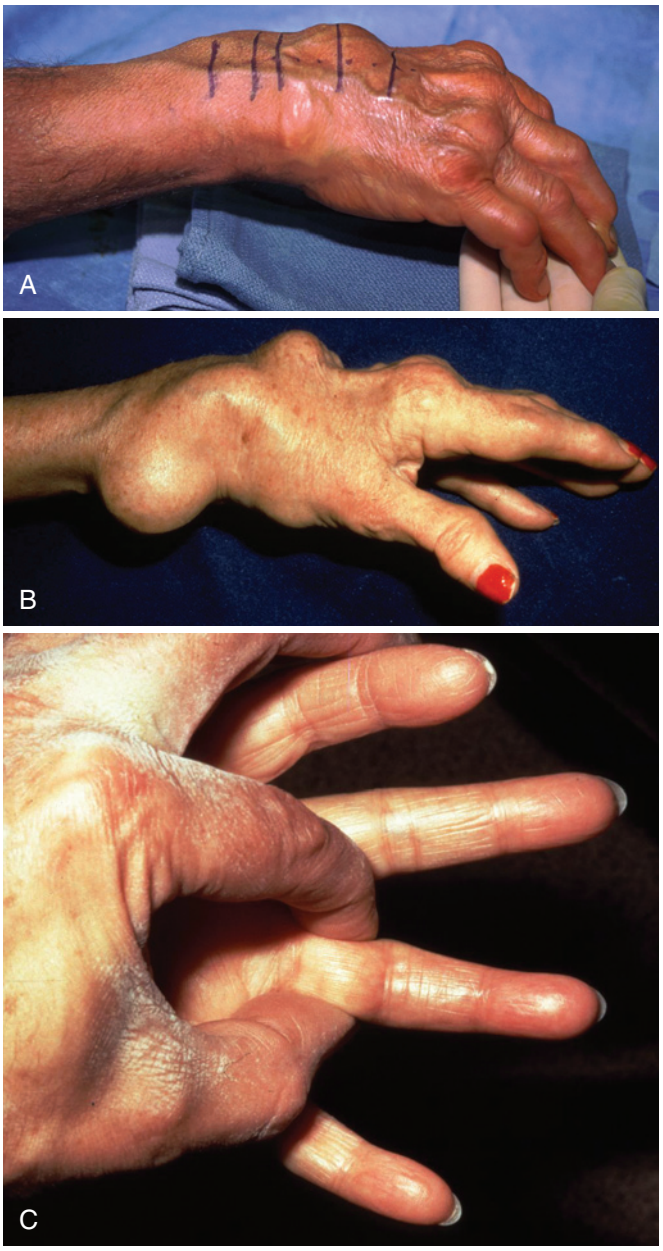

FIGURE 55.6 Examples of dorsal (extensor) and flexor tenosynovitis. **A,** Dorsal tenosynovitis affecting only the extensor digitorum communis compartment. **B,** More extensive dorsal tenosynovitis affecting multiple extensor tendon compartments. Note the bulging along the course of the abductor pollicis longus and extensor pollicis brevis, extensor pollicis longus, and common digital extensors. **C,** Digital flexor tenosynovitis manifested as volar fullness over the proximal phalanges. tunnel. The flexor tendons within the digits are enclosed in a snug fibroosseous canal lined with synovium.

Dorsal (Extensor) Tenosynovitis in the Wrist

Dorsal tenosynovitis is characterized by swelling on the dorsal aspect of the wrist. It may be subtle or massive and may involve one tendon, a combination of tendons, or all the tendons in the dorsal compartments. Because the dorsal skin of the wrist and hand is thin and displaced easily as tenosynovium proliferates, dorsal tenosynovitis is usually obvious and may be the first sign of rheumatoid arthritis. Isolated dorsal tenosynovitis is painless. Patients tend to ignore the swelling, and tendon rupture with loss of active extension can be the first manifestation of the condition. When patients with dorsal tenosynovitis complain of pain, one must look for involvement of the radiocarpal or radioulnar joints.

Although early in the disease the synovial tissue remains thin and distends the sheath with fluid, as the disease progresses, this tissue thickens and takes on a more solid appearance, similar to that found within joints affected by advanced rheumatoid arthritis. Small fibrinoid "rice bodies" occasionally fill the tendon sheaths. The hypertrophic synovium adheres to tendon surfaces and may eventually invade the tendon substance and result in weakening and, not infrequently, rupture of the tendon. Occasionally, rheumatoid nodules are found within the tendon substance.

Spontaneous or drug-induced remission of early dorsal tenosynovitis can occur. Rest or local injection of a steroid solution, or both, may also result in remission. However, if the proliferative synovitis progresses, remission becomes unlikely. The dorsal tenosynovitis becomes unsightly, and the risk for tendon rupture increases. For this reason, early dorsal tenosynovectomy is recommended (i.e., if there is no improvement after 4 to 6 months of appropriate medical management). Although the appearance of the tendons within the compartments affected by tenosynovitis may be poor (as evidenced by fraying), tendon rupture rarely occurs after dorsal tenosynovectomy is performed.[73,110]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Dorsal Tenosynovectomy

A straight (preferred) or gently curved longitudinal incision is made over the dorsal aspect of the wrist just to the ulnar side of the midline (Figure 55.7). Full-thickness skin flaps, including the subcutaneous tissue, are reflected to expose the underlying extensor retinaculum and deep fascia. The superficial branches of the ulnar and radial nerves remain in the subcutaneous tissue of the flaps and thus are protected. Longitudinal veins are preserved if possible, but transverse communicating veins are divided. The fourth compartment is opened in a "Z" manner. The terminal branch of the posterior interosseous nerve on the radial side of the floor of the fourth compartment can be

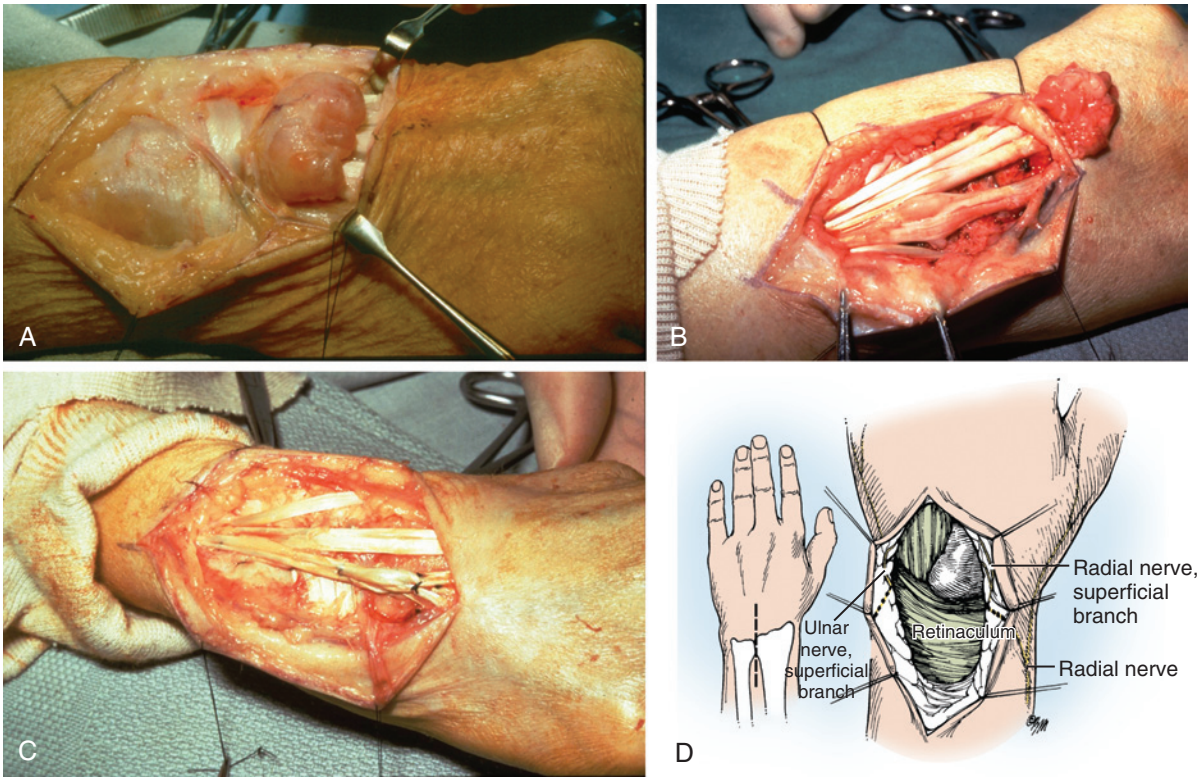

FIGURE 55.7 Surgical technique of dorsal tenosynovectomy. **A,** A straight dorsal incision has been made. The extensor retinaculum and the bulging dorsal tenosynovitis are seen. **B,** The retinaculum has been incised in the midline and reflected radially and ulnarward. Tenosynovitis is seen surrounding the extensor tendons. Dorsal tenosynovectomy and retinacular relocation have been completed. The dorsal retinaculum has been placed deep to the extensor tendons. **C,** Capsular closure is completed and tendon transfer is performed. Note the extensor carpi ulnaris relocation using a portion of the dorsal retinaculum. **D,** Exposure for dorsal tenosynovectomy. We prefer a straight rather than a slightly curved incision (as shown). Note the superficial branches of the radial and ulnar nerves protected in skin flaps. (**A-C,** From Millender LH, Nalebuff EA: Preventative surgery: tenosynovectomy and synovectomy. *Orthop Clin North Am* 6:765–792, 1975, with permission; **D,** copyright © Elizabeth Martin.)

resected to partially denervate the wrist joint. The septum between the third and fourth compartments is opened and the EPL tendon is identified and protected. The vertical septum between each compartment is divided. The radial flap of retinaculum is hinged on the septum between either the second and third compartments or the first and second compartments (if the second compartment requires tenosynovectomy). The ulnar flap of retinaculum is hinged on the septum between the fourth and fifth compartments.

The first dorsal compartment is not opened unless it is involved significantly. Hypertrophic synovium is removed from each extensor tendon sheath in a systematic manner. A limited dorsal tenosynovectomy can be done through a single compartment incision (e.g., the fourth) if indicated. In this case, the fourth compartment is opened in the same Z manner, but not extended radially or ulnarly. The posterior interosseous nerve is resected as just described. The tenosynovium is dissected from the extensor tendons with small scissors or with a rongeur.

As much of the diseased tenosynovium is removed as possible, although it is sometimes necessary to leave material that is densely adhered to the extensor tendon's surface. Frayed areas of the tendons are repaired with absorbable suture. If an area of tendon appears so attenuated or frayed so that tendon rupture seems imminent, the tendon at risk can be sutured to an adjacent extensor tendon above and below the area of damage, or the frayed and attenuated areas can be imbricated. If extensive tendon infiltration is found, similar infiltration may be present in other areas or on the contralateral side, and early surgery in these areas should be considered to prevent rupture.

After complete tenosynovectomy has been performed, the wrist joint is evaluated. If synovitis is present, the joint is opened and wrist synovectomy is performed with a small curved rongeur. The dorsal aspects of the ulna and radius are examined, and any bone spicules, which might cause attrition ruptures, are removed with a rongeur. The distal ulna is resected if it is dislocated and prominent dorsally. This is discussed in greater detail in the section on the distal radioulnar joint (DRUJ).[53]

The dorsal retinaculum is passed deep into the extensor tendons and sutured in place to provide a smooth gliding surface beneath them. If bowstringing is anticipated as a potential problem (e.g., in a patient with good wrist extension), half of the retinaculum may be retained over the tendons (Figure 55.8). The ECU tendon may be stabilized in a dorsal position with a narrow segment of the retinaculum.

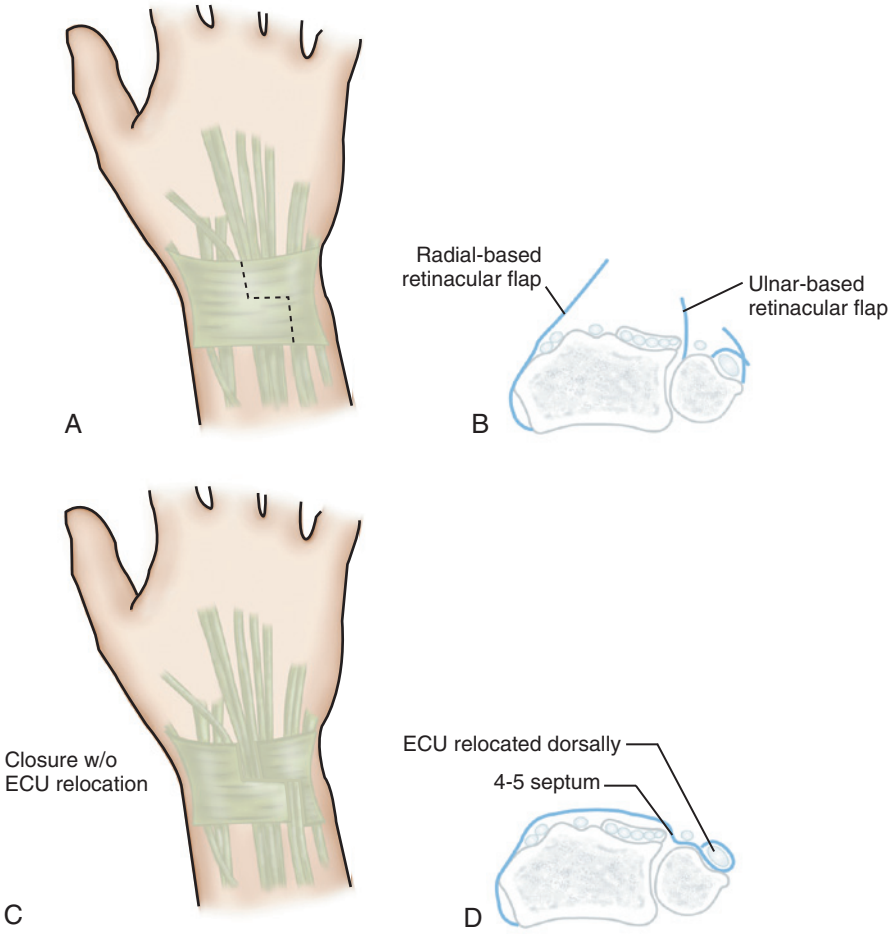

FIGURE 55.8 Illustration of the basic operative technique. **A,** The retinaculum is opened in a "Z" fashion. **B,** Usually, the radial-based retinacular flap is hinged on the 1-2 septum and the ulnar flap on the 4-5 septum. The fifth compartment is opened as needed. **C,** The retinaculum is usually closed in a lengthened position. If needed, one flap can be placed under the tendons. **D,** Also if needed, the ulnar flap, which is hinged on the 4-5 septum, can be looped under the extensor carpi ulnaris (ECU). The synovial side of the retinaculum is placed against the ECU. (**A-C,** From Slutsky DJ: *The principles and practice of wrist surgery*, Philadelphia, 2010, Elsevier. **D,** copyright Elizabeth Martin.)

The tourniquet can be released and bleeding controlled before final closure. If the tourniquet is released and bleeding is minimal, no drain is necessary. However, a small Penrose or suction drain prevents hematoma formation if the tourniquet is not released. The hand and wrist are immobilized in a bulky conforming dressing and a volar plaster splint. The wrist is held in neutral with the MP joints in extension. The IP joints are left free. The drain is removed 24 to 36 h after surgery. Dorsal tenosynovectomy can be performed in conjunction with other procedures such as thumb fusion, volar synovectomy, or finger tenosynovectomy.

Postoperative Management. Hand motion is started 24 to 48 h after surgery. Active extension and flexion exercises are emphasized. Motion usually returns rapidly, but in a patient with a low pain threshold, formal hand therapy may be required. The MP joint should be splinted in extension to prevent extensor lag until active extension is possible. The wrist is supported with a volar splint for 2 weeks after the procedure.

When patients have difficulty regaining active MP joint extension, taping the fingers with the PIP and DIP joints in flexion during active extension exercise is helpful in improving joint movement. All the extensor power is concentrated at the MP joint level, and extensor tendon excursion is increased over the areas of surgery (Figure 55.9).

Complications. Complications after dorsal tenosynovectomy are infrequent. The most serious complication is skin necrosis or sloughing. When this occurs, the extensor tendons are exposed and are at risk for rupture or scarring. Hematoma formation under the thin dorsal flaps of rheumatoid patients (especially those taking corticosteroids) is the most frequent cause of delayed skin healing. Special care must be taken to prevent hematoma formation. The skin is closed without tension, and a drain should be used routinely. The proximal and distal ends of the wound can be left open if necessary to avoid hematoma formation. A layered closure to cover the tendons with subcutaneous tissue can sometimes be done. Occasionally, it is useful to put the extensor retinaculum over the tendons to protect them if skin breakdown occurs. Sutures should not be removed prematurely. If skin sloughing occurs, the wound can be treated by debridement and skin coverage. The MP joints are splinted in extension until the wound has healed by secondary intention in 2 to 3 weeks.

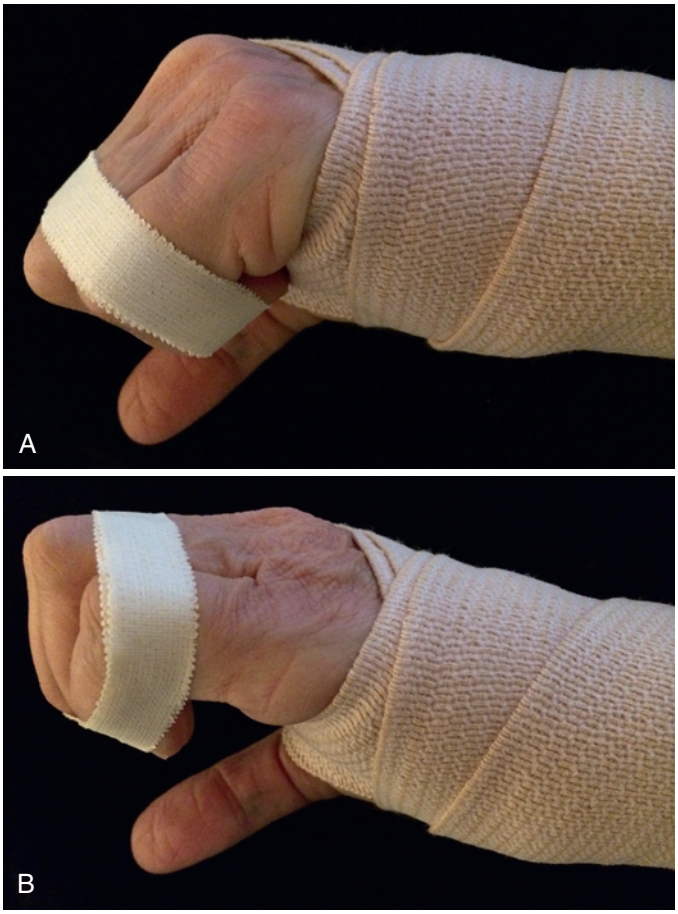

FIGURE 55.9 Postoperative metacarpophalangeal (MP) joint exercises can be done with the proximal interphalangeal and dorsal interphalangeal joints taped in flexion. This maximizes extensor tendon excursion as the MP joint moves from flexion **(A)** to extension **(B)**.

Occasionally, postoperative adhesions may result in either an extensor lag of the MP joints or loss of active finger flexion. Hand therapy is adjusted to emphasize flexion or extension as necessary. If pain or flexor weakness prevents flexion, passive flexion exercises and dynamic flexion splints can be added. If a significant extensor lag develops, a dynamic dorsal extension splint is used. Loss of motion after dorsal tenosynovectomy occurs more often in patients whose tendons are found to be in poor condition at the time of surgery, in patients with multiple joint involvement, and in those with low pain tolerance. Tenolysis after dorsal tenosynovectomy is rarely necessary. However, if significant impairment of function persists after 6 months of therapy, tenolysis should be considered.

Flexor Tenosynovitis in the Wrist

Although swelling on the dorsal aspect of the wrist is often prominent because of thin skin in the area, hypertrophic synovitis on the volar aspect of the wrist may not be obvious. However, proliferative synovitis of the flexor tendon sheaths occurs commonly and affects the anatomic structures. Compression of the median nerve can occur and cause symptoms of carpal tunnel syndrome. Restriction of the free-gliding motion of the flexor tendons results in impaired active and passive motion of the fingers.

As in extensor compartment tenosynovitis, flexor tenosynovitis eventually destroys the tendons' outer surfaces. The tendons adhere to one another, and as synovial tissue invades the tendon substance, ruptures can occur. There may occasionally be complete destruction of the flexor tendons within the confines of the carpal canal.

Even though rheumatoid flexor tenosynovitis may respond temporarily to local corticosteroid injection, we believe that early surgical decompression of the carpal canal combined with flexor tenosynovectomy is indicated to prevent permanent damage to the median nerve. Flexor tenosynovectomy with decompression of the nerve prevents permanent pain, numbness, thenar muscle loss, and spontaneous rupture, as well as preserves independent tendon-gliding function.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Flexor Tenosynovectomy

An incision is made in the midpalm, parallel to the thenar crease, and extended proximally while curving ulnarward at the wrist (Figure 55.10). The incision is extended 4 to 5 cm above

CRITICAL POINTS *Dorsal Tenosynovectomy*

Indications

- Persistent dorsal tenosynovitis after 4 to 6 months of appropriate medical management.
- Extensor tendon rupture.

Pearl

- Tape the IP joints in flexion for postoperative exercise if the patient has difficulty regaining active MCP extension.

Technical Points

- Use a straight midline incision.
- Make transverse incisions distal and proximal to the retinaculum.
- Use a longitudinal incision volar to the sixth compartment.
- Elevate the radially based retinacular flap by dividing the septa between compartments.
- If tenosynovitis is limited to a single compartment, use a longitudinal incision for limited tenosynovectomy.
- Remove the tenosynovium from each tendon.
- Repair a frayed tendon or suture a tendon at risk for rupture to an adjacent tendon.
- Remove any tenosynovium infiltrating the tendon substance and repair.
- Perform synovectomy of the wrist joint if necessary.
- Perform a distal ulnar resection if necessary.
- Transpose the retinaculum beneath tendons; split transversely, transpose half, and reattach the left half dorsal to preserve function.
- Stabilize the ECU in a dorsal position with a retinacular flap if necessary.
- Close the skin over a drain.

Postoperative Care

- Splint with the wrist in neutral and the MP joints in extension.
- Leave IP joints free and start finger motion within 24 h.
- Use a wrist splint for 2 weeks after the patient is able to maintain active MP extension.

the wrist in a zigzag manner. Care should be taken to protect the palmar cutaneous branch of the median nerve at the level of the wrist flexion crease. The deep fascia is divided to expose the median nerve. The palmar fascia is incised and separated from the superficial surface of the transverse carpal ligament, which is divided to open the carpal canal.

The median nerve is freed from adherent synovial tissue. The motor branch of the median nerve is identified and traced into the thenar musculature. If compression of this branch by the fascia of the thenar muscles has occurred, the fascia is divided. The hypertrophic tenosynovium surrounding the flexor tendons is excised, and areas of tendon fraying are repaired as described for the extensor tendons. Occasionally, unsuspected ruptures of the deep flexor tendons may be discovered at this time. Therefore, it is critical that the function of the flexor tendons be known before surgery. If the flexor tendons are functioning by pulling through scar tissue, complete removal of all diseased tissue is not done. Careful dissection is required when performing an extensive flexor tenosynovectomy, and thought must be given to the consequences of separating each of the deep flexor tendons out of the mass of tenosynovium binding them together. It may be more prudent to separate the superficial flexor tendons and leave the deep flexor ones in situ; that is, do not separate the flexor digitorum profundus (FDP) into its four component tendons but merely separate them en masse from their scarred bed.

After tenosynovectomy is performed, the floor of the carpal canal is inspected and palpated. Any exposed bone spicules, particularly over the volar surface of the scaphoid bone, are removed with a rongeur because they can result in tendon rupture by attrition. Exposed bone surfaces are covered by mobilizing and suturing local soft tissue.[68] Ertel and colleagues described a volar rotation flap to close the defect if primary closure is not possible (Figure 55.11).[35]

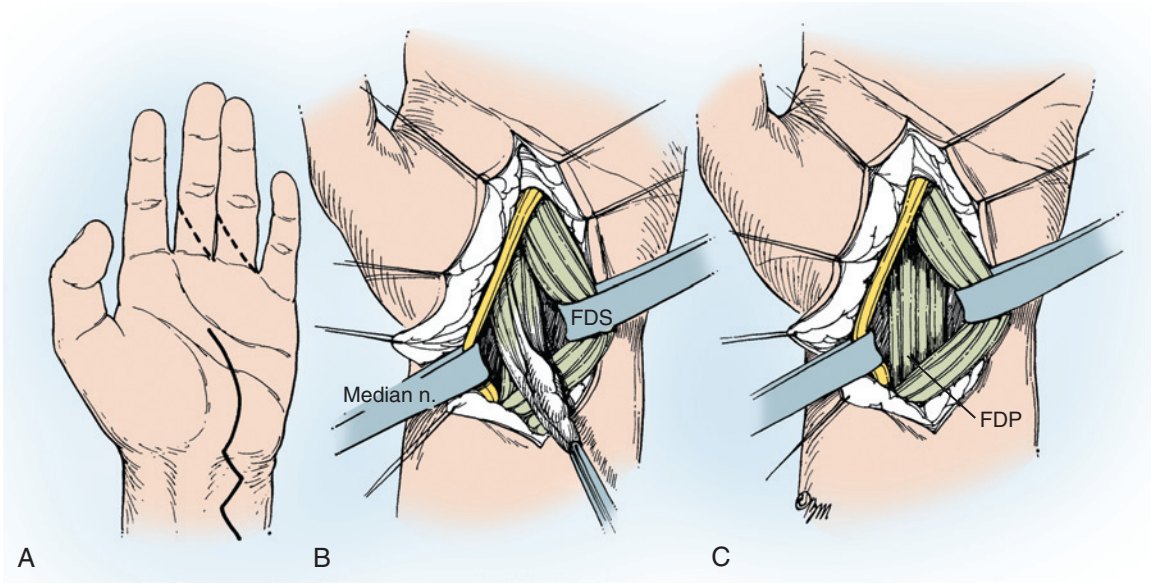

FIGURE 55.10 A-C, Surgical technique of wrist flexor tenosynovectomy; incisions for wrist, palm, and digital flexor are shown. The flexor tendons are exposed at the wrist and elevated into the wound. The median nerve is retracted with a Penrose drain. The flexor tenosynovium is excised from the flexor tendons. *FDP*, Flexor digitorum profundus; *FDS*, flexor digitorum superficialis. (Copyright Elizabeth Martin.)

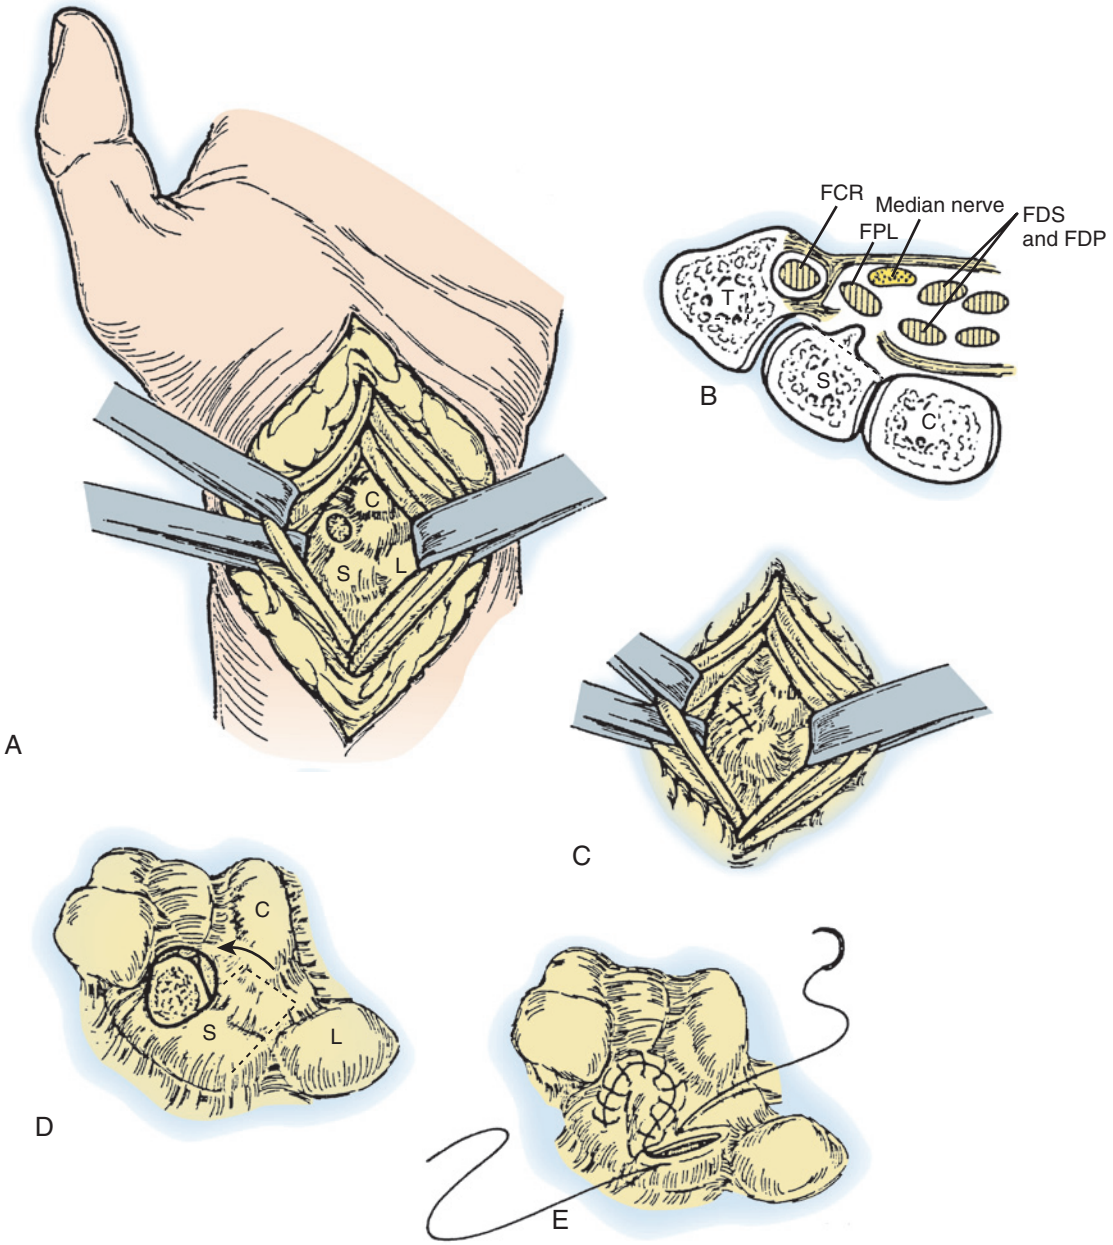

FIGURE 55.11 A scaphoid osteophyte can erode through the volar wrist capsule **(A)** and result in the "Mannerfelt lesion." **B,** Attrition rupture of the flexor pollicis longus (FPL) tendon. During volar tenosynovectomy, the osteophyte is resected and the defect in the capsule is closed either primarily **(C)** or with local rotation flaps of the wrist capsule **(D, E)**. *C,* Capitate; *FCR*, flexor carpi radialis; *FDP*, flexor digitorum profundus; *FDS*, flexor digitorum superficialis; *L,* lunate; *S,* scaphoid. (Copyright Elizabeth Martin.)

CRITICAL POINTS *Volar Tenosynovectomy*

Indications

- Symptoms or signs of median nerve compression.
- Persistent tenosynovitis after injection/medical management.
- Flexor tendon rupture.

Pearls

- If multiple FDP tendon ruptures are found at the time of surgery, do not perform individual tenosynovectomies but leave the FDP mass intact.
- If "catching" is found when testing for tendon excursion after tenosynovectomy, check for flexor tendon nodules in the digits and palm.

Technical Points

- Make an incision from midpalm (parallel to the thenar crease) to 4 to 5 cm proximal to the wrist flexion crease.
- Protect the palmar cutaneous nerve.
- Expose and protect the median nerve in the forearm.
- Divide the volar fascia and transverse carpal ligament longitudinally under direct vision.
- Perform tenosynovectomy.
- Inspect the floor of the carpal canal, debride any scaphoid osteophytes, and cover with a soft tissue rotation flap if present.
- Check for free tendon excursion.

Postoperative Care

- Splint the wrist in neutral.
- Start immediate active finger motion.

Traction is applied to the flexor tendons to check finger motion. Smooth motion of the fingers and thumb should be present. Catching signals the presence of tendon nodules in the palm or digits. If smooth motion of the tendons is not present, the involved tendon must be explored as far distally as necessary to remove the nodules. After removal of the nodules, the defect in the tendon is repaired with interrupted fine sutures.

Flexor Tenosynovitis in the Digits

As described previously, the fibroosseous canal is lined by synovium. This canal is not distensible, and even mild synovial hypertrophy can affect finger function significantly. Discrete rheumatoid nodules can form in one or both flexor tendons within the sheath. Such nodules may occur at different levels. The size of these nodules and their relationship to the annular pulleys determine the degree of finger dysfunction.

Several clinical patterns of rheumatoid "trigger finger" can occur and are based on the size and location of the nodules. Small, localized areas of disease cause catching of the tendons during flexion. This resembles the triggering that occurs in nonrheumatoid stenosing tenosynovitis. Flexor tendon nodules in the distal aspect of the palm can cause the finger to lock as it is flexed. A nodule in the FDP tendon in the region of the A2 pulley over the proximal phalanx can cause the finger to lock in extension.

Generalized tenosynovitis within the fibroosseous canal can result in palpable swelling on the volar aspect of the digit and limit motion. Usually, active motion is more restricted than passive motion. This loss of finger motion can result in stiffness of the IP joints as the periarticular soft tissue structures contract. As the IP joints become stiff, making a diagnosis becomes more difficult because one cannot tell whether the lack of finger motion is due to joint stiffness or restricted excursion of the flexor tendons. Prolonged flexor tenosynovitis within the fibroosseous canal can ultimately result in tendon rupture. Flexor tenosynovectomy and excision of flexor tendon nodules are indicated regardless of the type of tenosynovitis or triggering present.

❖ AUTHORS' PREFERRED METHOD OF TREATMENT: Digital Tenosynovectomy

We explore the flexor tendon sheaths of rheumatoid patients with digital tenosynovitis through zigzag incisions on the volar aspect of the digits (Figure 55.12). Such incisions can be extended proximally or distally to provide additional exposure if necessary. If multiple fingers are involved, a single transverse incision across the distal part of the palm can be used to expose the proximal portions of the flexor tendon sheaths. The diseased tenosynovium surrounding the tendon is excised. However, *the annular pulleys are preserved to prevent bowstringing of the flexor tendons.* The pulleys can be narrowed if necessary, but as much pulley as possible needs to be preserved.

Nodules within the flexor tendons are excised and the defects are closed with fine sutures. After complete tenosynovectomy and nodule excision have been performed, traction is applied to the flexor tendons to confirm smooth gliding. Occasionally, another nodule is present at a different level within the fibroosseous canal and is revealed only after the obvious nodule is excised and flexor tendon excursion is tested. If passive flexion of the finger is greater than the flexion obtained by traction applied to the tendon, additional tenosynovectomy is necessary. The objective of flexor tenosynovectomy is to make active and passive finger flexion equal. Gentle manipulation of stiff joints can be performed to restore passive joint motion at this time.

One surgical solution is to excise one slip of the flexor digitorum superficialis (FDS) tendon to decompress the fibroosseous canal. Although we do not use this method routinely, we prefer it to resecting excessive amounts of annular pulley to allow free excursion of the tendons. The entire FDS tendon may be excised if it is severely diseased and prevents complete "pull-through" of the FDP tendon.

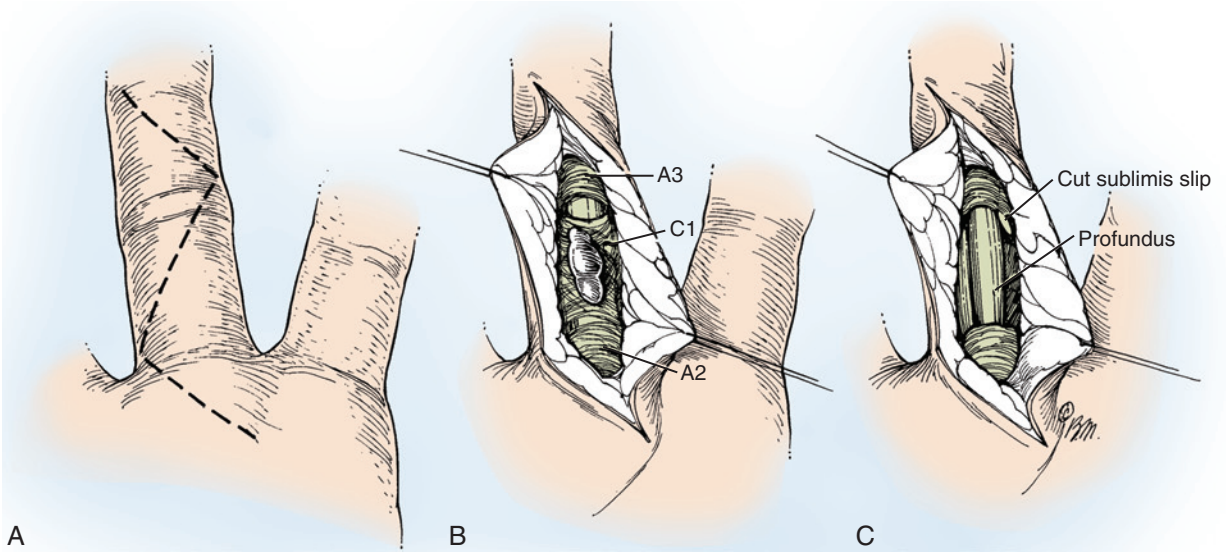

FIGURE 55.12 Digital flexor tenosynovectomy. **A,** The tendon sheath is approached through an extensile zigzag incision. **B,** Note the annular pulleys; the synovium usually bulges through the thin cruciate pulleys. As much annular pulley as possible is preserved when tenosynovectomy is performed. **C,** Half the superficialis tendon can be excised to allow free excursion of the remaining tendons without compromising annular pulley function. (Copyright Elizabeth Martin.)

Postoperatively, finger motion is started early, usually the day after surgery. The patient is taught to stabilize each joint of the operated on finger in sequence to exercise the superficial and deep flexor tendons independently; this thereby avoids adhesions between the two tendons.

Tendon Ruptures

Tendon ruptures in the hand are common in rheumatoid arthritis; the cause and location of them vary. Attrition ruptures occur as the tendon moves across bone roughened or eroded by chronic synovitis. Attrition ruptures of the extensor tendons occur most frequently either at the distal end of the ulna or at Lister's tubercle, which acts as a bony pulley for the EPL tendon. Attrition ruptures of flexor tendons occur on the volar aspect of the wrist where they contact the scaphoid. Tendon ruptures also can be caused by direct tendon invasion of rheumatoid tenosynovium, which erodes and weakens the tendon, or by ischemic necrosis from a diminished blood supply caused by pressure from proliferative synovium under the dorsal retinaculum, transverse carpal ligament, or flexor tendon pulleys.[68,79,130]

The treatment options for rheumatoid patients with tendon ruptures are fusions of various joints and tendon transfers. There are differences between tendon transfers performed in rheumatoid and nonrheumatoid patients. For a rheumatoid patient, (1) the joints to be moved by the transfer may be stiff or unstable; (2) the bed through which the transfer passes may be scarred or irregular and compromise tendon excursion; (3) the tendons to be transferred may have been weakened; and (4) if the wrist, MP, or PIP joints (or any combination of the three) are stiff or deformed, the tenodesis effect of wrist motion or the complementary motion of the MP and PIP joints cannot be relied on to enhance the performance of the transferred tendons. These factors must be considered carefully when planning tendon transfers to reconstruct rheumatoid tendon ruptures.

Diagnosis

Extensor Tendon Ruptures. Although the correct diagnosis of tendon rupture is not usually difficult to make, it requires both an observant patient and an informed physician. The sine qua non of tendon rupture is the *sudden loss of finger extension or flexion*. Tendon ruptures are generally painless and commonly follow trivial hand use or activity. Rheumatoid patients who become accustomed to frequent variations and limitations of hand function are likely to delay medical attention unless the functional loss after rupture of a tendon is obvious to them or is quite significant. Isolated ruptures of the EDQ or EPL may cause only limited functional loss and therefore go unrecognized or be overshadowed by more significant deformities.

The factors leading to rupture of a single tendon, unless corrected, are often responsible for subsequent ruptures with more significant functional loss. Frequently, after a rupture of the extensor tendon of the little finger, the ring finger extensor ruptures, followed by the long finger extensor, and so on (Figure 55.13). This occurs as the remaining intact tendons shift ulnarward and become abraded over the roughened edges of the distal ulna. Thus, the usual progression of extensor tendon ruptures is in a radial direction, with the index finger being the last one affected. In our experience, multiple extensor tendon ruptures (especially those that occur in rapid succession) are the result of attrition as the tendons wear against a bone spicule on the ulnar aspect of the wrist.

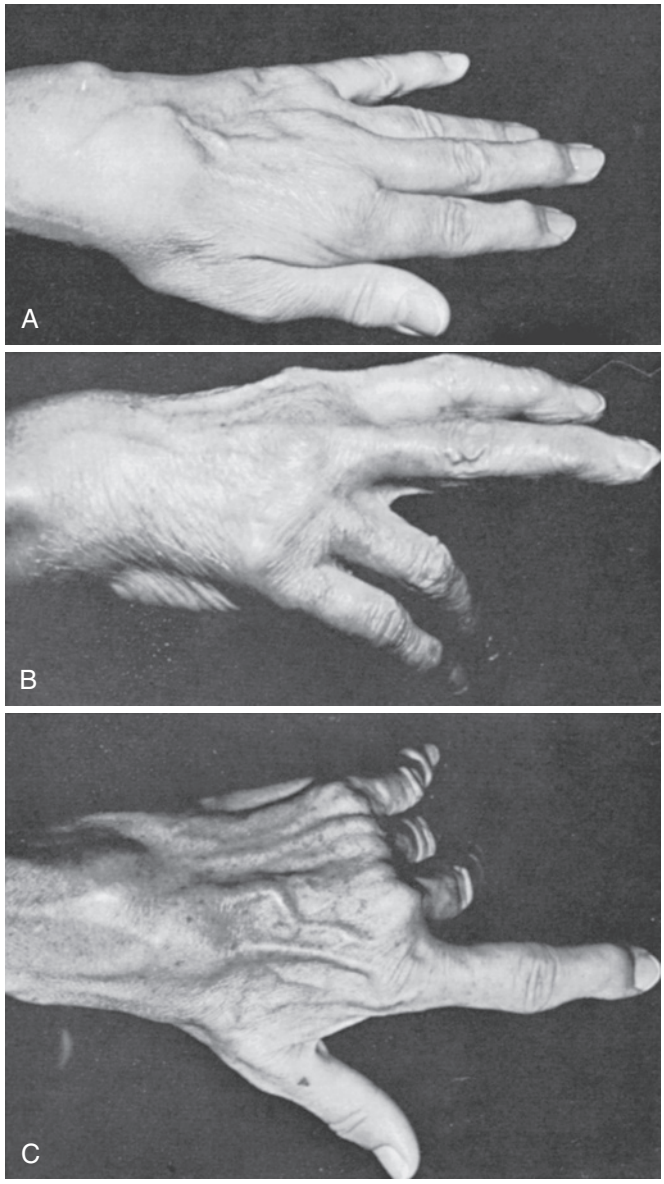

FIGURE 55.13 Examples of extensor tendon ruptures. **A,** Dorsal tenosynovitis and single rupture of the extensor digitorum communis (EDC) tendon to the ring finger. Note the minimal lag associated with a single rupture. **B,** Double rupture of the EDC to the ring and little fingers. When two tendons rupture, there is an appreciable extension lag and the disability becomes obvious. **C,** Triple rupture involving the long, ring, and little fingers. (From Millender LH, Nalebuff EA: Preventative surgery: tenosynovectomy and synovectomy. *Orthop Clin North Am* 6:765–792, 1975, with permission.)

Although sudden loss of extension of the little, ring, and middle fingers is most likely the result of multiple extensor tendon ruptures, three other conditions occur in rheumatoid arthritis that can mimic tendon rupture and should be excluded before surgery is performed to restore extensor power to the fingers. The most common of these conditions is MP joint dislocation, which results in a flexed and ulnar-deviated position of the finger. The lack of passive MP joint extension and the presence of palpable or visible extensor tendons on the dorsal aspect of the hand make the differential diagnosis

between MP joint dislocation and extensor tendon rupture straightforward. The second condition to be excluded is displacement of the extensor tendons into the valleys between the metacarpal heads. When such displacement occurs, extensor force is lost because the tendons now lie volar to the axes of motion of the MP joints. With this condition, the posture of the fingers is similar to the posture that occurs in patients with multiple extensor tendon ruptures.

Differentiation between extensor tendon rupture and displacement of the tendons between the metacarpal heads can sometimes be made if the patient is able to maintain MP joint extension actively after the joints are extended passively. This is not always the case, however, and occasionally it is necessary to explore the tendons at the level of the wrist at the time of MP arthroplasty to verify their continuity. Treatment of subluxation of the extensor tendons consists of relocation over the MP joints with or without MP joint arthroplasty.

The least common but most difficult condition to diagnose among those simulating multiple extensor tendon rupture is paralysis of the common extensor muscle secondary to posterior interosseous nerve compression as a result of elbow synovitis.[75] Several subtle differences allow tendon rupture to be differentiated from muscle paralysis. Patients with posterior interosseous nerve compression usually demonstrate some radial deviation of the wrist because of paralysis of the ECU muscle, in addition to the absence of active finger extension. Soft tissue fullness around the elbow signals proliferative synovitis of the radiohumeral and ulnohumeral joints, which can result in compression of the posterior interosseous nerve. In patients with posterior interosseous nerve compression, the extensors of the middle and ring fingers may be weaker than those of the index and small fingers. Thus, there is a greater extensor lag of the middle and ring fingers than of the index and little fingers.

In contrast, in rheumatoid attrition ruptures, the ring and little finger extensors are involved first. The best diagnostic test is the presence or absence of MP joint extension as the wrist is flexed. A positive "tenodesis effect" is found in the paralytic condition because the extensor tendons are in continuity. With tendon rupture, flexion of the wrist generally has no effect on finger extension because the extensor tendons are not in continuity. In addition, patients with multiple extensor tendon ruptures usually have dorsal tenosynovitis or a prominent distal ulna, which predisposes them to extensor tendon rupture, whereas patients with posterior interosseous nerve compression may have no such findings about the wrist.

Flexor Tendon Ruptures. Flexor tenosynovitis is not uncommon in rheumatoid arthritis. Although carpal tunnel syndrome is the most common manifestation of flexor tenosynovitis at the wrist, weakness, loss of dexterity of the hand, local or radiating pain, and discomfort with hand use can occur. Tendon gliding becomes restricted, and progressive loss of active finger flexion ensues. A discrepancy between active and passive finger flexion is characteristic of rheumatoid flexor tenosynovitis. Triggering, locking, loss of the normal finger cascade, and loss of active flexion can occur, particularly with tenosynovitis in the palm or in the fibroosseous canals. Joint stiffness makes concomitant flexor tenosynovitis more difficult to detect. Flexor tendon ruptures occur but are much less common than extensor tendon ruptures.

The presence of inflammatory flexor tenosynovitis adversely affects the outcome of reconstructive surgery. That is, there is less restoration of function after a tendon transfer done for a rupture caused by inflammatory synovitis than after one performed for an attrition rupture. The most common flexor tendon to rupture is the FPL. Patients with this rupture lose active flexion of the IP joint of the thumb. It occurs when the tendon is eroded by a volar osteophyte on the scaphoid that penetrates the volar wrist capsule and is known as the "Mannerfelt lesion."[68] The diagnosis of FPL rupture is not difficult unless there is a fixed-hyperextension deformity or stiffness of the IP joint.

An isolated rupture of the FDP tendon results in an inability to flex the DIP joint actively. A condition that mimics FDP tendon rupture and in fact is a precursor to such a rupture is a rheumatoid nodule in the tendon within the fibroosseous canal of the finger. The nodule restricts profundus excursion, and there is loss of active flexion of the DIP joint. This condition was discussed earlier.

Rupture of both the superficial and deep flexor tendons causes such obvious functional loss that the diagnosis is straightforward. The patient lacks active PIP and DIP joint motion and can flex the finger only at the MP joint. Of course, passive finger motion must be present to conclude that both tendons are ruptured.

After a flexor tendon rupture is recognized, the site of rupture must be determined. Flexor tendon ruptures can occur at the wrist, in the palm, and within the finger. Palpation for fullness (or lack thereof) within the finger can be useful in this regard. Ultimately, surgical exploration is often necessary to determine the exact site of a rupture.

Treatment of Extensor Tendon Ruptures

Rupture of the Extensor Pollicis Longus. Rupture of the EPL is common in rheumatoid arthritis (Figure 55.14).[64] Functional loss varies, depending on the functional capacity of the EPB and the status of the thumb joints. Although spontaneous rupture of the EPL can cause a "droop" or incomplete extension of the IP joint of the thumb, more commonly the patient maintains the ability to extend this joint despite the rupture. IP joint extension is a shared function of the EPL and the intrinsic

FIGURE 55.14 Extensor pollicis longus tendon rupture. Note that the major deformity is loss of metacarpophalangeal joint extension. The interphalangeal joint can be extended by intact intrinsic tendons, as seen in this patient.

muscles of the thumb. The intrinsics alone can extend this joint to neutral; the EPL is necessary for IP joint hyperextension. A patient with rupture of the EPL loses extension of the MP joint because the EPB is not strong enough to extend this joint by itself. Occasionally, no deformity occurs at either the MP or IP joint level, and the diagnosis is often missed unless a specific test for tendon function is done by asking the patient to extend the thumb with the palm resting on a flat surface while the examiner palpates the tendon of the EPL at the wrist.

If the tendon is ruptured and functional loss or deformity is significant, EPL function should be restored. The options available include end-to-end repair, tendon grafting, or tendon transfer. Although a tendon rupture can occasionally be repaired by an end-to-end technique, this is an exception and should not be expected. In general, tendon grafts through areas of rheumatoid tissue tend to become adherent. However, a graft used to repair an EPL rupture can function satisfactorily. The power and long excursion of the thumb flexor overcome the adhesions that form on the dorsum. The proximal motor must not be scarred or contracted for this to be effective, and for this reason, we prefer tendon transfers for the treatment of EPL rupture. The two most commonly used tendons for transfer are the EIP and ECRL. We prefer to use the EIP because (1) it can be taken from the index finger at the MP joint level without interfering with index finger's function and (2) in our experience the patient does not lose independent extension of the index finger as a result of this transfer.[80]

❖ AUTHORS' PREFERRED METHOD OF TREATMENT

The EIP tendon is identified at the level of the MP joint; it is usually the most ulnar of the two tendons, but it can be the most radial. The easiest way to differentiate between the two is to identify the most distal muscle belly, which is the EIP. It is withdrawn at the wrist through a second transverse incision and passed subcutaneously into the thumb. In the past, we did an end-to-end or weaving connection of the transferred tendon with the distal stump of the EPL. This was always tedious, and adjustment to the proper tension was difficult once the tendon was sutured. Now we pass the tendon directly to the MP joint level and weave it into the extensor mechanism. A temporary suture is used to judge tension. With the correct tension, the thumb remains in extension when the wrist is flexed.

With the wrist extended, passive flexion of the thumb to the little finger pulp should be possible. Weaving of the tendon through the extensor mechanism results in a strong connection and allows the initiation of motion with confidence after 4 to 5 weeks of immobilization. The result of a properly performed tendon transfer to restore EPL function is usually excellent. If necessary, dorsal tenosynovectomy and excision of a prominent, dorsally displaced distal ulna are performed at the same time as the EIP transfer.

Rupture of the Finger Extensors

Single Tendon Ruptures

Although single tendon ruptures can involve any finger, the little finger is affected most often (Table 55.2). The patient demonstrates incomplete extension of the finger at the MP joint level. The amount of extensor lag depends on whether both the EDQ and the EDC tendons are ruptured. With an isolated EDQ rupture, MP joint extension may lag only 30 to 40 degrees. The contribution of the EDC to extension of the little finger is tested by holding the index, middle, and ring finger MP joints in flexion and asking the patient to extend the little finger. An increased extensor lag demonstrates loss of the contribution to extension provided by the EDC. Because of the danger of additional ruptures that can complicate treatment, patients with a single tendon rupture are advised to undergo early surgical reconstruction. Surgical treatment of an isolated rupture of any one finger extensor is relatively easy, and the functional result is usually excellent (Figure 55.15).[73,96]

TABLE 55.2 Treatment Options for Extensor Tendon Ruptures

Type of Rupture	Treatment
Ruptures—all	Dorsal tenosynovectomy Removal of bone spikes Retinacular relocation to cover bone Ulnar head resection as needed
Single rupture	Primary repair Adjacent suture Intercalated graft
Double rupture (EDC of long, ring, and small fingers, EDQ)	As for single rupture plus EIP transfer
Triple rupture	As for double rupture plus FDS_{mid} through the interosseous muscle or around the side Wrist extensor, especially if wrist fusion is present EPL if MP fusion is present
Quadruple rupture	As for triple rupture plus another FDS

EDC, Extensor digitorum communis; *EDQ*, extensor digiti quinti; *EIP*, extensor indicis proprius; *EPL*, extensor pollicis longus; *FDS*, flexor digitorum superficialis, *MP*, metacarpophalangeal.

Operative Technique

Occasionally, end-to-end repair of a ruptured extensor tendon is feasible. With this technique, the MP joints are extended to allow direct repair of the ruptured tendons. The adjacent intact tendons look too long and the fingers are out of sequence, which should be expected, when the repair is completed. The posture of the hand improves 7 to 10 days after surgery as the proximal part of the repaired muscle–tendon unit stretches out. The wrist is splinted in extension to allow the MP joints to flex slightly.

If direct repair is not possible, we prefer to suture the distal tendon stump to an adjacent extensor tendon. Dorsal tenosynovectomy and removal of any bone spicules from the distal end of the ulna (or ulnar head resection) should be done at the same time to eliminate the cause of rupture. The dorsal retinaculum should be transferred deep into the extensor tendons to provide a bed for gliding if bone is exposed. This is done before the tendons are reconstructed. Partial transfer of the retinaculum is described in the section on tenosynovectomy.

Suturing to adjacent tendon is particularly easy for an isolated rupture of the middle or ring finger. For example, the distal end of the EDC tendon to the little finger or the EDQ is woven through the EDC of the ring finger and sutured.

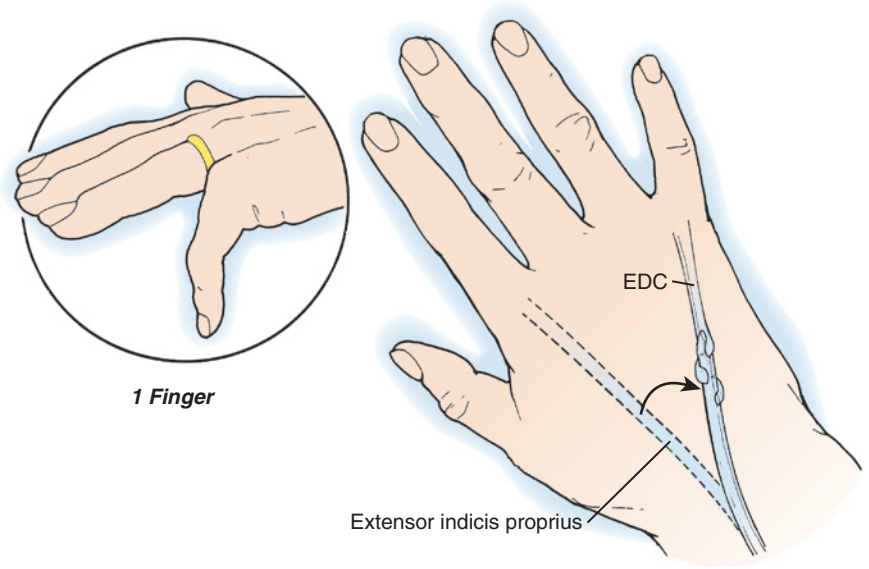

FIGURE 55.15 The extensor indicis proprius tendon is transected over the metacarpophalangeal joint and transferred to the stump of the extensor digiti communis (EDC; little finger) tendon. (From Williamson SC, Feldon P: Extensor tendon ruptures in rheumatoid arthritis. *Hand Clin* 11:449–459, 1995, with permission.)

Similarly, the distal end of the ring finger EDC can be transferred to the long finger EDC. If there has not been major loss of tendon substance, an end-to-end repair can be done. Nonabsorbable suture material is used, and tension is determined by restoring the appropriate extensor stance (in sequence) to the fingers. The tension must be sufficiently tight so that when the wrist is flexed moderately, the fingers are maintained in complete extension and, when the wrist is extended moderately, the MP joints flex only 20 to 30 degrees.

The use of intravenous regional anesthesia or local anesthesia with sedation ("MAC") simplifies the task of judging proper tension. After tendon suturing has been completed, the tourniquet can be released. When voluntary muscle control is regained, the patient is asked to extend the fingers. If there is a lag in extension, tendon tension can be corrected at this time. Skin closure is done under local infiltration anesthesia if this technique is used.[73] If the tourniquet is not released, a drain is used to prevent a subcutaneous hematoma.

Multiple Ruptures of the Extensor Tendons

As additional tendons rupture, surgical treatment becomes more complicated. With double ruptures of the long and ring finger extensors, it is still possible to use the adjacent suture technique; the stump of the ring finger tendon is attached to the little finger tendon, and the stump of the long finger tendon is attached to the index finger tendon. If the EDC to the little finger is not present, the ring finger tendon stump can be sutured to the EDQ.[138]

Options and Techniques for Extensor Tendon Reconstruction

Ring and Little Finger Ruptures

Double ruptures more frequently involve the ring and little fingers (Figure 55.16). Although the adjacent suture technique can be done in some of these patients by connecting both distal tendon stumps to the long finger tendon, there can be difficulty with the little finger. The distal tendon stump of this finger may be so short that it cannot reach the ring finger tendon without resulting in excessive abduction of the little finger. In this situation, a different method is required, and we use the EIP as a tendon transfer. Other tendon transfers, such as the ECU, have been advocated to restore extension in this situation. However, this wrist extensor is very important in maintaining wrist alignment and power, and we believe that it is best left in its normal position. In addition, it does not have the same excursion as the finger extensors, and its use results in lack of either full flexion or extension of the little finger. We have occasionally used the ECRB tendon as a transfer, with satisfactory but not excellent results.

When the extensor tendons of the ring and little fingers rupture (the so-called double rupture), MP joint extension can be restored with two tendon transfers: the EIP to the little finger and the distal stump of the ring finger to the intact common extensor tendon of the long finger.

Rupture of More Than Three Extensor Tendons

As additional extensor tendons rupture, restoring finger extension becomes more difficult. With three or four extensor tendons gone, the adjacent suture technique combined with EIP transfer is no longer sufficient to restore extensor power. A donor tendon for transfer that has a strong motor, is expendable, and has the necessary length to reach the distal tendon stump just proximal to the MP joints is needed. The superficial flexor tendons meet these criteria.[96] The FDS transfer was advocated first by Boyes[11a] for radial nerve palsy. He showed that patients learned to use a former finger flexor as an extensor.

With his technique, the transferred tendon was brought through a wide opening in the interosseous membrane to provide a direct route to the site of connection. We prefer this routing of the tendon transfer through the interosseous membrane for patients who have no scarring in the region of the

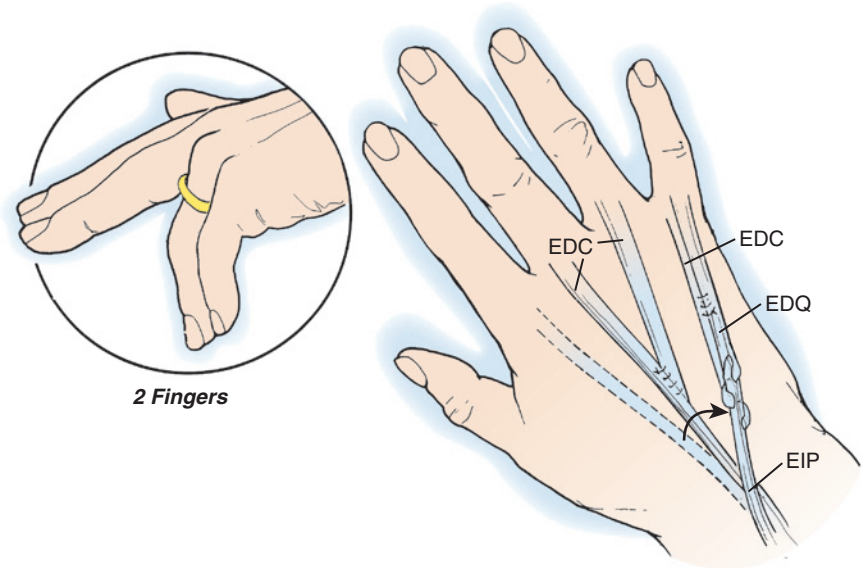

FIGURE 55.16 The extensor digitorum communis (EDC; ring finger) tendon stump is sutured end to side or woven into the EDC (long finger) tendon, and the extensor indicis proprius (EIP) tendon is transferred to the EDC (little finger) or extensor digiti quinti (EDQ) tendon stumps, or to both. (From Williamson SC, Feldon P: Extensor tendon ruptures in rheumatoid arthritis. *Hand Clin* 11:449–459, 1995, with permission.)

distal forearm or wrist. This more direct route of the sublimis tendon provides optimal function of the transfer. A window large enough to allow the muscle belly of the superficialis, rather than just the tendon alone, to be passed into and through the membrane should be made in the interosseous membrane. This helps preserve maximal excursion of the tendon after transfer (see Chapter 31 for details of the Boyes transfer through the interosseous membrane).

We have modified the Boyes technique for patients with scarring in the dorsal wrist area either from previous surgical procedures or from long-standing tendon ruptures. In these patients, we use the long finger FDS instead of the ring finger sublimis tendon as a motor to avoid a decrease in grasp power, and we route the tendon subcutaneously around the radial aspect of the forearm rather than going through the interosseous membrane and the area of scarring. This direction of pull was chosen to eliminate the risk of pulling the fingers into increased ulnar deviation (Figure 55.17).

The transfer is performed through three incisions. A small transverse incision is made in the distal palmar crease, and the tendon is divided after applying proximal traction. This provides enough length to reach the MP joints. A second incision is made on the volar aspect of the forearm. It should be placed ulnar to the midline so that the final transfer passes deep to the skin incision and thus minimizes tendon adherence. The third incision is made on the dorsal aspect of the hand, where the transfer is attached to the extensor mechanism of the ring and little fingers. Usually, we suture the middle finger tendon to the adjacent index finger tendon. Care must be taken to route the transferred tendon deep into the superficial radial nerve. Otherwise, symptomatic compression of the nerve can occur as a result of the tendon passing over the nerve.

With quadruple tendon ruptures, two superficial flexor tendon transfers are used: one to restore extension of the index and middle fingers and the other to restore ring and little finger extension (Figure 55.18). Again, the judgment of tension is critical. The transfer should be tight enough to have a tenodesis effect, as described previously. There is a tendency for the transfer to stretch postoperatively because of the strong flexor pull.

We have used the FDS transfer in patients who had previously undergone wrist fusion. The large excursion of the FDS allows the patients to achieve satisfactory extension of the fingers without the benefit of any tenodesis effect. For patients with multiple tendon ruptures and advanced disease of the thumb MP joint, this joint can be fused and the EPL used as a tendon transfer to the finger extensors.

We have found that primary intercalated or "bridge" grafts can be useful, particularly for triple tendon ruptures. The palmaris longus tendon or, if the wrist is fused, one of the wrist extensors can be used for the graft.[82] The dorsal wrist incision is extended proximally, and the proximal stumps of the ruptured extensor tendons are located and dissected free from scar and adherent soft tissue. The tendon in the best condition is selected for the motor if satisfactory excursion is available. The bridge graft is inserted between the proximal and distal tendon ends by using an interweaving technique. The graft should be put in tightly because the muscle will gradually stretch postoperatively. Bora and associates reported excellent results (MP joint motion, 10–75 degrees) in a long-term follow-up study in which the palmaris longus was used as a "loop" tendon graft to bridge the extensor tendon defect after multiple tendon ruptures (Figure 55.19).[10]

Tendon Transfers for Patients With Fused Wrists

For patients with fused wrists, the wrist motors can be used to restore finger extension. Although the excursion of these muscles is limited, many patients have limited MP joint motion and transfer of a tendon with less than optimal excursion may be sufficient. The wrist extensors are valueless with the wrist fused and can be used to extend the fingers without diminishing

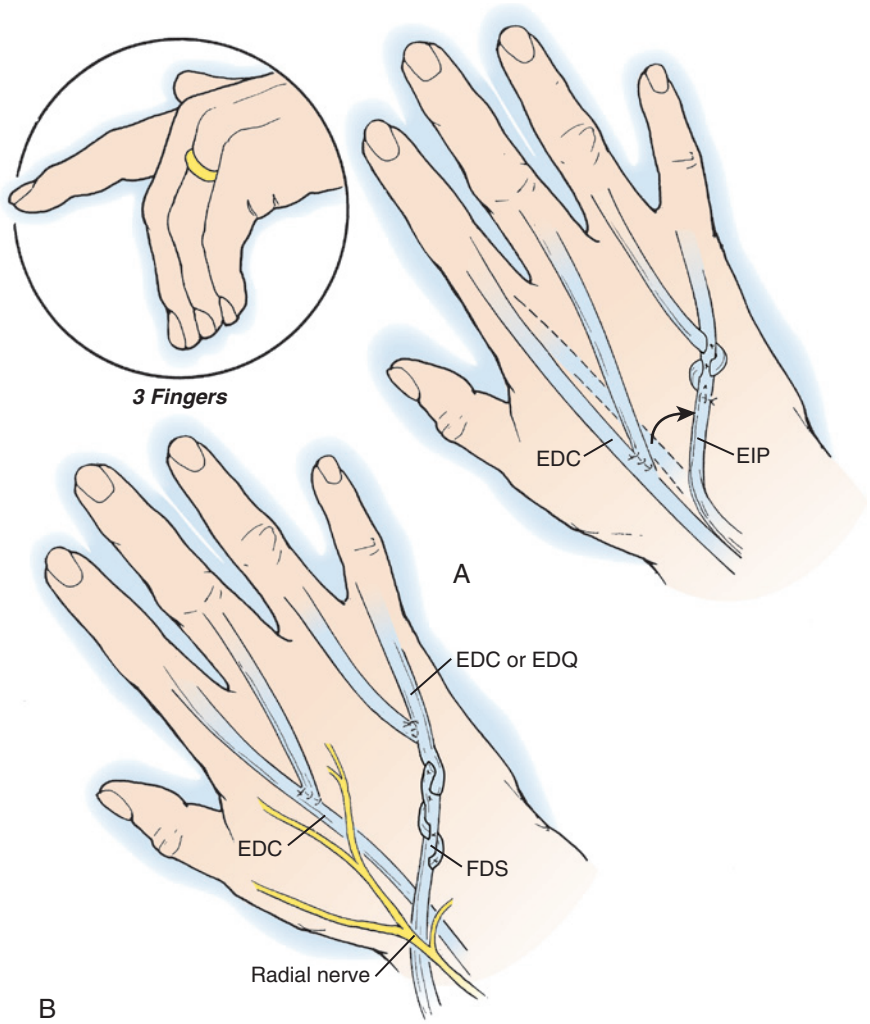

FIGURE 55.17 **A,** The extensor digitorum communis (EDC; long finger) tendon stump is sutured end to side to the EDC (index finger) tendon, and the extensor indicis proprius (EIP) tendon is transferred to the stumps of the ring and little finger EDC tendons. **B,** If the EIP tendon cannot be used for transfer, the flexor digitorum superficialis (FDS; middle finger) tendon is transferred to the stumps of the little and ring finger EDC tendons. Note that the FDS is passed beneath the superficial radial nerve. The EDC (long finger) is sutured side to side to the EIP or EDC (index finger) tendon stump. *EDQ,* Extensor digiti quinti. (From Williamson SC, Feldon P: Extensor tendon ruptures in rheumatoid arthritis. *Hand Clin* 11:449–459, 1995, with permission.)

the power of finger flexion that results when a FDS transfer is performed. We have used both wrist extensors and flexors to restore finger extension in this situation. The wrist extensors may be of sufficient length for transfer if they are dissected from their insertions on the bases of the metacarpals and the wrist unit is shortened slightly when the radiocarpal joint is prepared for fusion. The wrist flexors are frequently not long enough to reach the ruptured tendon ends, and a supplementary tendon graft is needed. When performing a wrist fusion that is to be followed later by a second-stage tendon transfer for multiple extensor tendon rupture, one or more silicone-rubber rods can be inserted at the time of wrist fusion. This makes the second-stage tendon graft procedure easier and minimizes the risk for postoperative adhesions.

Multiple Ruptures With Metacarpophalangeal Joint Disease

The not infrequent situation of multiple extensor tendon ruptures with associated MP joint disease warrants attention. We do not try to restore finger extension by tendon transfer before restoring joint motion. Unless the MP joints can be extended passively, any transfer will become adherent; thus, a staged reconstruction is usually necessary. Initially, MP arthroplasty is performed. Postoperatively, dynamic splinting is a substitute for the absent extensor tendons. At the second stage, appropriate transfers are done to provide active extensor power. With experience, it is possible to combine the MP joint arthroplasty with a tendon transfer in a single operative procedure.

The arthroplasty is done in routine fashion, after which an FDS tendon is brought around the forearm and sutured to the extensor mechanism at the arthroplasty site. The postoperative management of patients with combined arthroplasty and tendon transfers is geared toward protecting the tendon transfer. Therefore, active motion is delayed for 3 weeks, and restoration of complete active motion is not expected in such cases. The results of a combined procedure fall short when compared with an arthroplasty in the presence of normal tendons or with a tendon transfer in the presence of minimally involved joints.

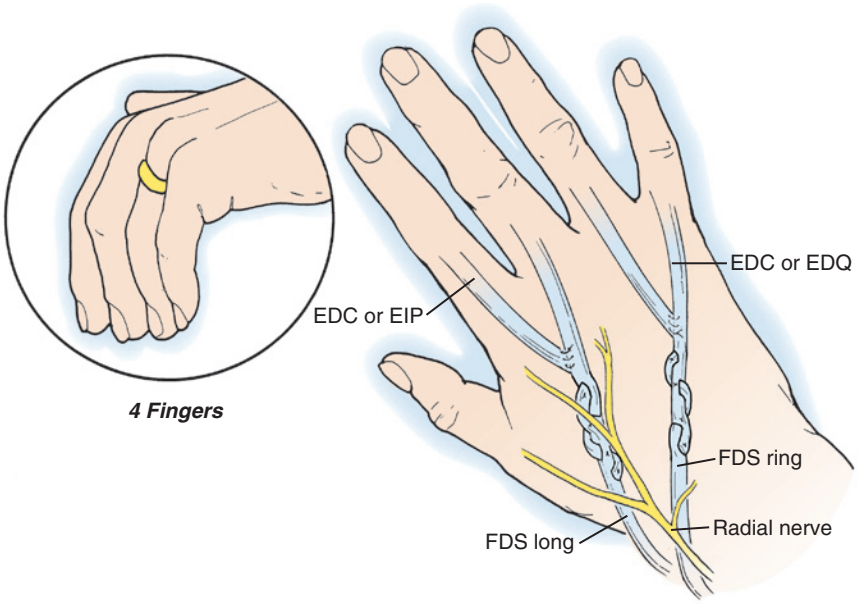

FIGURE 55.18 The donor flexor digitorum superficialis (FDS; ring finger) tendon is passed around the radial aspect of the forearm and transferred to the little and ring finger extensor digitorum communis (EDC) tendon stumps. The FDS (long finger) is transferred to the index and long finger EDC tendon stumps. *EDQ*, Extensor digiti quinti; *EIP*, extensor indicis proprius. Treatment of Flexor Tendon Ruptures

Rupture of the Flexor Pollicis Longus. The most common flexor tendon to rupture in patients with rheumatoid arthritis is the FPL. It is usually secondary to attrition at the level of the carpal scaphoid bone and has been referred to as the Mannerfelt lesion.[68] The functional loss is variable. If the patient has a good IP joint, the loss is apparent. If the MP joint has significant involvement or is fused, the loss of any IP joint motion results in substantial functional loss. Either terminal joint stability or restoration of active motion must be provided. Even if the IP joint is fused to provide stable pinch, the volar aspect of the wrist still must be explored. The bone spicule that has disrupted the FPL affects the tendons of the index finger next and must be removed. One of our patients was found to have ruptures of both the superficial and deep flexor tendons of the index and middle fingers, in addition to the thumb flexor.

Operative Technique. The volar aspect of the palm and wrist is exposed through a curved incision along the thenar crease and is extended proximally in a zigzag manner (Figure 55.20). The bone spicule on the ulnar aspect of the scaphoid bone, which protrudes into the radial side of the carpal canal, is removed, and the exposed bone is covered by mobilizing adjacent soft tissue. Attention is then directed toward restoration of tendon function. Surgical choices include the use of a bridge graft, a standard tendon graft, or a tendon transfer. If both tendon ends can be identified at the wrist level, we prefer to insert a short bridge graft. The palmaris longus is suitable for this, but if it is not present, a slip of the FCR or one of the multiple slips of the APL can be used. If suturing at the level of the rupture is difficult because of its location in the carpal tunnel, incisions can be made at the level of the MP joint and distal forearm and the graft passed across the tunnel and sutured distal and proximal to it. If the distal tendon stump cannot be brought into the wrist incision, we either use a full-length tendon graft or transfer a superficial flexor tendon. The preference is to use the superficial flexor of the long finger as the motor because it is longer and avoids compromising the grip function of the ring and little fingers.

The superficial flexor is detached in the distal part of the palm and sutured to the volar aspect of the distal phalanx of the thumb with a suture passed through the distal phalanx and tied over a button on the dorsal aspect of the nail plate. A soft rubber catheter or a tendon passer is used to bring the tendon through the sheath and pulley mechanism. The stump of the FPL is elevated, and the underlying cortex is roughened before final attachment of the graft or transfer. Carpal tunnel release and flexor tenosynovectomy are usually performed at the same time. The thumb and wrist are immobilized in moderate flexion for 3 weeks, after which active motion is started. If the carpal tunnel was opened to perform tendon reconstruction, the wrist is positioned in neutral for 3 weeks to prevent flexor tendon bowstringing.

Rupture of the Flexor Digitorum Profundus. Rupture of one or more of the deep flexor tendons is not uncommon. If a patient with these ruptures can maintain superficial flexor function (both range of motion and strength), functional loss is minimal. The treatment should match the degree of functional loss. If the distal tendon stump becomes adherent, the patient may lose active flexion but may maintain enough stability of the DIP joint to preclude the need for surgical stabilization.

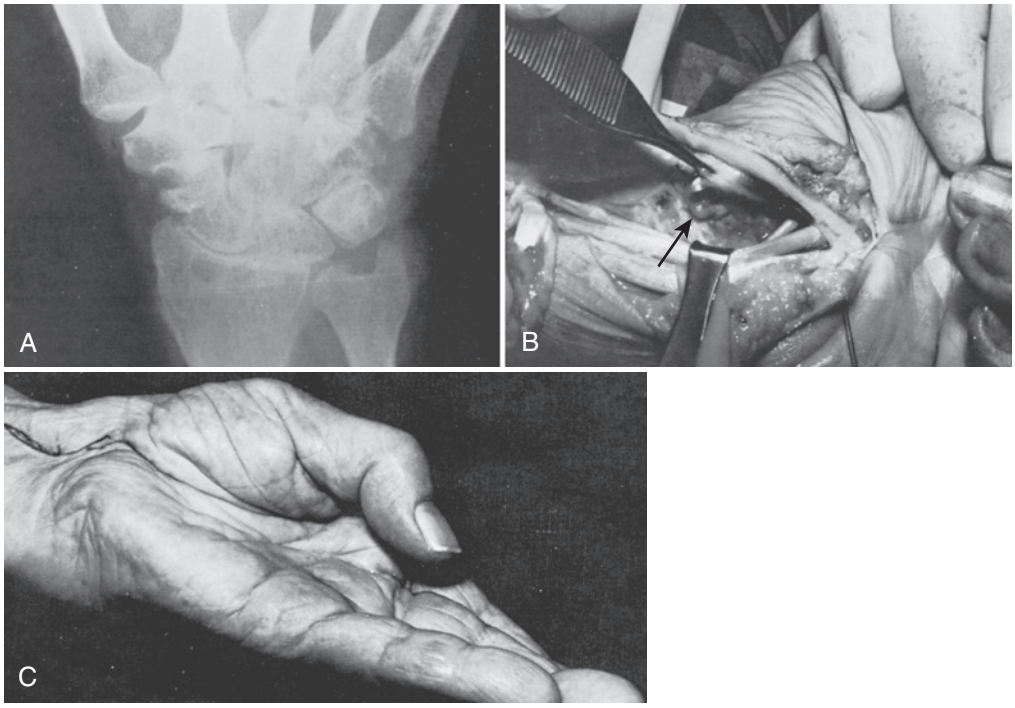

FIGURE 55.20 **A,** Radiograph of a patient with a ruptured flexor pollicis longus (FPL) tendon. Note the osteophyte of the scaphoid, which caused an attrition rupture of the FPL. **B,** Another patient with a ruptured FPL tendon. The flexor tendons are exposed, and the ruptured one is held with forceps. Synovium from the scaphotrapezial joint can be seen (*arrow*). A sharp spur on the scaphoid can be palpated adjacent to this capsular tear. Note the ruptured proximal tendon and intact finger flexors. **C,** Range of motion of the interphalangeal joint of the thumb 4 months postoperatively. (From Nalebuff EA: Reconstructive surgery and rehabilitation of the hand. In Kelly WN, Harris ED, Ruddy S, et al., editors: *Textbook of rheumatology*, ed 2, Philadelphia, 1985, WB Saunders, pp 1818–1826, with permission.)

The most important factor determining the type of treatment is the level of tendon rupture. Flexor tendon ruptures can occur within the finger, at the palm, or at the wrist. The palm is the easiest level at which function can be restored. Ruptures in the palm may be less obvious if the ruptured tendon adheres to the adjacent flexors. This obscures the diagnosis inasmuch as DIP joint flexion is possible with the finger extended and the flexor mass pulls on the distal tendon end through scar tissue; however, this is not so when the finger is flexed actively or passively at the PIP joint. This situation can be confused with a flexor tendon nodule that blocks active excursion of the profundus tendon. Clues to the proper diagnosis include the lack of a palpable nodule and an alteration in resting finger posture, with the finger assuming a more extended position than the adjacent fingers.

Flexor tendon ruptures at the palm and wrist levels are best treated by suturing the distal tendon ends to the adjacent intact tendon, although small bridge grafts can be used at the wrist level. Suturing to adjacent tendon cannot be done if the rupture occurs within the fibroosseous canal. In this case, surgery is performed only to remove diseased synovium from the intact superficial flexor, which is now vital to finger function. Caution should be used when considering staged flexor tendon reconstruction of the FDP through an intact FDS. The results with this technique have not been good. If the DIP joint hyperextends, we prefer to stabilize the DIP joint rather than consider a flexor tendon graft through an intact FDS tendon.

Rupture of the Flexor Digitorum Superficialis. Loss of FDS function alone causes no obvious functional loss. In fact, as described previously in the section on tenosynovitis, we occasionally resect half of the FDS to restore proper function of the deep flexor tendon. The diagnosis of FDS rupture can be made only by careful examination. The treatment should not jeopardize existing tendon function; however, suturing to adjacent tendons within the palm or the wrist is feasible. A tenosynovectomy should be performed to protect the FDP tendons.

Rupture of Both Superficial and Deep Finger Flexor Tendons. The loss of both flexor tendons of a finger results in obvious and significant functional loss: the finger "sticks out" from the other fingers and thereby "gets in the way." Restoration of active finger flexion is a goal that is not always possible to achieve. For this reason, it is far better to be aware of early nodular tenosynovitis and to perform a prophylactic tenosynovectomy before tendon rupture occurs. If ruptures have occurred at the wrist, function can be restored by suturing to adjacent tendons or by a bridge graft of the FDP tendon with the suture lines placed proximal and distal to the carpal tunnel area. It is not necessary to reconstruct FDS tendon ruptures at the wrist. Therefore, an intact portion of it can be used for bridge grafts to reconstruct ruptured FDP tendons. If the rupture is in the palm and the distal tendon stump is long enough, adjacent suturing to an FDP tendon is the best option. If not, transfer of an FDS to the distal profundus stump can be done.

Within the fibroosseous canal, the same problem encountered in tendon laceration at this level exists, except that the situation is worse. The disease is not localized, and the dissection needed for exposure leaves a very poor bed for tendon grafting. In addition, the adjacent joints may have restricted or painful motion (or both). In our experience, free-flexor tendon grafts have not produced good results in patients with rheumatoid arthritis. Occasionally, if no other alternative is available, we perform a staged-flexor tendon reconstruction using a silicone-rubber tendon rod, particularly for younger patients who have minimal joint involvement. The technique is essentially the same as described for posttraumatic flexor tendon reconstruction.

Finally, because of advanced age, poor status of the IP joints, or generalized disease, the wisest choice for some patients in whom both flexor tendons have ruptured within the finger is to fuse both the PIP and DIP joints in a functional position. In this way, satisfactory function can be restored and pain diminished. Suturing the proximal flexor tendon stumps to the base of the proximal phalanx may augment MP flexor strength if there is free excursion of the flexor tendon proximal to the rupture. Of course, this is a last resort, but it should be considered as a method to handle this complicated problem with selected patients.

THE WRIST

The wrist is the "cornerstone" of the hand. A painful, unstable, and deformed wrist impairs hand function regardless of the status of the fingers. In addition, wrist deformity is a major cause of finger deformity, and unless wrist alignment is preserved or restored, correcting finger deformities is difficult if not impossible. An understanding of the pathophysiology of rheumatoid wrist disease is necessary to appreciate the effects of wrist involvement on hand function and finger deformity.

Natural History of Rheumatoid Wrist Involvement

Rheumatoid synovitis follows predictable patterns. In the wrist, the ulnar styloid, the ulnar head, and the midportion of the scaphoid are frequently the earliest to be involved by rheumatoid synovitis. Progressive synovial proliferation in these areas leads to the various patterns of wrist deformity.

In the ulnar compartment, synovitis stretches the ulnar carpal ligamentous complex and may result in changes that Backdahl called the "caput ulna syndrome."[5] This syndrome is the result of destruction of the ligamentous complex, including the triangular fibrocartilage complex, which allows dorsal prominence of the distal ulna, possible supination of the carpus on the hand, and volar subluxation of the ECU. The caput ulna syndrome (seen in up to one-third of rheumatoid patients undergoing hand surgery) can result in significant disability. Patients with this syndrome complain of weakness and pain that are aggravated by forearm rotation. Examination of the wrist reveals prominence of the distal ulna, instability of the DRUJ, limited wrist dorsiflexion, and supination of the carpus on the forearm. As the ECU tendon subluxates volarward, normal function of this tendon is diminished, thereby allowing the wrist to deviate radially and setting the stage for attrition ruptures of the ulnar extensor tendons.

Radiocarpal involvement by proliferative synovitis begins beneath the radioscaphocapitate ligament in the region of the deep volar radiocarpal ligament. Destruction of these ligaments combined with intercarpal ligament damage eventually results in instability of the scaphoid. In this condition, the scaphoid assumes a volar-flexed (vertical) position. There is secondary loss of carpal height and radial rotation of the carpus and metacarpals on the radius.

FIGURE 55.21 This patient had failed metacarpophalangeal (MP) arthroplasties with fractured implants secondary to a fixed-radial deviation deformity of the wrist. This is treated by correction of the wrist deformity and subsequent revision MP arthroplasties. When performing revision MP arthroplasty, the procedure is identical to the initial technique—there are no shortcuts.

The combination of rotatory subluxation of the scaphoid, volar subluxation of the ulnar carpus, and dorsal subluxation of the distal ulna produces relative supination of the wrist in relation to the distal forearm. This common pattern of wrist collapse results in imbalance of the extensor tendons, radial shift of the metacarpals, and ulnar deviation of the fingers.[123] This deformity is thought to be one of the important factors initiating ulnar deviation of the MP joints, as well as recurrence of ulnar deviation after MP joint arthroplasty (Figure 55.21).[113] An untreated, end-stage rheumatoid wrist is dislocated volarward with complete destruction of the carpal bones and complete dissociation of the radioulnar joint. Early surgical treatment can prevent this severe pattern of destruction.

Operative Treatment for Rheumatoid Radiocarpal and Radioulnar Joint Deformities

Surgical procedures for the radiocarpal and radioulnar joints are either preventive or reconstructive. Preventive procedures include synovectomy of the radioulnar and radiocarpal joints, balancing of the wrist extensors, and tenosynovectomy. Reconstructive surgery includes distal ulnar excision, reconstruction of the ulnocarpal ligamentous complex, radiocarpal joint arthroplasty, partial wrist fusion, and total wrist arthrodesis.[66,67,71,92,104]

Synovectomy of the Radiocarpal and Radioulnar Joints

Indications. The indications for wrist joint synovectomy have never been clearly established. No studies have conclusively demonstrated that synovectomy changes the natural course of rheumatoid disease. In addition, because the wrist is a multiarticulated complex joint, total synovectomy is impossible. The indicators used for diagnosing wrist synovectomy vary among hand surgeons. Some have recommended a several-month trial period of conservative therapy before synovectomy. Flatt advocated early synovectomy because of the rapid joint destruction that can occur when active synovitis does not respond to medical therapy.[34] Hindley and Stanley found relative sparing of the midcarpal joint and suggested that early synovectomy may prevent progression.[47] We and others[125] have found that synovectomy can provide significant pain relief, even in patients with advanced disease. Synovectomy in some cases can thus be an alternative to wrist salvage.

We used wrist synovectomy in a small group of patients with persistent, painful wrist synovitis, and minimal-to-moderate radiographic involvement. Many authors, including Brumfield and colleagues,[15] found consistent and dramatic relief for pain and varying loss of wrist motion after wrist synovectomy in long-term follow-up reviews. Grip strength was found to be adequate, not weaker, after synovectomy.

We have found that synovectomy can relieve pain despite moderate destruction of the radiocarpal joint (based on radiographs). Thus, if a patient has clinical evidence of radiocarpal synovitis and other wrist surgery is being done, we include wrist synovectomy combined with denervation even when the radiographs show relatively advanced destructive changes.

Adolfsson and Frisen performed a limited series of arthroscopic dorsal wrist synovectomies with good short-term results.[2] Although we have done only a small series using this technique, early results are encouraging. We have found little morbidity and more rapid recovery after this procedure than after open wrist synovectomy. Synovectomy of the wrist may also be more effective and durable in the era of biologics and disease-modifying agents.

Operative Technique: Dorsal Approach for Synovectomy. The wrist is exposed with a straight, longitudinal incision as described for dorsal tenosynovectomy (Figure 55.22). The terminal branch of the posterior interosseous nerve can be found consistently on the floor of the fourth dorsal compartment, deep in the extensor tendons. This is an articular branch that innervates the wrist joint. It can be resected to partially denervate the wrist joint for pain relief.[16,28,135]

A transverse or "U"-shaped incision is made in the wrist capsule, and a distally based flap is elevated to expose the wrist and intercarpal joints. The distally based capsular flap allows the wrist capsule to be reefed easily to stabilize the joint by limiting flexion. Synovium is usually seen bulging from the proximal and distal carpal rows. Traction applied to the hand distracts the joints and allows synovectomy to be performed with a small rongeur. A small, blunt periosteal elevator can be used to provide better exposure within the joint. Periarticular erosions are treated by curettage. Synovium is removed from the area between the triquetrum and the fibrocartilage.

The DRUJ is exposed through a longitudinal incision proximal to the triangular fibrocartilage. The forearm is rotated to provide exposure as the synovectomy is performed. Bone spurs are removed from the distal end of the ulna, and again, periarticular erosions are treated by curettage. After the synovectomy is completed, the capsular incisions are closed with interrupted

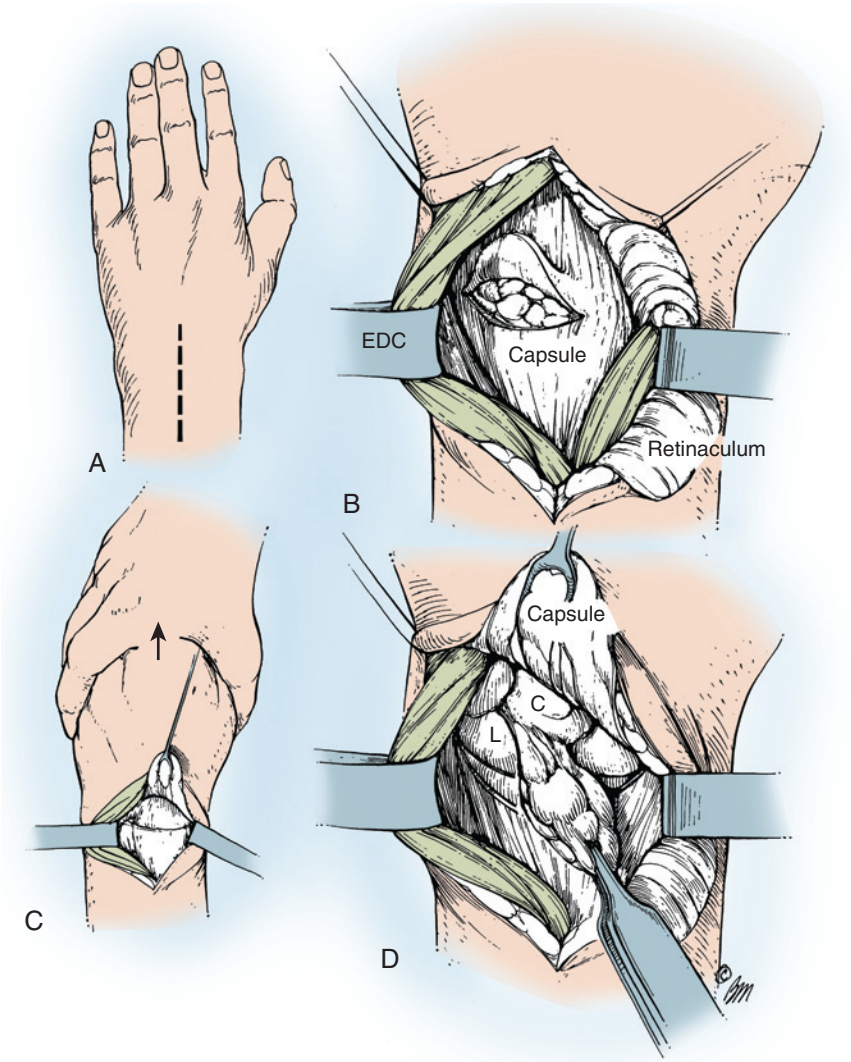

FIGURE 55.22 Technique for wrist joint synovectomy. **A,** The extensor tendons are exposed. A dorsal tenosynovectomy is performed. **B,** The extensor tendons are retracted and the wrist capsule is exposed. **C,** A transverse capsule incision exposes the underlying synovium. **D,** The proximal and distal carpal rows are exposed, and synovectomy is performed with a rongeur. The capsular flaps are preserved for closure. *C,* Capitate; *EDC,* extensor digitorum communis; *L,* lunate. (Copyright Elizabeth Martin.)

nonabsorbable sutures. Closure is performed with the forearm in supination to minimize the tendency for the ulna to subluxate and to allow tighter closure of the DRUJ capsule. Tendon rebalancing, dorsal tenosynovectomy, and relocation of the dorsal retinaculum are performed if necessary. The tourniquet may be released at this point and hemostasis obtained. If the tourniquet is not released, a drain is placed in the subcutaneous area before skin closure.

A bulky compression dressing is applied. The wrist is splinted in neutral, and the forearm is held in full supination with a sugar tong splint. The drain is removed in 24 h. Forearm supination is maintained for approximately 3 weeks, at which time the splints are removed and both forearm and wrist range-of-motion exercises are started.

The length of postoperative splinting depends on the extent of wrist ligament laxity present preoperatively and the degree of ligament disruption found at the time of surgery. The greater the laxity, the longer the wrist needs to be splinted postoperatively. Splinting for 4 to 6 weeks may be necessary to allow enough capsular healing to provide stability. We have found that the optimal range of motion after surgery is 30 to 40 degrees each of flexion and extension.

Operative Technique: Volar Wrist Synovectomy. Volar wrist synovectomy can be done when flexor tenosynovectomy is indicated. Volar wrist synovectomy, in conjunction with wrist flexor tenosynovectomy to prevent destruction of the deep volar ligaments and secondary rotation of the scaphoid, has been advocated by some.

When present, volar wrist synovitis is manifested by bulging of the volar capsule. The skin incision described for volar tenosynovectomy is used; that is, a transverse incision is made over the bulging volar wrist capsule. Traction is applied to the hand, and synovium is removed from the volar portion of the wrist with a rongeur. The capsule is closed with interrupted nonabsorbable sutures. Postoperative management is the same as that described for dorsal tenosynovectomy.

Distal Ulnar Excision and DRUJ Complex Reconstruction

Involvement of the DRUJ is a common cause of disability in a rheumatoid wrist. For this reason, distal ulnar excision and reconstruction of the triangular fibrocartilage are performed frequently in wrists affected by rheumatoid arthritis.

Distal ulnar excision was described first by Smith-Peterson in 1943 for rheumatoid arthritis. It remains our procedure of choice because it is reliable and allows adequate exposure to perform synovectomy of the DRUJ and to reconstruct the triangular fibrocartilage complex.[70] Swanson described distal ulnar excision and replacement with a silicone-rubber implant.[116a] We no longer use this implant because of problems with bone resorption beneath the implant collar, fracture of the implant stem, dislocation of the implant, and particulate synovitis. The importance of soft tissue reconstruction to correct supination of the carpus and subluxation of the distal ulna has been emphasized by many authors.[5] Total loss of the triangular fibrocartilage ligamentous complex complicates correction of the supination of the carpus on the distal end of the forearm and the dorsal prominence of the ulna. Distal ulnar excision for symptoms of the caput ulna syndrome is usually performed in conjunction with dorsal tenosynovectomy and tendon transfer for ruptured extensor tendons or in conjunction with wrist joint synovectomy or wrist joint reconstruction.

Other surgical techniques are available to reconstruct a DRUJ destroyed by the rheumatoid process, such as the Sauvé-Kapandji procedure in which the distal ulna is fused to the sigmoid notch of the radius with resection of a segment of ulna to allow rotation of the forearm.[131] Taleisnik believes that the Sauvé-Kapandji procedure is indicated for younger patients with painful DRUJ dysfunction because it provides stable fixation of the ulnar head, preserves ulnocarpal support, restores forearm rotation, and results in a better cosmetic appearance than does distal ulnar resection.[123] He prefers the Sauvé-Kapandji procedure to distal ulnar resection for patients with impending ulnar translocation not severe enough to warrant radiolunate fusion. In our experience, the Sauvé-Kapandji procedure does not prevent or correct ulnar translocation in a rheumatoid patient.

We prefer radiocarpal fusion for patients with established or impending ulnar translocation of the carpus.[21] In patients with juvenile rheumatoid arthritis who have had spontaneous fusion of the DRUJ, segmental osteotomy of the ulna similar to that done in the Sauvé-Kapandji procedure can be used to restore partial forearm rotation. Recently, we have used variations of partial distal ulna resection (hemiresection/interposition and matched distal ulna resection) for rheumatoid patients with good results.[3,6,84]

Operative Technique: Distal Ulnar Excision and DRUJ Reconstruction. The surgical principles of distal ulnar excision are important and include the following: (1) limited resection of the distal end of the ulna (2 cm or less) to minimize instability of the remaining ulna, (2) synovectomy of the DRUJ, (3) correction of carpal supination by suturing the remnant of the triangular fibrocartilage complex to the dorsal ulnar corner of the radius, and (4) reconstruction of the dorsal capsule and extensor retinaculum with volar-to-dorsal relocation of the ECU if it is subluxated.

The wrist joint is approached through the dorsal longitudinal wrist incision described previously. The extensor retinaculum is opened. It is usually thin or adherent (or both) over the capsule of the distal ulna, which makes separation of these two layers difficult. Identification of the volarly subluxed ECU may also be difficult. The tendon usually can be palpated on the ulnar aspect of the wrist. Frequently, tenosynovium is noted bulging in the region of the sixth dorsal compartment. Occasionally, the entire sixth compartment sheath is destroyed and the tendon is frayed or ruptured. If the ECU has subluxated volarward, it is released and replaced dorsal to the axis of wrist flexion. It can be held in place with a sling of tissue fashioned from the extensor retinaculum.

A longitudinal capsular incision is made over the distal ulna. The capsule and triangular fibrocartilage are reflected from the ulna and preserved. The periosteum of the ulna is elevated, and small bone retractors are placed around the distal ulna, which can be sectioned with a bone cutter, an osteotome, or a power saw. A towel clip is used to apply traction to the bone fragment when the soft tissue attachments are divided. Approximately 2 cm of bone is resected. If excessive bone is removed, stability of the distal ulna may become a problem. The dorsal edge of it should be beveled and smoothed to minimize the risk of postoperative attrition ruptures of the extensor tendons.

After the bone is removed, complete synovectomy of the DRUJ is performed. Although the triangular fibrocartilage often is destroyed, it should be protected during the synovectomy if it is present. Reconstruction of the soft tissue support for both the DRUJ and the radiocarpal joint is important to correct carpal supination and to stabilize the distal ulna. If the triangular fibrocartilage and radioulnar ligamentous complex are present, they are sutured tightly to the dorsal and ulnar aspect of the radius.

Various methods have been used to stabilize the distal ulna after resection of the ulnar head. Blatt and Ashworth incised the volar capsule to form a distally based flap.[9] The flap is brought dorsally and fixed to the ulna to reconstitute the ligament (Figure 55.23).

Linscheid and Dobyns used a different method.[66] A distally based strip of the ECU tendon is detached, woven through the ulnar collateral ligament and any remnants of the triangular fibrocartilage, and sutured to the radius (Figure 55.24). The dorsal radioulnar capsule is closed tightly, with imbrication of the tissues when necessary. This is facilitated by supinating the wrist to relocate the DRUJ. After this, the extensor retinaculum is relocated deep in the tendons. The position of the ECU tendon is corrected if necessary.

Another method uses a distally based slip of ECU tendon.[64] The tendon slip is passed through the distal end of the ulna, through a hole made in the dorsal cortex of the ulna, and is then sutured back onto itself (Figure 55.25).

Ruby and colleagues described transferring the origin of the pronator quadratus to the dorsal aspect of the ulna and placing the muscle belly between the radius and ulna to stabilize the distal ulna after resection of its head.[109] Their long-term results were satisfactory, but their study did not include rheumatoid patients. More recently this has been described by Bain and colleagues in combination with hemiresection arthroplasty.[6]

A Penrose or suction drain can be placed if the tourniquet is not released. A bulky hand dressing is applied with the wrist and fingers splinted in extension and the forearm in supination. The dressing is changed in 24 h, at which time the drain is

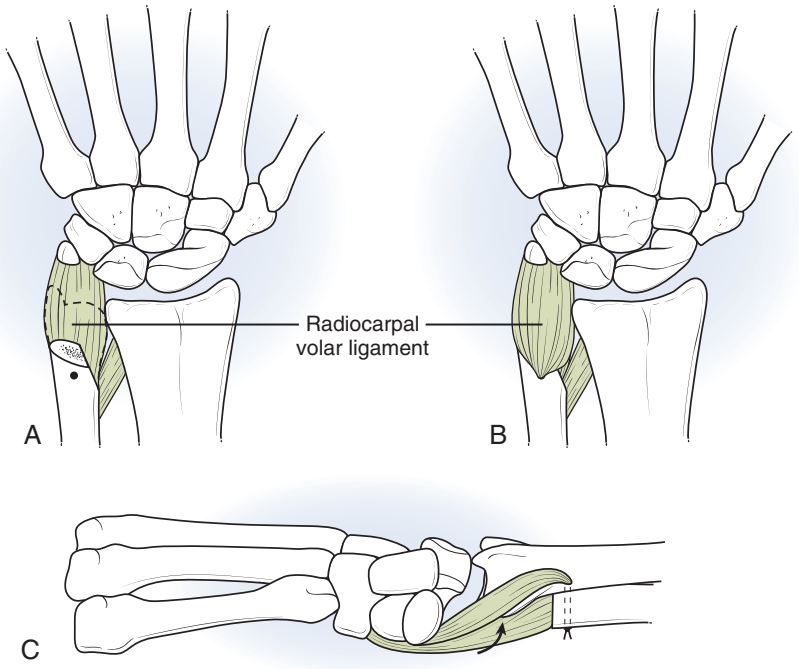

FIGURE 55.23 Stabilization of the distal end of the ulna with a flap of volar capsule. **A,** After distal ulnar excision and synovectomy are completed, a distally based flap of volar capsule is reflected. **B,** The free proximal end is brought dorsalward and sutured to the dorsal cortex of the ulna through drill holes. The flap acts as a volar restraining ligament to prevent dorsal subluxation of the distal ulna. **C,** Volar flap sutured over the dorsal cortex of the distal ulna. (Copyright Elizabeth Martin.)

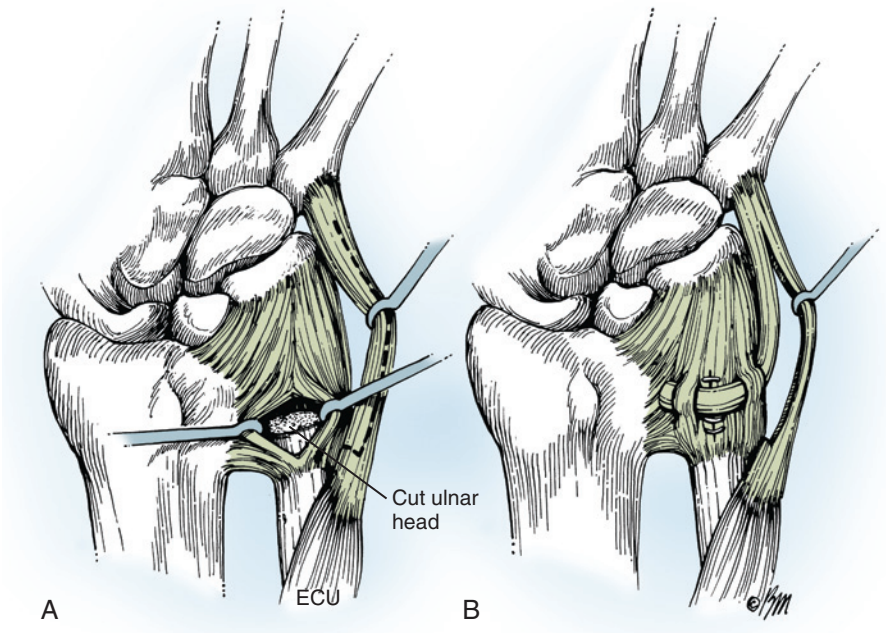

FIGURE 55.24 Reconstruction of the distal radioulnar joint (DRUJ) after synovectomy and distal ulna excision. **A,** The dorsal capsule of the DRUJ is opened longitudinally, a synovectomy is performed, and the distal end of the ulna is excised. (The slip of tendon to be stripped from the extensor carpi ulnaris [ECU] is shown by the *dashed line*.) **B,** A strip of ECU is mobilized, passed through the ulnar aspect of the joint capsule and across the joint's dorsal aspect and sutured to the dorsal capsule over the radius to correct the supination deformity. The radioulnar joint capsule is imbricated to correct the dorsal subluxation of the distal ulna. The dorsal retinaculum can be used to further reinforce the radioulnar joint capsule. The dorsal edge of the distal ulna should be beveled and smoothed to avoid postoperative attrition ruptures. (Copyright Elizabeth Martin.)

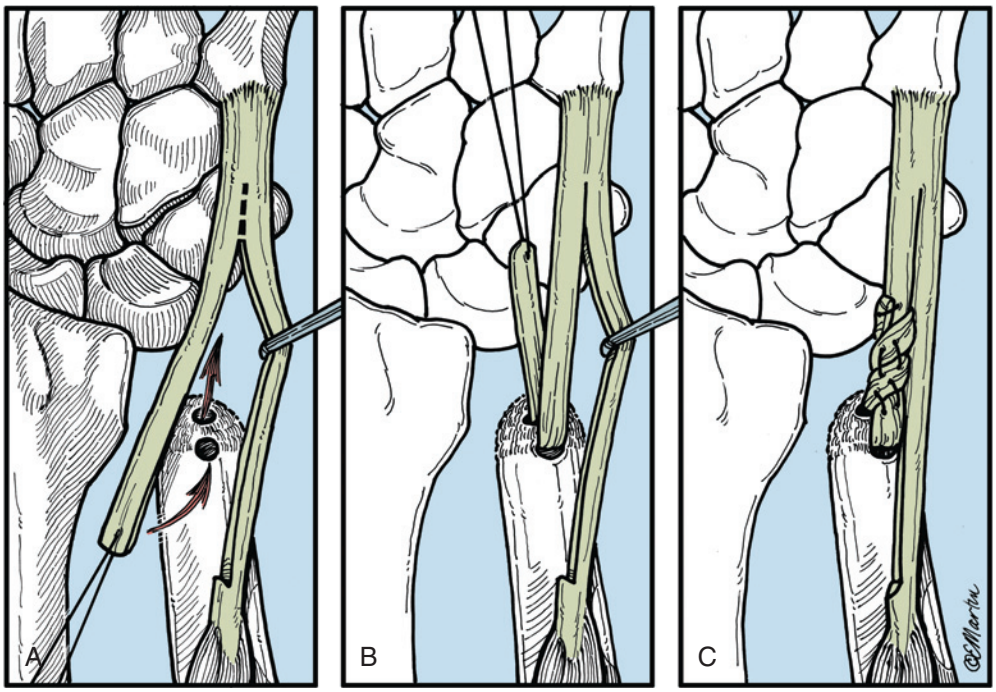

FIGURE 55.25 **A,** The distal end of the ulna has been exposed subperiosteally and osteotomized just proximal to the sigmoid notch. **B,** The extensor carpi ulnaris has been identified and split in half longitudinally from the musculotendinous junction to its insertion at the base of the fifth metacarpal. Half of the tendon is then harvested as a distally based slip. **C,** The proximal portion of the slip is passed through a previously drilled hole in the dorsal distal cortex of the ulna and brought out through the intramedullary cavity. The volar cortex is not violated. The free end of the distally based slip is woven about itself and then sutured under maximal tension to keep the ulna and wrist reduced. (From O'Donovan TM, Ruby LK: The distal radioulnar joint in rheumatoid arthritis. *Hand Clin* 5:249–256, 1989, with permission.)

removed. Finger motion is begun immediately. When the fingers are not being exercised, they are splinted in extension until the patient is able to actively extend them.

If the preoperative deformity or instability was minimal and if a satisfactory ligamentous reconstruction and tight capsular closure were possible at surgery, short-arm splints provide adequate immobilization postoperatively. Occasionally, a sugar tong splint to limit forearm motion is useful for pain relief during the first few days after surgery. Gentle forearm motion is allowed gradually as postoperative pain and swelling decrease. However, if the soft tissue closure is suboptimal, the forearm should be maintained in *supination* with a long-arm splint or cast for at least 3 to 4 weeks to allow soft tissue healing before starting forearm motion exercises. It is not uncommon to have mild crepitus or a click during forearm rotation for the first few weeks after motion is started. This usually diminishes gradually and resolves entirely after several months. It is helpful to warn the patient of this possibility before surgery.

Complications of Ulnar Head Excision. The most frequent complication after distal ulnar excision is painful forearm rotation. This often responds to prolonged splinting and a gentle motion exercise program under the direction of a therapist. No surgery is indicated for 3 to 4 months unless a definite cause of the symptoms is evident. If the symptoms do not abate after several months and the distal ulna is found to be unstable on examination, a soft tissue stabilization procedure using the ECU to reinforce the DRUJ joint capsule can be considered.

We have noted several extensor tendon ruptures after distal ulnar resection in rheumatoid patients. These occurred from

CRITICAL POINTS *Distal Ulnar Resection*

Indications
- Painful synovitis
- Painful/limited DRUJ range of motion
- Extensor tendon attrition rupture

Pearls
- Use a sugar tong splint postoperatively, if necessary, to control pain.
- Click and crepitus are not uncommon for several weeks after surgery but usually resolve spontaneously after several months.

Technical Points
- Use a dorsal longitudinal incision.
- Release and relocate the ECU tendon if subluxated volarward.
- Perform limited resection of the distal ulna (2 cm or less) through a longitudinal capsulotomy.
- Perform synovectomy.
- Bevel the dorsal edge of the ulna to minimize the risk for postoperative tendon rupture.
- Taper the end of the ulna to a smooth "bullet" shape.
- Correct carpal supination by suturing the remnant of the triangular fibrocartilage complex/volar capsule to the dorsal edge of the radius.
- Stabilize the ulna with a tendon slip/pronator quadratus if necessary.
- Reconstruct the dorsal capsule to stabilize and pad the distal ulnar stump.
- Close the skin over a drain.

Postoperative Care
- Apply a short-arm splint for 2 to 3 weeks.
- Allow gentle forearm rotation, as tolerated, and increase forearm motion exercises after 3 weeks.

attrition by the sharp edge of the distal ulnar shaft. We now bevel the dorsal edge of the distal ulna at the osteotomy site and use local tissues to provide a soft tissue layer over the distal end of the ulna after ulnar head resection.

Tendon Transfers to Restore Wrist Balance

A frequent wrist imbalance in rheumatoid arthritis is supination and ulnar translocation of the carpus on the radius. As stated previously, this deformity is associated with the caput ulna syndrome and rotator instability of the carpus. In caput ulna syndrome with volar subluxation or dislocation of the ECU tendon, there is unopposed radial deviation of the carpus from the pull of the radial wrist extensors. This is exacerbated if there is a concomitant intercarpal dissociation with a collapse deformity of the scaphoid.

Clayton advocated correcting wrist imbalance by transferring the ECRL to the ECU in patients who cannot actively deviate the wrist ulnarly.[11,25,52] We have used this transfer in patients with radial deviation of the wrist that is correctable passively. The procedure should be considered in conjunction with wrist joint synovectomy, dorsal tenosynovectomy, and distal ulnar excision. However, indications for this procedure are limited because most of our patients already have advanced wrist involvement with fixed deformity. In these advanced cases, correction requires major reconstructive surgery (wrist fusion).

Preoperatively, to evaluate whether the relocated ECU will function, we place the forearm in supination and evaluate wrist extension. If the ECU functions as an extensor in this position, it will function appropriately in the relocated position. If not, ECRL transfer is indicated.

Operative Technique for ECRL Transfer

After dorsal tenosynovectomy, distal ulnar excision, and ligamentous reconstruction are performed, the ECRL is divided at the base of the second metacarpal. This can be done through either a separate small incision or the primary surgical incision. The tendon is rerouted dorsal to the finger extensors and sutured into the repositioned ECU tendon. At the completion of the transfer, the wrist should be able maintain a neutral position in the coronal plane (radial and ulnar deviation). The wrist is splinted in the corrected position for 4 weeks before beginning exercises.

Extensor Carpi Ulnaris Tendon

Operative Technique for Repositioning. During any surgical procedure on the dorsal aspect of the wrist, the ECU tendon should be released from its volarly subluxated position and repositioned in its normal dorsal position. If the extensor retinaculum has been reflected radially, a strip of this retinaculum can be split and looped around the ECU to hold the tendon dorsal to the axis of wrist flexion. Alternatively, when the retinaculum has been reflected radially and ulnarward, the ulnar portion can be placed deep to the ECU and used as a sling to hold the tendon in the corrected position. If there is a tendency for the tendon to subluxate, it can be sutured to the capsule over the dorsal aspect of the carpus.

Reconstruction of the Radiocarpal Joint

The indications for reconstruction of the radiocarpal joint by either arthrodesis or arthroplasty include deformity and instability that interfere with function, persistent pain unresponsive to conservative therapy, and progressive destruction of the joint seen on radiographic examination.

Historically, arthrodesis has been the reconstructive procedure of choice for the rheumatoid wrist.[93] In 1971, Mannerfelt and Malmsten described the use of a Rush rod that was introduced into the third metacarpal and driven across the radius to obviate the need for external fixation.[67] In 1973, we reported a modification of the techniques described by Mannerfelt for 60 patients who underwent wrist fusion.[61,71] All the patients had relief of pain and improved hand function. Although wrist fusion diminishes pain, wrist motion is lost, which is in itself a disability, especially in patients with stiffness of the opposite wrist.[51]

In the mid-1970s, Swanson developed a silicone-rubber wrist arthroplasty for reconstruction of the rheumatoid wrist. In 1980, we reported early results with 35 Silastic® wrist implant arthroplasties. In 1986, we reviewed the long-term follow-up (average, 5 years) of 71 patients who had undergone wrist arthroplasty with the implants. We found a fracture rate of 20% and a failure rate of 25% when fractures and revisions for pain and recurrent deformity were combined.[12] Subsequent studies by have corroborated these results. Although silicone synovitis has been noted after the use of some silicone-rubber implants in the hand and wrist, this condition did not occur in our series of wrist arthroplasties. Based on experience and these reports, we have abandoned the use of this procedure.

Total wrist arthroplasties have been used with inconsistent results.[26,133] We feel that the potential benefits still are outweighed by the risks and therefore continue to manage painful, destroyed rheumatoid wrists using other methods.

Choice of Operation for the Rheumatoid Wrist

Because of the increased number of surgical options now available for the reconstruction of joints affected by rheumatoid arthritis, preoperative clinical assessment must be done carefully. After evaluation, a considered recommendation for treatment can be made. Patient education, nonoperative treatment (including splinting and the judicious use of steroid injections), and hand therapy with modification of wrist use patterns are all important.[105]

Distal ulnar excision alone may be indicated in a patient whose symptoms are limited to the radioulnar joint and whose radiocarpal joint is stable and functional, even when the radiocarpal joint shows significant destruction on radiographs.[42,43] Distal ulna excision combined with radiocarpal synovectomy can be performed when there is mild-to-moderate loss of articular cartilage from the radiocarpal joint or early erosive changes within the carpus.

We have found that synovectomy alone can slow or even prevent progression in some cases. When soft tissue procedures or limited bone procedures are not appropriate, the decision to perform a total wrist arthrodesis or an arthroplasty must be made. We favor radiocarpal fusions for patients with destruction limited to the radiocarpal joints and/or early collapse patterns of the wrist and whose midcarpal joints are preserved. We advise total wrist fusion in patients who have significant wrist deformity or instability, advanced joint destruction, poor wrist extensor function, or poor bone stock.

Partial Wrist Fusion

Partial wrist fusion has applications in rheumatoid as well as in nonrheumatoid wrist disease.[21,66,92] Limited wrist fusion is useful in rheumatoid patients whose disease has destroyed the radiocarpal joints but has left the midcarpal joints relatively unaffected. Taleisnik demonstrated the paucity of ligaments in the midcarpal region of the wrist.[122] Because the synovium is concentrated in areas with abundant ligaments, the midcarpal area is the last to become involved and is frequently preserved even when the radiocarpal joint is not.

The earliest wrist changes in a rheumatoid patient occur as the volar ligaments stabilizing the proximal row are lost, which results in vertical rotation of the scaphoid and the lunate, ulnar translocation of the lunate, or both. These changes can be arrested in their early stages before progressive collapse and joint destruction occur by fusion of the lunate or scaphoid (or both) to the radius. Of course, a destroyed radiocarpal joint can be salvaged by this fusion as well.[6,66,81,92,103,128] Limited arthrodesis of the involved joints combined with synovectomy of the less involved joints may relieve pain yet preserve 25 to 50% of wrist motion (Figure 55.26).

Operative Technique for Partial Wrist Arthrodesis. The wrist is exposed as described previously for synovectomy. The proximal and midcarpal rows are identified, and a synovectomy is performed with a small rongeur. Articular cartilage is removed from the joints selected for limited fusion. Cancellous bone is exposed by removing or "fish-scaling" the subchondral plate. The contours of the individual carpal bones are preserved to allow apposition of the prepared surfaces. It is important to preserve the overall dimensions of the carpus; that is, the carpal bones should not be "collapsed" onto one another after the cartilage and subchondral plate are removed. Rather, the resulting space should be filled with bone graft. When a proximal row fusion is performed, we usually fuse the radius, scaphoid, and lunate bones. If the articular surface of the scaphoid is preserved, the fusion may be limited to the radiolunate articulation alone, as reported by Chamay and colleagues[18] and by Linscheid and Dobyns.[66] If a midcarpal fusion is necessary, we include all the joints surrounding the capitate.

Autogenous bone graft is used to supplement the fusion site. Cancellous bone is packed between the individual bones to be fused. The distal ulna can be used as bone graft if distal ulnar excision has been performed. Alternatively, bone may be harvested from the distal radius either by removing Lister's tubercle or by making a small window in the distal radius. We prefer internal fixation with multiple 0.045-inch smooth Kirschner wires for the midcarpal joints and small cannulated screws (Acutrak, Herbert-Whipple, or ASIF system) for the radiocarpal joints. Kirschner wires can be cut beneath the skin or left protruding through it. Compression staples can also be used.

Postoperatively, the wrist is immobilized in a short-arm cast for 4 to 6 weeks, at which time the Kirschner wires are removed. Immobilization in a cast is necessary for an additional 3 to 4 weeks until there is evidence of solid fusion on radiographs. We expect to retain 25 to 50% of normal wrist motion after limited wrist arthrodesis.

Taleisnik described partial wrist fusion combined with carpal bone implant arthroplasty in selected rheumatoid patients with radiocarpal destruction or ulnar translocation and an unsatisfactory midcarpal articular surface of either the capitate or the scaphoid.[122] If the articular surface of the capitate head has been eroded, he excises the proximal pole of the capitate and replaces it with either a condylar implant (e.g., a pyrocarbon button with stem) or a soft tissue spacer (e.g., a rolled-up length of tendon graft—"anchovy"). If the articular surface of the scaphoid is unsatisfactory but the capitolunate articulation has been preserved, he fuses the lunate to the radius and replaces the scaphoid with an implant. In both procedures, the radiocarpal joint

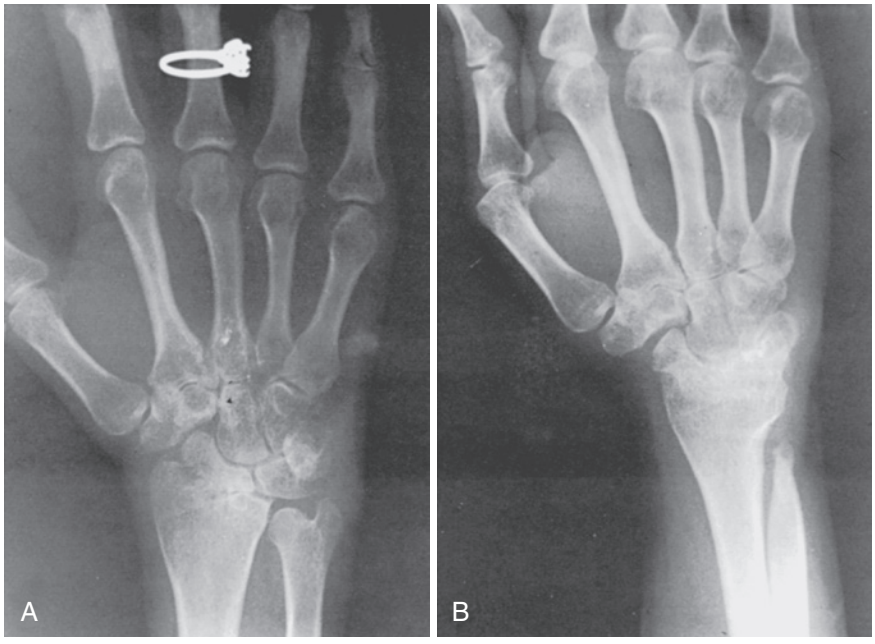

FIGURE 55.26 Partial wrist fusion. **A,** Isolated destruction of the radiocarpal joint and ulnar translocation of the carpus with preservation of the midcarpal joints. **B,** Correction of wrist alignment with preservation of some wrist motion by partial wrist fusion (radius-scaphoid-lunate).

is stabilized and midcarpal motion is maintained. We have found very few indications for this procedure in our practice.

Operative Technique for Wrist Arthrodesis. The wrist is exposed through a dorsal longitudinal incision (Figure 55.27) similar to that for the wrist procedures described previously.[72] A dorsal tenosynovectomy and associated procedures are performed. The radiocarpal joint is exposed by elevating a distally based flap of the wrist capsule. The distal ulna is exposed and excised as described previously. The radioulnar capsule and triangular fibrocartilage are preserved for closure later. With traction and moderate flexion, synovectomy of the radiocarpal joint is performed. The capsule is released from the radial styloid while avoiding the APL and EPB tendons located in the first dorsal compartment. The cartilage and sclerotic bone are removed from the distal radius and proximal carpal row with a rongeur to provide proper alignment. The amount of bone resected is determined by the degree of deformity and subluxation.

In the standard procedure, the medullary canal of the radius is perforated with a pointed awl to provide a channel for the Steinmann pin to be used for internal fixation.[61] The pin is tapped through the carpus and exits between the second and third or between the third and fourth metacarpals, depending on the alignment between the carpus and radius. The pin should exit between the MP joints. After this step, the pin is tapped with a mallet retrogradely into the previously prepared channel in the radius and countersunk approximately 2 cm proximal to the level of the MP joints. Cutting the pointed end of the pin with a sterile bolt cutter minimizes the risk of penetrating the cortex as the pin is advanced by tapping it with a mallet. Power should not be used to insert the pin into the radius because of the increased chance of penetrating or fracturing the cortex. Bone chips from the resected segment of the ulna are packed into the radiocarpal joint before the carpus is impacted against the radius. One or two small staples or an obliquely placed Kirschner wire can be used to provide additional fixation of the radiocarpal joint if necessary. The Kirschner wire generally has to be removed later; the staples can remain in place permanently.

If there is severe loss of carpal bone stock, a Steinmann pin is introduced into the third metacarpal to provide stability. If the MP joints are dislocated and MP joint arthroplasties are indicated, the rod can be drilled through the distal end of the metacarpal and countersunk proximally, and an MP joint arthroplasty can be performed subsequently. If MP joint arthroplasty is not indicated, the Steinmann pin is introduced into the third metacarpal through a hole in the cortex made just proximal to the collateral ligament. This avoids passing the pin through the interosseous muscles and through the MP joint. Leaving the rod buried in the metacarpal has not caused problems.

This method requires that the wrist be fused in a neutral position; that is, the metacarpal is aligned with the radius. We have found that this is an excellent wrist position for most rheumatoid patients and have used this method for patients requiring bilateral wrist fusions. The position of the wrist can be varied only 5 to 10 degrees by adjusting the direction of the pin as it is driven into the radius. The position of the wrist cannot be altered after the rod has been inserted. The single rod, albeit large in diameter, does not provide secure rotatory stability of the carpus to the distal radius.

Feldon's Two-Pin Modification. Feldon uses a modification of the technique described earlier for wrist fusion in both rheumatoid and nonrheumatoid patients. The wrist is prepared as described previously. Instead of using a single large Steinmann pin, two relatively thin (3/32- to 7/64-inch diameter) pins are inserted through the second and third web spaces between the metacarpal bones, across the carpus, and into the medullary canal of the radius. This results in a "stacked-pin" effect in the radius that provides rotational stability, as well as anteroposterior and lateral stability, without the need for supplementary internal fixation (Figure 55.28). The pins are thin enough that they can be bent slightly after insertion into the radius to allow final correction and adjustment of wrist position. Thus, if slightly more dorsiflexion is desired after the rods are in place, the wrist is gently manipulated into the correct position. The use of thinner Steinmann pins minimizes the potential for compression of the intrinsic muscles of the hand (interossei) by a large rod.

Care must be taken to insert the pins through the dorsal portion of the web space to avoid potential damage to the neurovascular structures in the palm. It is sometimes helpful to make a small window in the dorsal cortex of the distal radius. This allows the pins to be guided into the medullary canal of the radius under direct vision. The pins may lie dorsal to the capitate bone because of the configuration of the wrist; this is not of concern (see Figure 55.29, *B*). An additional cancellous bone graft can be harvested from the distal radius as well. The pins are cut short beneath the skin in the web spaces and

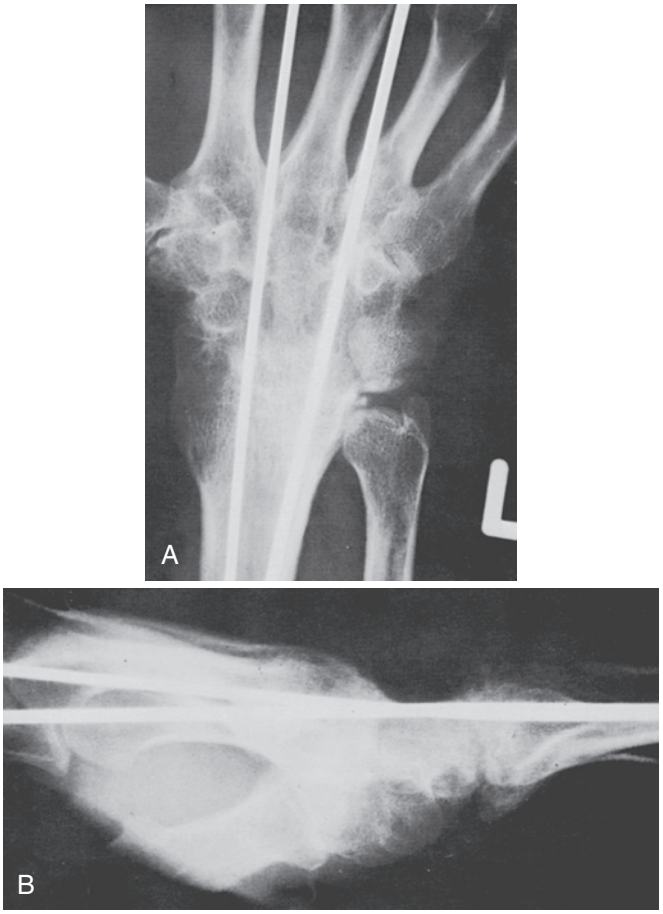

FIGURE 55.28 Wrist fusion using dual Steinmann pins for internal fixation. **A,** Solid fusion was obtained with the wrist in slight ulnar deviation. **B,** The wrist is in slight extension. The pins are positioned on the dorsal aspect of the wrist to minimize the risk for damage to the soft tissue structures in the palm and to facilitate placement of the pins in the medullary canal of the radius. Note that the Steinmann pins may be dorsal to the fused carpus.

removed after solid bone union has occurred, usually between 4 and 6 months postoperatively, or if they become symptomatic. However, the pins have been left in situ for many years without adverse effect. The pins are removed under local anesthesia by making a vertical incision in the web space and grasping the end with a 10- to 12-inch "diamond jaw" needle holder.

Solid union has been obtained in more than 30 patients over the past several years. This technique has been used in rheumatoid patients even when carpal bone stock has been minimal. Advantages of this method include ease of hardware insertion and removal, the ability to adjust the position of the wrist at the time of surgery in both the anteroposterior and lateral planes, and stable fixation even with suboptimal bone stock. Recently, we have been using ASIF wrist fusion plates with good results for rheumatoid patients with good bone stock (Figure 55.29).

Tourniquet release, drainage, and closure are performed as described previously. A bulky dressing and a sugar tong or long-arm splint are used until the first dressing change. After this, only a short-arm cast or a splint is necessary if the internal fixation is stable and the soft tissue reconstruction of the DRUJ allows early forearm rotation. The forearm is held in supination for 2 to 3 weeks if this joint must be protected. Short-arm cast or splint immobilization facilitates early motion of the elbow and shoulder, as well as the forearm, and is much easier for patients to tolerate. The patient may walk with platform crutches 7 to 10 days after wrist fusion.

When the single Steinmann pin technique is used, the pin is not removed unless it causes discomfort or migrates. The pin rarely migrates distally enough to penetrate the skin. Should this occur, it is removed and supplementary external fixation is used if appropriate. Reintroduction of a pin that has come through the skin should be avoided because of the risk for infection.

Combined Wrist Arthrodesis and MP Joint Arthroplasty

It is not unusual for a patient with severe rheumatoid arthritis to require both wrist fusion and reconstruction of the MP joints (Figure 55.30). Ordinarily, this would necessitate two separate surgical procedures. However, we have performed both procedures during one operation.[76,122] Such a combined procedure is indicated for patients with painful wrists (but without significant wrist deformity) who are appropriate candidates for MP joint arthroplasty. The single, definite contraindication to this combined procedure is a severely deformed or dislocated wrist that would require extensive exposure to correct the radiocarpal alignment.

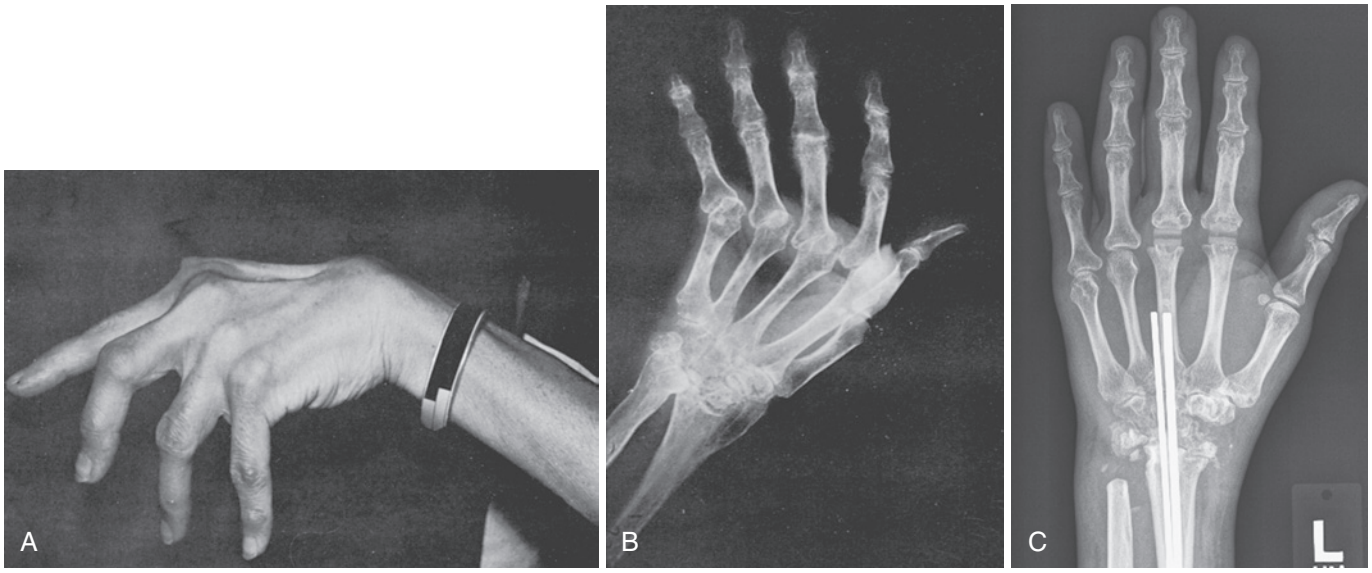

FIGURE 55.30 Wrist fusion combined with metacarpophalangeal (MP) joint arthroplasty. **A,** Photograph of patient with a painful wrist and dislocated MP joints. **B,** Radiograph demonstrating the destroyed wrist joint and dislocated MP joints. **C,** Radiographic appearance after arthroplasty. Note how far the Steinmann pin has been countersunk into the third metacarpal.

A less extensive exposure, without dislocation of the radiocarpal joint, can be used to prepare the wrist for fusion. This allows the MP joint arthroplasty to be performed with minimal chance of excessive postoperative edema and its attendant risk of skin sloughing and other complications. The procedure is a modification of the technique for wrist arthrodesis described earlier.

Complications of Wrist Fusion

In our experience, pseudarthrosis occurs infrequently in rheumatoid patients, is usually asymptomatic, and rarely requires further treatment. Other complications occur rarely but include deep wound infection, superficial skin necrosis, transient median nerve or superficial radial nerve compression, fracture of the healed fusion, and pin migration.

THE METACARPOPHALANGEAL JOINTS

The MP joint is the key joint for function of the fingers. Rheumatoid destruction of it results in severe deformity and functional loss. The MP joints are condylar and allow motion in two separate planes. Because of this anatomic configuration, their inherent stability is less than that of the IP joints, and they are therefore more vulnerable to the deforming forces present in rheumatoid arthritis.

The causes of deformity of the MP joints have been the subject of much debate. There are multiple factors leading to the classic ulnar drift and volar dislocation seen in rheumatoid patients. An understanding of the various factors leading to these deformities is important for the surgeon dealing with these problems.[88,90]

Etiology of Rheumatoid MP Joint Deformities

The deforming forces begin as proliferative synovitis stretches the capsule and ligamentous structures. In the MP joints, this proliferation occurs in the recess between the metacarpal head and attachment of the collateral ligament and results in destruction of the collateral ligaments. Flatt believes that loosening of the ligaments markedly decreases the stability of the joint and is one of the early factors leading to progressive deformity.[38] The normal MP joint is stable in full flexion, with little lateral motion possible in this position. However, in a rheumatoid patient, the flexed MP joint can often be deviated 45 degrees. The following factors affect the altered MP joint and ultimately result in volar subluxation or dislocation and ulnar deviation: wrist deformity, flexor and extensor tendon forces, intrinsic muscle imbalance, and the forces of gravity and pinch.

Shapiro showed that wrist collapse leads to radial deviation of the metacarpals and, subsequently, to an increased tendency for ulnar deviation of the MP joints affected by the rheumatoid process.[113] This is an expansion of the intercalary collapse theory of Spoor and Landsmeer.[114a]

The extrinsic extensor and flexor tendons also affect ulnar drift. In the rheumatoid hand, the extensor tendons are often shifted or even dislocated ulnarward. Selective stretching of the radial-side transverse lamina (sagittal band) fibers by synovial proliferation and the normal ulnar shift of the extensor tendons during MP flexion as the fourth and fifth metacarpal bones descend (which may be increased in patients with rheumatoid arthritis because of laxity of the fourth and fifth CMC joints) contribute to this ulnar subluxation.

Flexor tendon forces also contribute to MP joint deformity.[114] Flatt demonstrated that during pinch there are palmar and ulnar forces in the index and long fingers and a palmar force at the MP joint level in all four fingers.[38] Stretching of the collateral ligaments of the MP joints, which support the flexor tendon sheath, allows a volar and ulnar shift of the A2 pulley mechanism, which can increase the tendency toward MP joint deformity significantly. The anatomic configuration of the joint and the forces of the intrinsic mechanism contribute to the tendency toward ulnar deviation.

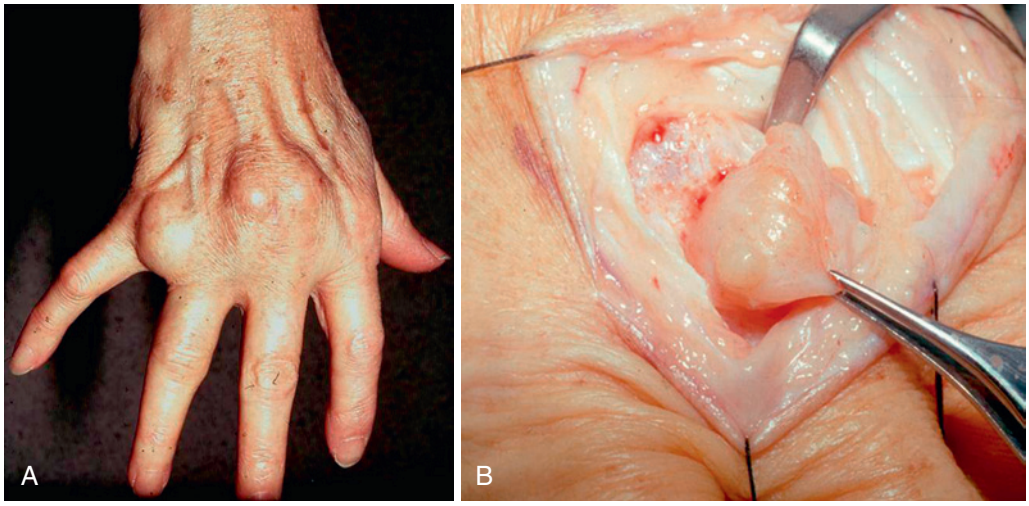

FIGURE 55.31 **A,** Metacarpophalangeal (MP) joint synovitis affecting the long and ring fingers. **B,** Proliferative synovium is excised via MP joint arthrotomy.

Indications for Operative Treatment of MPJoint

Operative procedures for the MP joint are either preventive or reconstructive. The only potentially prophylactic procedure is synovectomy (Figure 55.31). Reconstructive procedures include surgical reconstruction of the soft tissue and various types of arthroplasties.

Synovectomy

The indications for either synovectomy alone or synovectomy with soft tissue reconstruction are difficult to define because no study has shown definitively that these procedures affect the natural course of the disease. Although synovectomy is considered by some to arrest local disease or to slow progression of the disease and allow erosive lesions to heal, recurrence is always possible. Recurrent synovitis may take place as early as several months or as late as many years after the procedure. It is impossible to predetermine patients in whom recurrence is likely to develop. In addition, 30 to 50% of patients with rheumatoid arthritis will have spontaneous remission, thus making it difficult to evaluate the effectiveness of any preventive surgery.[34] Because of the inconclusive results after synovectomy, most rheumatologists and surgeons today take a conservative attitude toward synovectomy of the MP joints.

Synovectomy is indicated for the infrequent patient with persistent MP joint synovitis, minimal radiographic changes, and minimal if any evidence of deformity. Intermittent, painful synovitis (i.e., infrequent) is an additional indication for synovectomy. Before considering synovectomy, the patient must have undergone an adequate trial of conservative therapy, which includes systemic medication, splinting, and up to three local intraarticular corticosteroid injections.

We consider a 6- to 9-month period of conservative therapy necessary before performing synovectomy. Within this period, some patients being considered for the procedure will have a medical remission, and unnecessary surgery can be avoided. Others undergoing conservative therapy will show rapid joint destruction, so these patients would not have good results from synovectomy. The third group of patients undergoing conservative therapy will continue to have persistent localized synovitis with minimal, if any, deformity and minimal radiographic changes. These patients, we anticipate, will benefit on a long-term basis from synovectomy.

Combined Synovectomy and Soft Tissue Reconstruction

Our indications for combined synovectomy and soft tissue reconstruction to correct deformity are limited because the persistence of multiple deforming forces and progression of the disease frequently result in recurrence. Synovectomy with soft tissue reconstruction is considered in a patient who is a candidate for synovectomy but who also has early volar subluxation and ulnar drift. If the disease appears to be progressing slowly and the patient is young, soft tissue reconstruction may slow recurrence of the deformity. Occasionally, a patient is initially seen with an inability to extend the MP joint actively because of complete dislocation of the extensor tendons but has the ability to maintain active extension if the MP joints are extended passively. Extensor tendon relocation with synovectomy is indicated for this patient. We have found that soft tissue surgery alone is indicated infrequently.[45]

Contraindications to MP Joint Surgery

There is a group of patients for whom surgery should not be suggested. Even though these patients have definite subluxation, ulnar drift, advanced radiographic changes, and a weakened grip, they are usually free of pain and have good hand function. Although MP joint deformity is present, surgery will not increase joint function and would probably weaken their grip, especially in those with good PIP joint function. Such patients are best treated with night splints and evaluation every 3 to 4 months. If they maintain satisfactory function, observation should be continued. If they show progressive deformity and dysfunction, they will become candidates for operative treatment.

Operative Techniques for MP Joint

Synovectomy

MP joint synovectomy on multiple joints is performed through a transverse incision centered over the dorsal aspect of the joint.

Synovectomy for a single joint can be performed through a longitudinal incision located just ulnar to it. A longitudinal incision is also used when multiple procedures are being performed in one finger to decrease the risk for excessive swelling. The initial skin incision must not be too deep to avoid damage to the extensor tendons that lie immediately beneath the skin. The dorsal veins and nerves are located within fat pads in the interdigital spaces. These structures must be protected because injury to them can result in painful neuromas or dysesthesias or increase the risk for postoperative swelling (or both), with resultant adherence of the extensor mechanism.[72]

The mechanism is exposed, and the areolar tissue overlying the sagittal bands is separated so that the degree of extensor tendon subluxation to the joint's ulnar side can be determined. In early cases, there is minimal subluxation of the tendon and no significant intrinsic tightness. We prefer to expose the joint by making an incision through the ulnar-side sagittal band, volar to and parallel with the extensor tendon; others enter the joint from the radial side. For patients without extensor tendon subluxation, Swanson described splitting the extensor mechanism in the middorsal line to avoid damaging either the radial or the ulnar sagittal bands. Intrinsic release is performed at this stage, if necessary (see later).

The extensor mechanism is separated from the underlying capsule with small, blunt-tipped scissors. This dissection is often difficult because the capsule has been thinned and disrupted by proliferating synovium that has herniated dorsally or because the capsule is scarred and adhers to the extensor mechanism. The transverse orientation of the fibers of the sagittal bands serves as a guide to the plane between the capsule and the extensor mechanism, which is retracted radially and the joint capsule is incised transversely. Bulging synovium is excised by sharp dissection or with a small rongeur. Traction applied to the finger allows easier access to the volar pouch. Synovectomy of the recess between the collateral ligament and metacarpal neck is performed with a small pituitary rongeur or a curet. Cystic areas of the metacarpal head undergo curettage.

After completing the synovectomy, the extensor mechanism is repositioned. If it subluxates ulnarward, it must be secured as described previously. No attempt is made to close the dorsal capsule. The wound is closed over a Penrose or suction drain placed in the subcutaneous area, and a bulky conforming dressing is applied. Active motion is begun 1 to 2 days postoperatively, and a program of dynamic splinting similar to that after MP joint arthroplasty is maintained for 4 weeks.

Intrinsic Release

Intrinsic release is usually performed in conjunction with MP joint synovectomy or arthroplasty, but it can be performed as an independent procedure in one or more fingers (Figure 55.32).[45] Either a transverse or a longitudinal incision can be used. After the dorsal neurovascular structures have been mobilized and the extensor mechanism has been identified, areolar tissue is freed from the entire ulnar side of the mechanism. The sagittal, transverse, and oblique fibers of the intrinsic mechanism are identified. A longitudinal incision is made in the sagittal band adjacent to the extensor tendon. A curved hemostat is passed beneath the transverse and oblique fibers and exits around the thickened portion of the oblique fibers. These structures are divided, and a section of the oblique fibers can be excised. If release of the bony attachment is required to obtain adequate position of the MP joint, the proximal portion of the tendon is grasped with a clamp, and the tendon attachment into the proximal phalanx is sectioned with scissors.

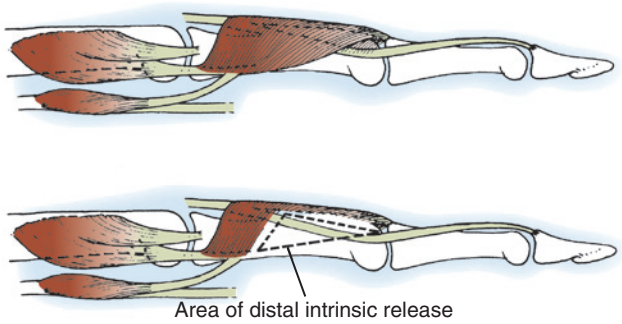

FIGURE 55.32 Technique for ulnar intrinsic release. The ulnar intrinsic tendon is exposed, and a triangular section of the extensor hood, including the lateral band, is resected.

In the small finger, the abductor digiti quinti is a strong, ulnar-deforming muscle that must be released. A blunt retractor is used to hold the skin and subcutaneous tissue out of the way. The fascial sheath is incised to expose the hypothenar muscles. The abductor digiti quinti is separated from the flexor digiti quinti and selectively sectioned at its musculotendinous junction. The ulnar neurovascular bundle lies just volar to these muscles and must be protected. Flatt emphasized the importance of releasing only the abductor digiti quinti without sacrificing the flexor digiti quinti. He showed that releasing the flexor digiti quinti results in limited MP joint flexion and increased weakness.[33]

Harris and Riordan described an alternative method of releasing tight intrinsics. After the intrinsic mechanism is exposed, a triangular portion of the oblique fibers is excised.[45] With this method, the transverse fibers, which act as a yoke to flex the MP joints, are left intact. However, this method does not release the bone insertion and may not provide adequate correction in some patients.

Flatt described a modified intrinsic release that he uses for early subluxation of the MP joint or for persistent flexion contracture. He releases the portion of the transverse fibers that aids flexion of the MP joint.[33] If tightness persists after this release, the bone attachment of the intrinsic tendon is released as well.

Crossed Intrinsic Transfer

The crossed intrinsic transfer is an additional method to restore finger alignment and prevent recurrent ulnar drift. In principle, the intrinsics are released from the ulnar sides of the index, long, and ring fingers and transferred to the radial aspect of the adjacent fingers to provide additional radial stability. We do not use this procedure frequently. Oster and colleagues found that it can provide effective long-term correction of ulnar drift.[99] In a subsequent follow-up study, El-Gammal and Blair found a decrease in active range of motion of the MP joint after 5 years.[32]

Crossed intrinsic transfer is performed in conjunction with MP joint synovectomy and soft tissue reconstruction. The intrinsic tendons of the index, long, and ring fingers are exposed

as described previously. In Straub's method, the tendon is released from the extensor mechanism over the midportion of the proximal phalanx and dissected proximal to its musculotendinous junction. The bony attachment is released from the base of the proximal phalanx to allow free excursion of the muscle–tendon unit. Each tendon is transferred to the radial intrinsic mechanism of the adjacent finger. The tendon is woven into the lateral band and sutured.

Flatt and associates believe that the intrinsic transfer performed as described here may cause a swan neck deformity. They suture the intrinsic tendon to the radial collateral ligament of the adjacent finger rather than weaving the tendon into the lateral band of the adjacent finger.[33]

In the Flatt method, the intrinsic tendons are exposed and released as described earlier. The extensor expansion is opened on the radial side to expose the collateral ligament. The intrinsic tendon is sutured to the radial collateral ligament at its phalangeal attachment with several interrupted 4-0 sutures. The tension at which the attachment is made is correct if complete finger alignment is restored at the completion of the repair. The finger is splinted for 3 weeks before beginning exercises. A dynamic splint is then applied and used for an additional 3 weeks.

Extensor Tendon Relocation

Realignment of an ulnarly dislocated extensor tendon is necessary to correct deformity, restore extension, and prevent recurrent dislocation. The degree of extensor tendon subluxation varies from minimal to complete dislocation with the tendon fixed within the intermetacarpal valley. Several different operative techniques have been described to centralize the extensor tendon.

Longitudinal incisions are used when only one or two fingers are to be done. If all four fingers are to be done, adequate exposure can be achieved through a transverse incision. The subluxated extensor tendon is identified, and the sagittal fibers along its ulnar side are incised. A hemostat is placed beneath the transverse and oblique fibers of the intrinsic tendon on the ulnar side, and an intrinsic release is performed. The extensor tendon is dissected free and relocated over the dorsal aspect of the MP joint. The tendon can be maintained in the relocated position by one of three methods. The simplest, but least effective, method is to reef the stretched radial sagittal fibers. After the tendon has been relocated, the lax fibers are imbricated with absorbable 4-0 suture. We use this procedure when there is no tendency for the tendon to resubluxate. If, however, there is a tendency for radial deviation of the wrist, which increases the tendency for ulnar subluxation of the tendon, more secure fixation of the tendon must be obtained.

An effective method is described by Harrison. A 4-cm slip of extensor tendon, 5 mm wide, is detached proximally and freed distally to the distal portion of the MP joint. This slip is passed through a hole drilled into the dorsal cortex at the base of the proximal phalanx.[46] Zancolli described a method for rebalancing and stabilizing the extensor mechanism by attaching the extensor tendon to the proximal phalanx through drill holes.[141]

We have had good results with direct attachment of the extensor tendon to the proximal phalanx. The attachment is made by either suturing the tendon to the joint capsule just proximal to the base of the proximal phalanx or attaching the tendon directly to the dorsal aspect of the proximal phalanx with a suture passed through drill holes in the proximal phalanx or a small bone anchor using absorbable sutures (Figure 55.33).

FIGURE 55.33 Ulnarly subluxated extensor tendons of the index and long fingers have been relocated by using small bone suture anchors to attach the extensor tendons directly to the proximal phalange, just distal to the metacarpophalangeal joint.

Postoperative Management of Soft Tissue Procedures

At the completion of the surgical procedure, a bulky conforming dressing is used to immobilize the hand with the MP joints in extension and correct alignment. The drain placed in the subcutaneous area is removed on the first postoperative day. Exercises for PIP joint motion, supervised by a hand therapist if necessary, are started immediately, and the MP joints are splinted in extension and slight radial deviation for 4 to 6 weeks. A "resting" splint is used at night for 3 months to maintain finger position. Long-term splinting and carefully supervised therapy are important in preventing recurrence of the deformity.

MP Joint Arthroplasty in Rheumatoid Arthritis

In the late 1950s and early 1960s, several authors described techniques to correct the deformities of arthritic MP joints. The procedures included joint resection and interposition of soft tissues between the metacarpal and proximal phalanx. Despite improved digital alignment and moderate motion from these resection arthroplasties, the results were unpredictable and recurrent deformities were common.

Swanson, in the mid-1960s, devised a flexible hinge implant to improve the reliability of the resection/interposition arthroplasty. The silicone-rubber implant was designed to function as an internal splint that would maintain alignment and stimulate a capsular response termed *encapsulation*.[116] The flexible stem of the implant was allowed to glide in the medullary canal. The combination of the implant and scar tissue provides joint stability and alignment while allowing a reasonable arc of motion. Swanson called his implant a "load-distributing flexible hinge." That silicone implant is composed of a high-molecular-weight, crosslinked silicone elastomer. In 1975, an improved silicone elastomer with a fourfold increase in tear propagation strength was made available for use. The most recent modifications have

further increased fatigue/crack growth resistance and have been used since 1986. The result was a resection arthroplasty with a painless and functional arc of motion that was much more reliable and predictable than a resection arthroplasty alone.

Flexible-hinge arthroplasty has remained the most accepted and widely performed technique for the treatment of severely involved MP joints in rheumatoid arthritis. However, strict attention to technical detail is necessary for this operation to succeed. Recently, new implant designs have sought to replicate the anatomy of the MP joint to preserve function and improve on the limitations of silicone arthroplasty.

Indications

The goals for implant arthroplasty of the MP joint are relief of pain, correction of deformity, and improvement in function and appearance. Implant arthroplasty should fulfill the following criteria: restoration of functional range of motion, adequate stability, resistance to lateral and rotational forces, biologic compatibility, adequate material properties, and the opportunity for satisfactory soft tissue reconstruction.

The typical patient with rheumatoid arthritis has a combination of MP joint ulnar deviation and volar subluxation deformity, pain from synovitis, deformities at other joints, and grasp weakness. MP joint arthroplasty can improve the patient's function by correcting deformity, as well as relieving pain and improving appearance. Combined or staged procedures (or both) may be necessary (Figure 55.34).

Initially, MP joint reconstructive surgery was advocated only for patients with severe deformity and limited function. This standard has been modified with increased confidence in the outcomes of arthroplasty. Current trends favor surgery in less deformed hands for the following reasons: (1) less bone is resected in patients with mild deformity than in those with severe deformity; and (2) soft tissues (e.g., the capsule and collateral ligaments) are better preserved, which ultimately facilitates soft tissue reconstruction. Nevertheless, silicone MP joint arthroplasty is not indicated for mild deformities. Likewise, radiographic deformity alone is not a sufficient indication for MP joint reconstruction. Realistic goals and expectations by both the patient and the surgeon are necessary ingredients for a successful outcome in MP joint surgery.

Contraindications

Active infection is a contraindication to MP arthroplasty. A previous MP joint infection is a relative contraindication to implant surgery. The surgeon should give consideration to the duration of the infection and the pathogens involved. Bone loss and soft tissue problems after an adequately treated infection may preclude arthroplasty. Other general contraindications include inadequate skin coverage, compromised neurovascular status, insufficient bone stock, and an irreparable musculotendinous system.

Patients with severe, progressive rheumatoid arthritis (arthritis mutilans) may have inadequate bone to support or receive the implant. Typically, the phalanges and metacarpals of patients with juvenile rheumatoid arthritis have very small intramedullary canals that may make it impossible to insert even the smallest implant. In such cases, simple resection arthroplasty should be considered to realign the digits. Extensor tendon dysfunction must be considered but it is not a contraindication to MP joint

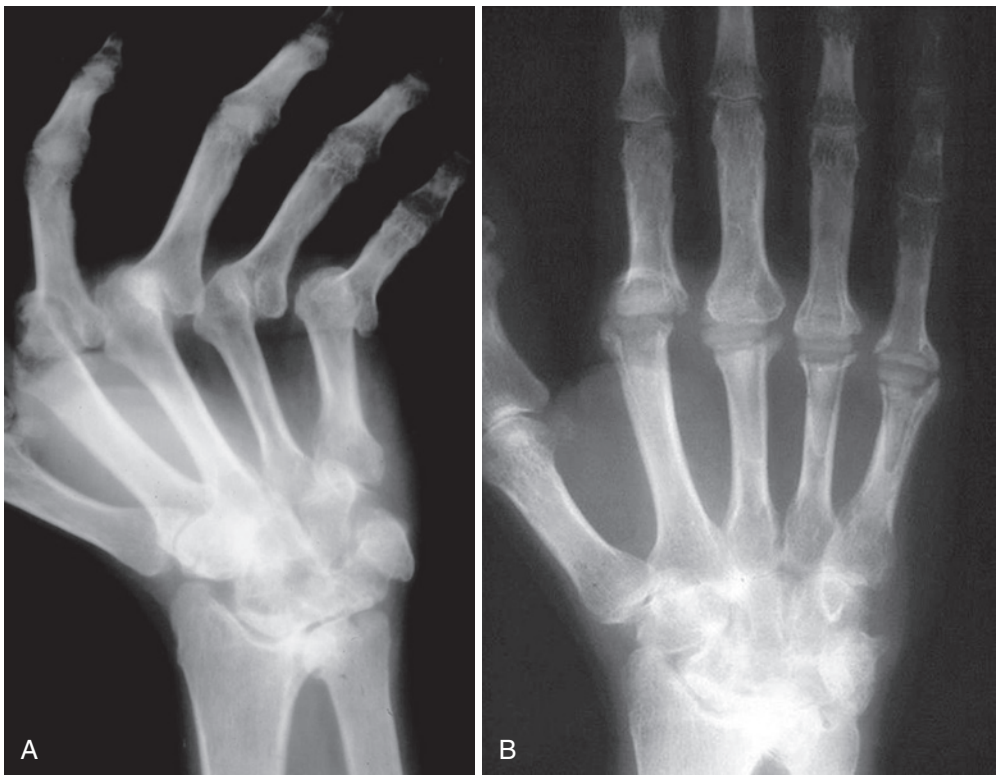

FIGURE 55.34 **A,** Radial deviation of the wrist should be addressed prior to metacarpophalangeal (MP) joint arthroplasty. **B,** In this patient with a painless and supple wrist in spite of degenerative changes on radiograph, the compensatory radial deviation deformity corrected spontaneously after MP joint arthroplasties corrected ulnar deviation of the fingers.

arthroplasty. MP joint arthroplasty and extensor tendon reconstruction can be done as either a combined procedure or in stages.[77]

Patients with multiple deformities from rheumatoid arthritis may require a staged reconstruction.[77] Wrist deformity and pain must be considered when planning MP joint surgery. We have found that many of our patients with ulnar deviation deformities of the MP joints compensate (involuntarily) by radially deviating their wrists to help align their fingers with the forearm. This occurs in patients with supple, painless wrists in spite of moderately severe radiograph changes at the radiocarpal and/or midcarpal joints. In these patients, the radial deviation deformity corrects automatically after the MP joint alignment is improved by arthroplasty (see Figure 55.34). However, a fixed radial deviation deformity of the wrist can lead to recurrent ulnar deviation of the fingers after arthroplasty (see Figure 55.21); if there is significant wrist pain, hand function may still be limited even after successful MP joint reconstruction. Therefore, the wrist problem should be addressed before or in conjunction with MP joint reconstruction.

Arthroplasty Options

Many implants have been used over the past 30 years in an attempt to achieve pain-free, well-functioning MP joints. Such implants can be categorized into one of three design types: metal-hinged prostheses (Flatt), flexible implant (Swanson), and third-generation prostheses. The first hinged prostheses used for MP joint arthroplasty were simple metal uniaxis hinges. Evolution of this type resulted in multiaxis hinges with combinations of metal, ceramic, and polymer components. Despite early promising results, recurrent deformity, dislocation, and loosening plagued these designs in the longer term.

Flexible silicone implants have been the most extensively used and studied and currently remain the implant of choice. Despite their limitations, they are relatively easy to implant, can be revised without undue difficulty, and are reasonable in cost. The newer designs of silicone implants (e.g., NeuFlex® and SBI) have more cube-shaped barrels that better approximate the shape of a normal MP joint and are available in both straight and preflexed configurations. These are now preferrable to the older Swanson design.[36,101,136]

The group of third-generation prostheses includes surface replacement and hybrids of hinged and flexible ones. The most recently studied is the pyrolytic carbon MP implant. They have an articulating, unconstrained design with a hemispheric head and grooved, offset stems to re-create the bony anatomy. The material is made of an isotropic carbon coating over a graphite substrate and has wear properties similar to those of ceramic. The designs were developed to provide greater strength and durability.

At this time we believe that there are limited indications for surface replacement MP arthroplasty of any type in rheumatoid patients because the outcomes have been variable with high rates of subsidence in patients, and complication and revision rates higher than those for silicone MP joint arthroplasty.[100]

Surgical Technique

Flexible Implant Arthroplasty. There are three major design choices in flexible implant arthroplasty: the original Swanson design (Wright Medical), the Small Bone Innovations (SBI) flexible implant, and the NeuFlex (DePuy) implants. The surgical technique for each of the designs is essentially identical. A single longitudinal incision can be used when the surgery is confined to a single digit.

When two or more arthroplasties are done simultaneously, a single transverse skin incision is made over the affected MP joints. With multiple joint implantations, surgery is started on the index finger and proceeds sequentially to the little finger. In patients with rheumatoid arthritis, the skin is often thin and care should be taken to avoid damage to the underlying veins, superficial nerves, and extensor tendons. The skin is retracted with sutures, and the extensor mechanism of each digit is exposed by blunt dissection. It is usually necessary to divide the junctura between the index and middle fingers and to separate the conjoint tendon going to the ring and little fingers.

Attenuation of the radial sagittal band fibers and ulnar translocation of the extensor tendons are common. The tendons and extensor mechanism are elevated from the underlying joint capsule after the ulnar side of the extensor tendon is identified and freed. Release of the shortened ulnar sagittal band is often required to mobilize the extensor tendon. We prefer to approach the joint from the ulnar side to release the fibers (Figure 55.35). A longitudinal incision is made between the volar edge of the extensor tendon and the sagittal fibers. Adherences between the extensor tendon and the underlying joint capsule are freed, and the tendon is retracted to the radial side to expose the MP joint capsule.

The ulnar intrinsic tendon is identified and released in most cases (Figure 55.36). Passing a right-angled clamp around the tendon will help isolate it and protect the neurovascular bundle volar to it. It is tagged with a suture if a crossed intrinsic transfer or lengthening is planned. Release of the ulnar intrinsic can help correct ulnar deviation of the finger. If the intrinsic is not contributing to the deformity at the MP (or the PIP) joint, we do not divide it.

A longitudinal midline incision is made through the joint capsule, and the exposed synovium is removed. The collateral ligaments usually need to be released to correct the deformity

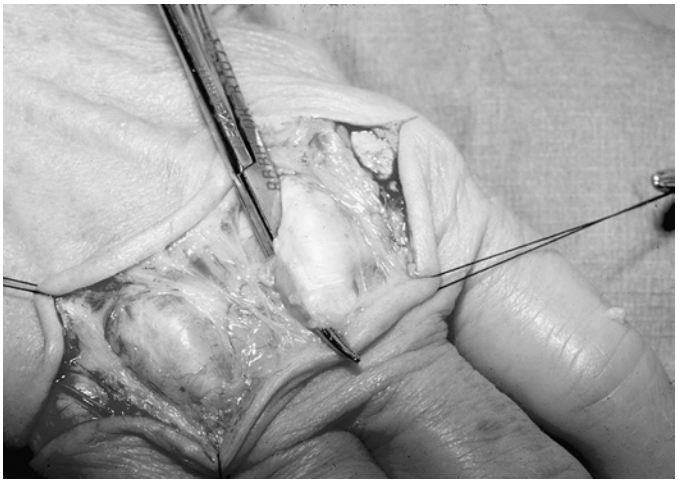

FIGURE 55.35 A transverse incision is used to expose the metacarpophalangeal joints. The superficial nerves and veins that run between the metacarpal heads are preserved. The ulnar sagittal band is identified with a hemostat and then released with a transverse incision parallel to the extensor tendon.

FIGURE 55.36 The ulnar intrinsic is identified in the hemostat (*arrow*) and relaxed to correct the significant ulnar deviation of the metacarpophalangeal joint.

FIGURE 55.38 This preoperative radiograph demonstrates dorsal erosion of the proximal phalanx of the index finger (*arrow*). This should be recognized preoperatively to avoid perforation of the proximal phalanx or excessive bone resection of the metacarpal (or both).

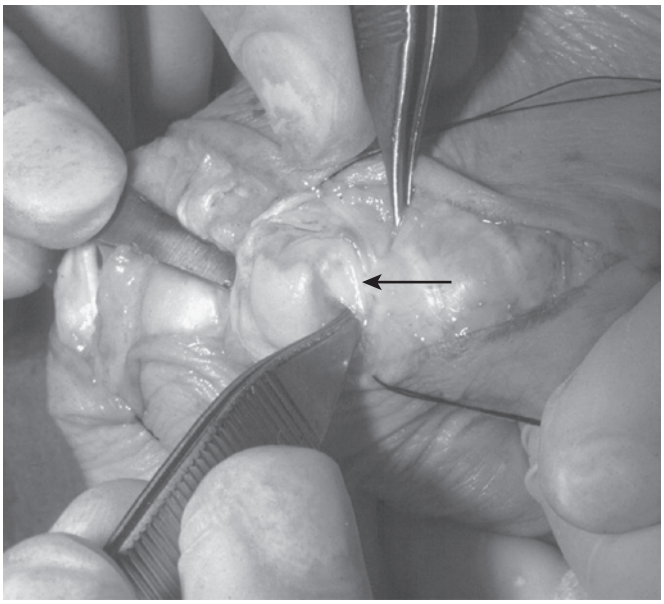

FIGURE 55.37 The capsule has been incised and the metacarpophalangeal joint flexed. The collateral ligament can then be identified and released, if necessary, from the metacarpal neck (*arrow*).

or allow access to the joint, or both. However, if there is minimal deformity and the collateral ligaments are competent, release of the ligaments may not be necessary.

A knife blade is placed in the collateral ligament sulcus at the metacarpal neck and swung dorsalward along the neck to detach the origin of the collateral ligament while preserving its distal attachment to the proximal phalanx. Flexion of the joint facilitates this step (Figure 55.37). Preservation of the radial collateral ligament is especially important for reconstructing the joint. Reattachment of this ligament allows correction of the ulnar deviation deformity and provides resistance to the lateral forces generated during pinch.

Before the metacarpal head is resected, the configuration of the base of the proximal phalanx should be checked. If dorsal erosion has occurred, the base of the proximal phalanx is squared by resecting bone from the volar portion of the base of the phalanx (Figure 55.38). In this case, less of the metacarpal head will be resected. If the proximal phalanx is not checked first, too large a space for the implant can result after bone has been resected from both sides of the joint to provide flush surfaces for the barrel of the implant to rest against. If the preoperative radiographs are unclear, a small portion of the metacarpal head can be removed to allow visualization of the joint before the entire metacarpal head is resected.

The metacarpal head can now be resected. The periosteum is incised transversely at the proposed resection site on the dorsal aspect of the metacarpal neck. The periosteum is left intact proximally to provide tissue for reattachment of the collateral ligament and capsule (Figure 55.39). With the blade of a small oscillating saw oriented perpendicular to the shaft, the metacarpal head is resected level with the origin of the collateral ligaments. This is best done with the joint flexed and a flat elevator placed on the volar surface of the metacarpal for support. The synovectomy can now be completed and the amount of space available for the implant checked by applying distal traction to the finger. If there is not enough space to accommodate the implant, more of the metacarpal head is resected. It is better to err on the side of too little initial bone resection than too much.

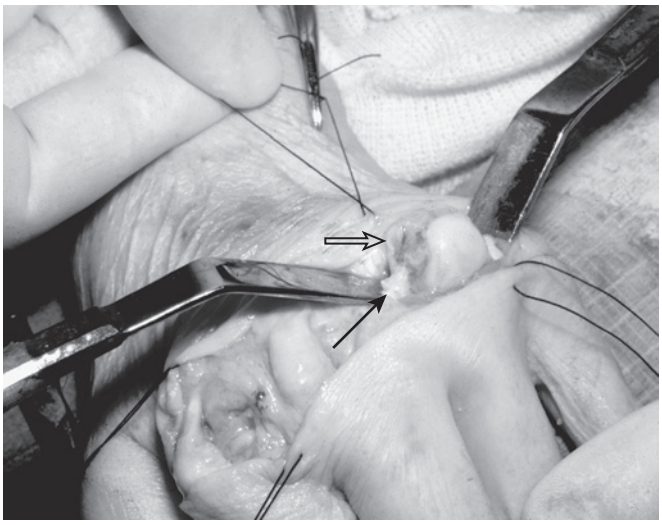

FIGURE 55.39 After the collateral is released (*closed arrow*), the periosteum is stripped proximally (*open arrow*) to provide tissue for repair of the collateral ligament when needed.

FIGURE 55.41 A trial implant is in place, and adequate space for the implant is demonstrated.

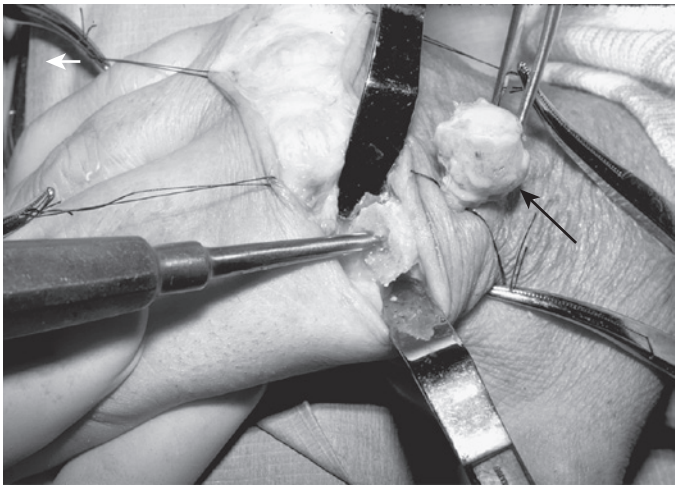

FIGURE 55.40 The metacarpal head has been removed (*arrow*) perpendicular to the metacarpal, and the medullary canal is perforated with an awl.

Flexion of the joint exposes the base of the proximal phalanx. The base is brought dorsal to the metacarpal. Resection or release of the volar plate may be necessary to allow adequate exposure and alignment of the proximal phalanx. This may also gain additional space for the implant after bone resection and preclude the need for additional bone removal. Care is taken to avoid injury to the flexor tendons while releasing the volar plate. A limited flexor tenosynovectomy can be performed at this time if needed, and flexor tendon excursion can be checked.

The base of the proximal phalanx should be exposed completely. An oscillating saw or rongeur is used to provide a base flush with the proximal phalanx. Usually only the joint margins or, if necessary, a thin portion of the subchondral bone needs be removed.

After bone removal is completed, a pointed awl is introduced into the medullary canals of the proximal phalanx and metacarpal (Figure 55.40). The phalanx is prepared first because it usually determines the size of the implant to be used. This prevents overreaming of the metacarpal. The exception to this is in the fourth (ring finger) metacarpal. The canal of it is generally narrower than that of the ring finger and is prepared first to avoid overreaming the proximal phalanx. Rasps are used to shape a rectangular opening in the proximal phalanx, which helps resist rotation of the implant stem. Power burs with a blunt leading tip can be helpful when the diaphysis is constricted. For the index and long fingers, the rectangular opening should be angled so that it is slightly more dorsal on the ulnar side. This will supinate the fingers slightly, which facilitates opposition to the thumb and thereby chuck pinch. In the other fingers, the rectangular opening is made parallel to the volar surface of the proximal phalanx. Preparation of the metacarpal is similar, with the rectangular opening being parallel to the bone's volar surface.

At this point it is essential to confirm that there is sufficient space for insertion of the implant. A 1-cm space is ideal and usually allows placement of the implant without buckling (Figure 55.41). If the space is too small, insertion of the implant will be difficult and subluxation can occur and result in limited joint motion or recurrent deformity (or both). The space can be increased by several methods: release or resection of the ulnar intrinsic and capsule, release or resection of the volar plate, and resection of additional bone.

The joint is now ready for insertion of the implant and soft tissue reconstruction. A 2-0 absorbable suture is woven into the radial collateral ligament at the base of the proximal phalanx for the index and middle fingers. Traction applied to the suture after placement deviates the proximal phalanx radialward if the suture has been properly placed (Figure 55.42). The collateral ligament need not be repaired for the ring and little fingers unless necessary to correct finger alignment. The radial collateral ligament of the index and middle fingers is generally sutured to the periosteal sleeve on the dorsal and radial aspect of the metacarpal. The ligament can be reattached through drill

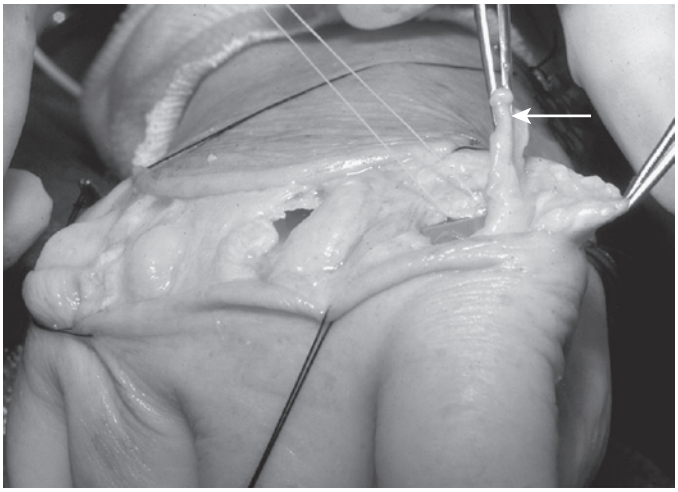

FIGURE 55.42 The radial collateral ligament is held in forceps (*arrow*) and prepared for repair in slight overcorrection.

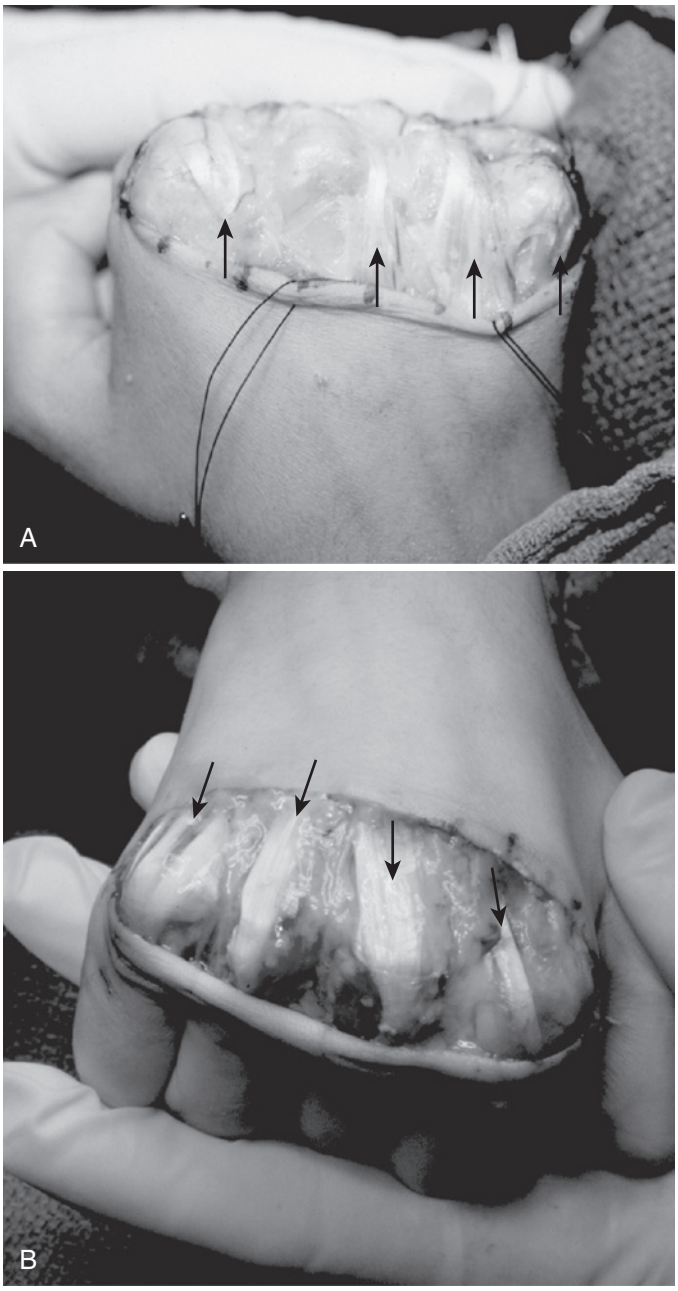

FIGURE 55.43 Example of extensor tenodesis. **A,** The extensor tendons are ulnarly subluxated (*arrows*). **B,** Tenodesis of the tendon to the proximal phalanx has been performed. With full metacarpophalangeal flexion, the extensor tendons remain centralized (*arrows*).

holes on the dorsal/radial edge of the metacarpal if insufficient periosteum is present. The suture is not tied until after the implant is in place. If the radial collateral ligament is so attenuated that it cannot be reattached, the volar plate can be used to reconstruct the ligament.[60]

The implant is inserted with smooth forceps to minimize injury to its surface. Implant insertion is done with the metacarpal and the proximal phalanx positioned at right angles to one another. Generally, the metacarpal stem is inserted first. The central portion of the implant is held with a smooth instrument while the phalanx stem is inserted. The joint is extended to seat the implant. The surgeon should check to be sure that both stems of the implant are in their respective medullary canals. If the implant buckles with the joint extended or dislocates with the joint flexed, there is not enough space and either a soft tissue release or additional bone resection must be done.

The finger is held in extension and slight radial deviation while the collateral ligament suture is tied with sufficient tension to maintain the joint in 5 to 10 degrees of radial deviation. Redundant capsule is trimmed, and the capsule is closed to cover the implant. Capsular closure helps protect against dislocation of the implant and speeds the encapsulation process. If doing multiple implants, the most radial finger is done first and the more ulnar digits aligned to it. Our technique of MP joint arthroplasty is demonstrated in Video 55.1.

Extensor Tendon Centralization. Laxity of the radial sagittal fibers with ulnar displacement of the extensor tendon after insertion of the implant typically requires reinforcement of the radial side. If there is mild subluxation, placement of several 4-0 absorbable mattress sutures shortens the radial sagittal fibers and brings the extensor tendon into a centralized position. If the tendon is dislocated or does not stay centralized during passive MP joint flexion, a more formal centralization procedure is necessary, as described previously. Once all implants are in place, the previously divided tendon junctura can be repaired, if necessary, to help prevent tendon subluxation (Figure 55.43).

At the conclusion of the procedure, the fingers should align in slight radial deviation. Passive MP joint flexion of 70 to 80 degrees should be possible without capsular suture failure or extensor subluxation. The skin edges are closed with 5-0 nylon sutures. In most cases, with careful attention to hemostasis, the skin is closed with the tourniquet still inflated. A drain placed in the subcutaneous space helps prevent postoperative hematoma formation. A well-padded hand dressing is applied with the MP joints supported as follows: the position of immobilization of the MP joints is determined by their preoperative position. If the major problem was ulnar deviation or subluxation without fixed flexion, the fingers are placed in a functional position with the MP joints slightly flexed. If the patient had severe MP joint flexion deformity preoperatively with weak or absent extension, the MP joints are splinted in extension. This may result in interphalangeal flexion because of tight flexor tendons

but usually corrects as the soft tissues stretch over time. Each finger is maintained in slight radial deviation with tape supporting the ulnar side of the proximal phalanx to protect against ulnar deviation. The wrist is supported in slight extension and neutral deviation by a plaster splint that also supports the MP joints in the desired position. The PIP joints are usually left free.

Technical Points. An alternative approach to exposure of the joint is through the stretched radial sagittal fibers. This method requires shortening of the radial sagittal fibers once the implant is in place.

Consideration of release of the ulnar intrinsic tendon should be based on the amount of deformity present and the finger involved. Specifically, the ulnar intrinsic provides a supination force for the index finger and is helpful in pinch. Therefore, it can be left intact when the deformity is mild and correctable without release. The final decision for release of the ulnar intrinsic can be made after resecting the metacarpal head in patients with mild deformity. If the MP joint deformity cannot be corrected completely, the intrinsic should be released.

Intrinsic release may also correct a concomitant swan neck deformity by decreasing the extensor force to the PIP joint. However, intrinsic division reduces the patient's ability to spread the fingers in a normal fashion after the arthroplasty. Lengthening of the intrinsic tendon is an alternative to complete division. This should diminish the deforming force while preserving some ulnar intrinsic function. Keeping the intrinsics intact should also be considered for patients with significant laxity (e.g., those with SLE). Complete ulnar intrinsic release in such patients may result in a radial deviation deformity after reconstruction.

Inadequate bone resection or soft tissue release can result in not enough space for placement of the implant, causing implant fracture or limited motion, or both. Dislocation of the implant can occur if too much bone is resected or if there is inadequate soft tissue release. Sharp bone edges must be smoothed to prevent injury to the implant.

Perforation of the dorsal or volar aspect of the proximal phalanx can occur during preparation for the distal stem. Typically, an unrecognized deformity of the base of the proximal phalanx leads to perforation. This is not usually a problem if the stem is redirected distal to the perforation.

Rehabilitation

Most MP joint reconstructions are now performed on an outpatient basis. We recommend that the dressing be changed and the drain removed in 1 to 2 days. A static splint to maintain the MP joint in the corrected position (nearly full extension and slight radial deviation) is applied and supplemented with soft tape to keep the fingers in proper alignment. It is clear, however, that a single postoperative protocol does not work for all patients who have undergone MP arthroplasty. A splinting and exercise program for each patient needs to be specifically designed around that person's preoperative deformity and the condition of the soft tissues at surgery.

The initial Swanson protocol used a dynamic splint with slings under the proximal segments of the fingers to maintain MP joint extension and slight radial deviation. We found that this method often resulted in limited flexion of the ring and little fingers and modified it by leaving the slings off these fingers (Figure 55.44). Now we use low-profile custom volar splints to support the MP joint in nearly full extension for 6 weeks; a lip on the ulnar side controls radial deviation. Generally, the PIP joints are left free and motion of them is encouraged. The splint is removed for range-of-motion exercises several times daily. If the PIP joints are supple, splinting them in extension during the MP joint exercises facilitates obtaining MP joint flexion. Careful postoperative monitoring is necessary to be sure that the reconstructed joints are responding as

FIGURE 55.44 **A,** A low-profile dynamic extensor splint can be used to support the metacarpophalangeal (MP) joints in extension while allowing active flexion. **B, C,** A short-arm cast extended distally to support the MP joints in extension is an alternative to dynamic splinting in selected patients. Note the use of tape to maintain MP joint alignment.

desired. The protocol should be changed as necessary to accommodate the patient's progress.

Currently, for most patients we use a short-arm cast extended distally to support the MP joints in about 30 degrees of extension and leave the IP joints free for 4 to 6 weeks after removal of the sutures. For patients with severe preoperative flexion deformities, the MP joints are held in full extension for 4 to 6 weeks. Gradual mobilization is started after the cast is removed, and a period of dynamic splinting may be helpful after the cast is discontinued. Use of a static splint to maintain the corrected position at night for 3 months is recommended.

The need to customize postoperative splinting and therapy for each patient by taking into account the nature of the disease (e.g., rheumatoid, psoriatic, lupus) and the severity of the deformity before arthroplasty, as well as the condition of the soft tissues and flexor and extensor tendons, cannot be emphasized enough. For example, patients with supple PIP joints tend to flex these joints rather than the reconstructed MP joints during grasp. For these patients, postoperative MP joint flexion can be maximized by having them exercise while wearing finger splints that limit PIP joint motion (Figure 55.45). Careful planning and close follow-up maximize hand function after MP joint arthroplasty.

Complications

Complications associated with MP joint arthroplasty include recurrent ulnar deviation, extensor lag, limited MP joint flexion, implant fracture, infection, and silicone-induced particulate synovitis.[41] Most patients have some recurrent ulnar deviation and loss of MP joint extension over time. Bieber and colleagues reported on 210 Swanson-design MP implants.[8] These patients were monitored for an average of 5.3 years. At the initial postoperative evaluation, ulnar drift improved from the preoperative average of 25 degrees to <5 degrees. The preoperative average extension deficit decreased from 56 to 10 degrees, whereas the average range of motion increased from 17 to 51 degrees. At long-term postoperative evaluation, the average ulnar drift had increased to 12 degrees, the average extension deficit had increased to 22 degrees, and the average range of motion had decreased to 39 degrees.

In another long-term follow-up study, Kirschenbaum and coworkers reported on a series of 144 arthroplasties at an average of 8.5 years after surgery.[59] They found an average recurrence of 7 degrees of ulnar deviation, improvement in mean extension to a range of 7 to 19 degrees, and a mean range of flexion from 56 to 66 degrees. At the time of the last follow-up, motion of the MP joints had not deteriorated significantly. However, range of motion alone is not the only determinant of success or failure of MP arthroplasty in any given patient.

Reported fracture rates for all designs of MP silicone implants range from 1 to 26%. When earlier (less tear-resistant) designs are excluded, the incidence of implant fracture varied from 0.9 to 10%. The studies of Bieber and associates and Kirschenbaum and coworkers found fracture rates of 0% and 10%, respectively, for the Swanson design.[8,59]

Encapsulation of the implant tends to maintain a functional joint even with implant fracture. However, with a significant increase in ulnar deviation or shortening of a finger, implant failure should be suspected and can be confirmed with radiographs of the hand. Burgess and coauthors reported the

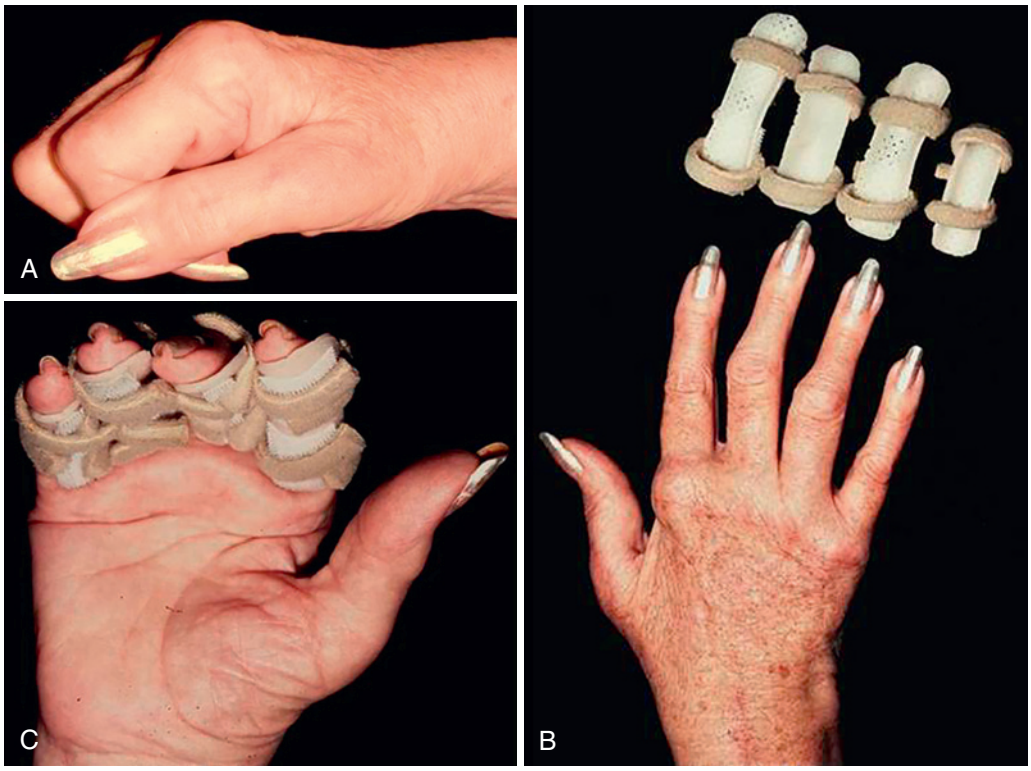

FIGURE 55.45 **A,** Supple proximal interphalangeal joints allow grasp with minimal metacarpophalangeal (MP) joint flexion. **B, C,** In patients with good interphalangeal (IP) joint flexion, MP joint motion after arthroplasty can be maximized by using splints to keep the IP joints in extension during postoperative exercises.

results of their series of MP arthroplasty revisions, which demonstrated satisfactory clinical, if not optimal, objective outcomes.[17]

Titanium grommets have been used to protect the stems of the implant against the bone edges and may decrease implant fracture rates.[78] Schmidt and associates evaluated the effect of grommet use in 151 Silastic MP arthroplasties.[111] There were no significant differences in clinical outcomes with respect to swelling, correction of ulnar deviation, range of active movement, and grip strength. However, the use of grommets slightly reduced reactive osteolysis, protected the spacers from breakage, and slightly decreased the amount of pain with only a few additional complications in the midterm 3.9-year follow-up. The favorable bone response and better bone preservation at the metaphysis with use of grommets, as described by Swanson, were not seen. As such, the main advantage seems to be prevention of implant fracture. Insertion and fitting of grommets, however, add to the complexity of the procedure. We limit their use to cases with previous implant fracture or when the resected bone edges are particularly sharp.

Infections around implants are rare, and rates of deep infection requiring excision of the implant have varied from 1.6 to 9%. Removal of the implant with a short period of antibiotic coverage generally controls the problem. We do not usually reinsert an implant after an MP joint infection has been brought under control. By removing the implant, the operation is converted to a "resection" arthroplasty. Range of motion is reduced, but pain is eliminated and digital alignment can be maintained by splinting for 6 weeks.

Outcomes

In patients with rheumatoid arthritis, the ability to correlate clinical and radiographic parameters to subjective patient interpretation of outcome is difficult, if not impossible. Patient satisfaction and radiographic parameters have not shown significant correlations. The results of MP joint arthroplasties are as varied as the patients undergoing them. Chung and colleagues reviewed all published series of the Swanson MP joint arthroplasty used for the treatment of rheumatoid deformity.[23] Based on these authors' findings, use of the Swanson implant has been shown to effectively correct ulnar drift deformity and improve the appearance of the rheumatoid hand. Several major research design deficiencies hindered analysis, including unclear overall design, lack of uniform outcome measurements, confounding patient characteristics and clinical factors, and varying follow-up intervals.

One of the most important considerations in MP joint arthroplasty is restoration of function. The literature indicates that the expected active range of motion is 40 to 50 degrees (with passive motion typically being greater) after uncomplicated arthroplasty. After implant arthroplasty, the functional arc usually is shifted to greater extension, which is generally advantageous for hand function.[23,139] Postoperative range of motion is influenced by many factors, including the type of arthritis, the condition of adjacent joints, the controlling tendons, and the tissue elasticity of the patient.

Hume and colleagues reported that a functional arc between 33 and 73 degrees is necessary for most activities of daily living.[49] It is important to understand that range of motion alone may not be the ultimate determinant of the outcome of MP joint implant arthroplasty. Despite good motion, hand function can be compromised if finger stiffness or poor position limits grasp or pinch. Rothwell and associates, in a prospective study, showed improvement in standardized hand function tests.[108] In the final analysis, patient satisfaction may be related most to pain relief and improved appearance at moderate-term follow-up.

Quantitative assessment of hand function related to activities of daily living may be a more meaningful outcome measure than recording range of motion, correction of deformity, strength, and radiographic changes. Rothwell's study included the evaluation of hand function after Silastic MP arthroplasties with the Baltimore quantitative test of upper extremity function.[108] The results demonstrated that MP arthroplasty significantly improved hand function within 6 weeks and the benefits were maintained up to 4 years. Most improvement occurred in functions requiring pinch, span, or hook grip. The authors attributed this to correction of ulnar drift, stabilization of the fingers for pinch grip, and the change in arc of MP joint motion, which restored the ability to open the hand for grasp. The gains in hand function should continue provided that there is no further deterioration in thumb or wrist function. The patients in whom scores declined between 1 year and 3 to 4 years also showed significant deterioration of the shoulder or elbow, which affects ultimate hand function.

In our practice it is common for patients with bilateral hand deformities to request MP joint arthroplasties in the second hand. *To us, this is the best test of patient satisfaction with the operation.*

THE PROXIMAL INTERPHALANGEAL JOINTS

Synovectomy

Although synovectomy is performed infrequently at the wrist and MP joints for the reasons discussed previously, the indications for synovectomy of the PIP joint are broader. Progressive PIP joint synovitis that stretches the extensor mechanism results in a boutonnière deformity that is difficult to reconstruct. The outcome of PIP joint arthroplasty is less reliable than MP joint arthroplasty, and PIP joint fusions are more disabling. For these reasons, preservation of PIP joint function is important. In addition, the PIP joint is more stable than the MP joint, and recurrent deformity after synovectomy is less common than after MP joint synovectomy. PIP joint synovectomy is associated with relatively little morbidity.[4,137]

Operative Technique

The joint is exposed through a slightly curved incision on the dorsal aspect of the finger (Figure 55.46). The extensor mechanism is uncovered while preserving the longitudinal dorsal veins. The joint is exposed through a longitudinal incision splitting the central slip or through an incision between the lateral band and the central tendon. The location of the capsulotomy is determined by the site of bulging synovium. Hypertrophic synovium is removed by sharp dissection or with a small rongeur. Gentle distal traction of the finger and flexion of the joint facilitate the synovectomy.

Occasionally, the synovium bulges laterally. In this case, incising the transverse retinacular ligament and reflecting the lateral band dorsally expose the synovium bulging through the

CRITICAL POINTS *Metacarpophalangeal Joint Arthroplasty*

Indications

- Painful or deformed MP joints from arthritis (rheumatoid, osteoarthritis, posttraumatic)

Pearls

- Correct the wrist deformity before MP arthroplasty.
- Reconstruct the radial collateral ligament with slight overcorrection of the deformity.
- Begin supervised hand therapy postoperatively.

Technical Points

- Use a longitudinal incision for a single implant and a transverse one for multiple implants.
- Preserve longitudinal veins and sensory nerve branches.
- Divide the ulnar sagittal band.
- Release the ulnar intrinsic if necessary.
- Reflect the extensor tendon radialward; preserve the joint capsule.
- Divide the collateral ligaments at the metacarpal neck; preserve insertion of the radial collateral ligament on the proximal phalanx.
- Resect the metacarpal head.
- Perform synovectomy.
- Release the volar plate if necessary.
- Prepare the medullary canals (proximal phalanx first except for the fourth metacarpal).
- Size the implant.
- Preplace suture in the radial collateral ligament.
- Insert the implant; it should not buckle or dislocate.
- Repair the radial collateral ligament and joint capsule.
- Centralize the extensor tendon.
- Check the flexor tendon.
- Close over a drain.

Postoperative Care

- Splint with MP joint in maximum extension and slight radial deviation; prevent ring finger and little finger MP hyperextension.
- Use a dynamic splint or cast with the IP joints free for 4 to 6 weeks.

accessory collateral ligament. A longitudinal incision volar to the collateral ligament allows the synovectomy to be performed without injuring the ligament and facilitates removal of synovium from the volar pouch.

The extensor mechanism is repaired with absorbable 4-0 suture. A conforming hand dressing is applied with the PIP joint positioned in extension. Postoperatively, early motion is begun to preserve PIP joint function. Active flexion and extension are started 1 to 2 days after surgery. The joint is splinted in extension, except during exercise periods, for 2 weeks.

FINGER DEFORMITIES

Two finger deformities commonly occur in rheumatoid arthritis: the so-called swan neck and boutonnière. The former is characterized by PIP joint hyperextension with DIP joint flexion, and the latter is the reverse deformity. Neither the swan neck nor the boutonnière deformity is unique to rheumatoid arthritis. Rather, they represent the end result of muscle and tendon imbalance caused by rheumatoid disease. Thus, we

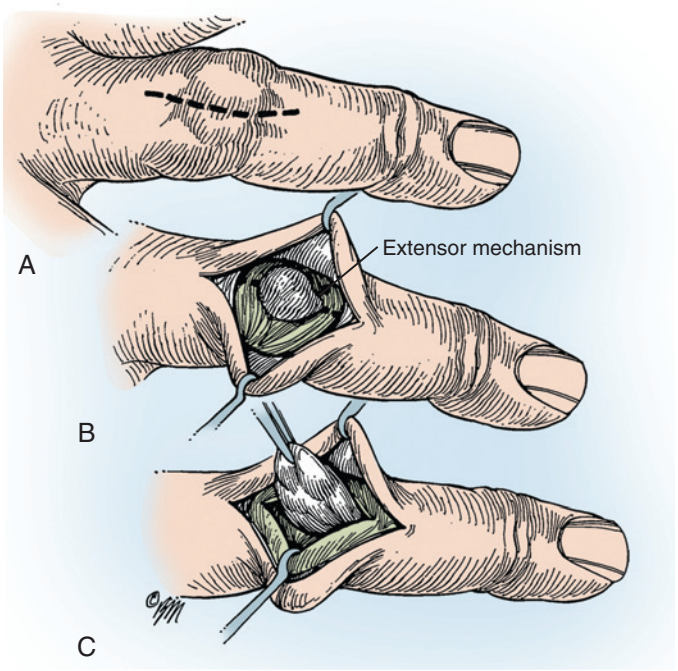

FIGURE 55.46 A-C, Technique for proximal interphalanageal joint synovectomy. Exposure of the extensor mechanism demonstrates proliferative synovium bulging between the lateral bands and central slip. A longitudinal incision through the stretched extensor mechanism exposes the synovium, which is excised sharply. (Copyright Elizabeth Martin.)

occasionally see patients who have both deformities in adjacent fingers of the same hand. Many factors cause the deformities and contribute to the degree of functional loss that they produce. The following subsections discuss the variety of operations recommended to correct these deformities and the diversity of opinion regarding treatment.

Swan Neck Deformity

Although all swan neck deformities have a superficial resemblance to one another, they vary considerably. Careful determination of the type of deformity present is essential for proper selection of treatment. The significant functional loss associated with this deformity is related directly to the loss of motion at the PIP joint, which ranges from no loss to partial loss to almost complete loss of flexion. Patients with almost complete loss of PIP joint flexion can be subdivided further into those with and those without preservation of joint space by radiographic examination. The deformities are classified into one of four types, depending on PIP joint mobility and the condition of the joint surfaces, as shown in Tables 55.3 through 55.5. This classification serves as the basis for treatment of fingers with swan neck deformities.[87,94,95]

Type I: PIP Joints Flexible in All Positions

Some rheumatoid patients with swan neck deformities demonstrate hyperextension of the PIP joint with DIP joint flexion yet maintain the ability to flex the PIP joint completely. The deformity can originate at either the DIP or the PIP joint. At the DIP joint it starts with stretching or rupture of the terminal extensor tendon attachment, which results in the so-called mallet deformity. Imbalance of the extensor mechanism secondary to DIP

TABLE 55.3 Classification System for Finger Swan Neck Deformities

Type	Characteristics
I	Full range of motion No intrinsic tightness No functional limitations
II	Intrinsic tightness Limited PIP motion and an extended MP joint with ulnar deviation corrected
III	Stiff PIP in all positions of the MP joint Radiograph good
IV	Severe arthritic changes

MP, Metacarpophalangeal; *PIP*, proximal interphalangeal.

TABLE 55.4 Treatment Options for Swan Neck Deformity of Fingers

Type	MP Joint	PIP Joint	DIP Joint
I		Splint Dermadesis FDS sling Littler ORL reconstruction	Fusion
II	Intrinsic release	As for type I	Fusion
III	As for type II MP joint reconstruction as needed	As for type II PIP joint manipulation Skin release Lateral band mobilization Check flexor tendons	Fusion

FDS, Flexor digitorum sublimis; *MP*, metacarpophalangeal; *ORL*, oblique retinacular ligament. *PIP*, proximal interphalangeal.

joint flexion coupled with laxity of the volar plate of the PIP joint allows the PIP joint to assume a posture of hyperextension. In patients with early deformity, this progression can be observed. However, in patients with an established deformity, the sequence of events described can be inferred if the DIP joint deformity is more severe than the PIP joint hyperextension.

For other patients, the deformity may originate at the PIP joint as synovitis stretches out the volar capsule or if rupture of the superficial flexor tendon removes the force restraining PIP joint hyperextension. In these cases, DIP joint flexion is secondary. Swan neck deformity originating at the DIP or the PIP joint is classified as type I if full passive motion of the PIP joint is maintained. These patients have only a small functional loss related to the limitation of DIP joint extension and usually do not have associated MP joint disease.

Treatment of patients with type I swan neck deformity is directed at preventing or limiting the PIP joint hyperextension, restoring DIP joint extension, or both. Use of a Silver Ring splint can be helpful in correcting PIP hyperextension while allowing motion (Figure 55.47).[87] Several surgical procedures can be considered, including DIP joint fusion, dermadesis (i.e., volar to the PIP joint), flexor tenodesis of the PIP joint, and reconstruction of the retinacular ligament.

DIP Joint Fusion. Although correction of the flexion deformity of the DIP joint to restore balance to the finger can be obtained by reattaching the extensor mechanism to reestablish active control of the joint, the reconstructed tendon is subject to the same rheumatoid changes that led to the deformity in the first place. In addition, secondary arthritic changes within the joint may make attempts to restore motion unwise. An alternative treatment is to fuse the DIP joint.[19] We prefer this approach, particularly when the mallet deformity is primary.

We use a dorsal curved skin incision or a "Y" incision. The extensor mechanism is divided transversely. The joint is flexed, and the collateral ligaments are divided to improve exposure. The articular cartilage is removed, and the bone ends are shaped to provide good bone contact. Either a small headless screw or one or more Kirschner wires can be used for internal fixation. We prefer screw fixation unless the medullary canals are too small to accommodate it.

TABLE 55.5 Soft Tissue Procedures for Rheumatoid Swan Neck Deformity of Finger

Technique	Indications	Contraindications	Complications
Intrinsic release	Positive intrinsic tightness test		
Manipulation of the PIP joint	Stiff joint with acceptable articular surfaces	Excessive force required	Injury to the extensor mechanism Boutonnière deformity Loss of motion in the postoperative period
Skin release	Blanching of the skin with full PIP joint flexion		
Sublimis tenodesis Littler oblique retinacular ligament reconstruction	PIP hyperextension that interferes with flexion; may be combined with any of the others	Mild PIP deformity with severe mallet deformity (treat with DIP fusion)	Flexion contracture
Lateral band mobilization	Stiff joint with acceptable articular surfaces, not amenable to manipulation	Bone loss, instability, painful degeneration	Boutonnière deformity Loss of motion in the postoperative period
Flexor tendon exploration and tenolysis	Active motion limited		

DIP, Dorsal interphalangeal; *PIP*, proximal interphalangeal.

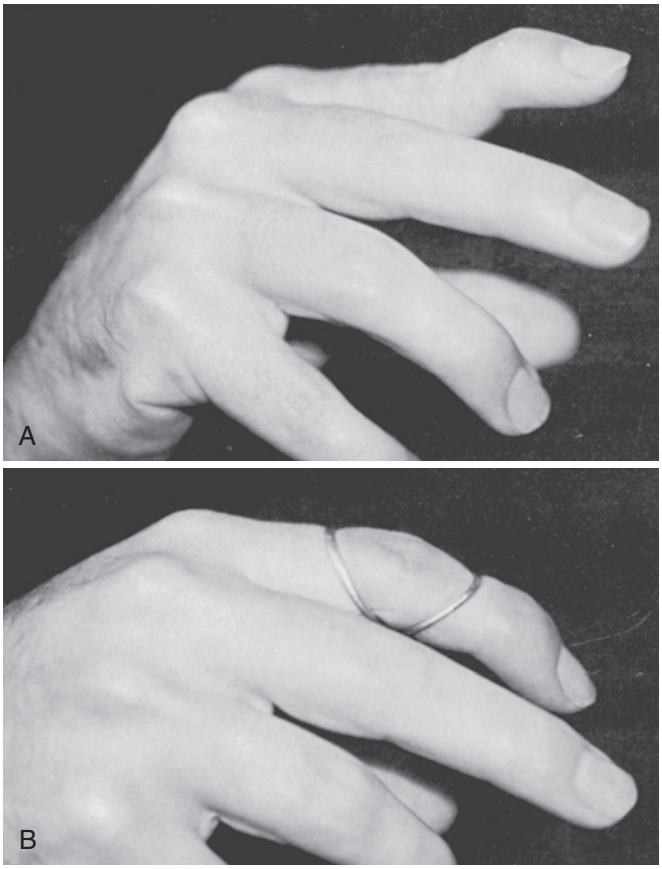

FIGURE 55.47 A mild, supple swan neck deformity **(A)** can be corrected with the Silver Ring splint **(B)**.

An Acutrak small joint fusion screw, Acutrak II microscrew, Herbert screw, Herbert-Whipple screw, or a similar headless screw system can be used for internal fixation of DIP joint fusions.[37] These provide rigid internal fixation and do not need to be removed after the fusion heals. Intramedullary placement ensures the preferred straight position of the joint. The relatively rigid fixation provided by the screw device precludes the need for prolonged postoperative splinting—2 to 3 weeks is sufficient.

The screw systems have several disadvantages, however. If a screw is inserted incorrectly, the threads can damage the germinal matrix of the nail and result in nail plate deformity. The distal phalanx must be large enough to accept the trailing threads of the screw. If using a Herbert-type screw, fixation can be lost if the leading screw threads extend beyond the isthmus of the middle phalanx and toggle in the soft bone of the metaphysis. For that reason, we prefer a continuously threaded design and have used these screws more and more frequently. The results are positive when attention is paid to the technical details of inserting the screws (Figure 55.48).

If a longitudinal Kirschner wire is used for internal fixation, we use the following technique. To be certain that the wire is introduced into the medullary canal of the middle phalanx, predrill a small hole in the middle phalanx into the canal. Then pass a slightly larger wire distally through the distal phalanx. This wire should emerge from the pulp just volar to the nail bed; it is then passed retrograde across the joint into the

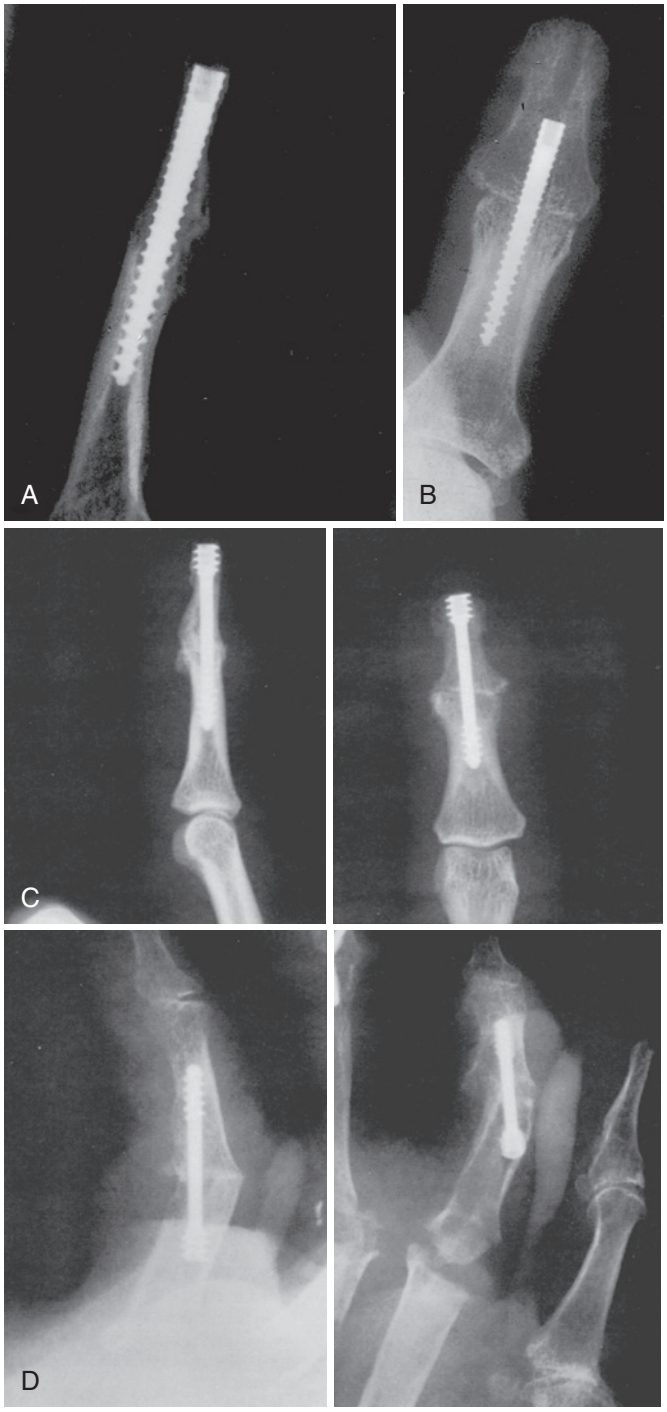

FIGURE 55.48 Self-compressing screws provide excellent internal fixation for the fusion of small joints in rheumatoid patients. The Acutrak small joint fusion system has been used to fuse the dorsal interphalangeal (DIP) joint of a finger **(A)** and the interphalangeal (IP) joint of a thumb **(B)**. **C, D,** Herbert screws can be used for both DIP and proximal interphalangeal (PIP) joints in the fingers and for the thumb IP joint. The leading threads of a screw used to stabilize the DIP joint fusion should extend only into the isthmus of the middle phalanx to avoid loss of fixation from toggling of the screw in the softer bone of the metaphysis. Metacarpophalangeal joint arthroplasties do not preclude the use of Herbert screws for PIP joint fusion in a rheumatoid patient.

predrilled hole in the middle phalanx. Care should be taken to not drill the Kirschner wire too far proximally to avoid damage to the PIP joint. The minimum pin size that should be used is 0.045 inch.

The DIP joint is fixed in neutral position (full extension), which is the preferred position for correction of the swan neck deformity. The Kirschner wire can be either cut off just below the skin or left exposed. If the wire is left exposed, removal after fusion is easy and the risk for pin tract infection is minimized. However, the finger cannot be immersed in water and the protruding pin must be covered to prevent injury to the patient and others. Burying the pin under the skin allows washing of the hand but increases the risk for skin irritation, skin breakdown, and subsequent infection.

Generally, we use only one longitudinal Kirschner wire for DIP joint fusion. However, if necessary, an obliquely placed wire is added to control rotation. To facilitate fusion, it is common to add bone grafts to the fusion site. These grafts are essential for patients with extensive erosive changes and significant loss of bone substance.[59] The metacarpal heads removed for implant arthroplasty provide a good source of local bone graft material. External support with a small aluminum splint is advisable for the first 4 to 6 weeks after fusion.

If the pin has been buried, it can be removed in the office after the fusion has healed entirely. Local anesthetic can be injected directly into the skin and subcutaneous tissue overlying the pin or a digital block can be given. A stab wound is made over it, and the pin is extracted with a needle holder. Occasionally, the pin may migrate proximally so that it is completely or almost completely buried in bone. This requires more extensive dissection to locate and remove the pin and should therefore be done in the operating room under optimal conditions that allow removal of some bone from the distal phalanx to expose the end of the pin.

Operative Technique for DIP Joint Fusion With a Screw. Before beginning this procedure, the lateral radiograph of the finger should be checked to be sure that the width of the medullary canal of the distal phalanx is sufficient to accept a screw. The DIP joint is exposed and its surfaces are prepared as described previously. The medullary canal of the middle phalanx is located with a Kirschner wire. The canal is prepared with either a larger Kirschner wire or the appropriate drill/reamer, depending on the type of screw system selected. A Kirschner wire is inserted through the base of the distal phalanx into the medullary canal. The wire is driven distally and exits on the tip of the finger just below the hyponychium. A transverse stab wound is made where the Kirschner wire exits. The wire is withdrawn, and the appropriate drill/tap is inserted through the stab wound into the tuft of the distal phalanx, and advanced proximally until it emerges at the base of the phalanx.

Next, the appropriate length of screw is inserted and advanced until it emerges at the base of the distal phalanx. The screw tip is aligned with the hole in the middle phalanx under direct vision and then advanced with the fusion surfaces held tightly together. The trailing threads of the screw are recessed into the tuft. If a Herbert-type screw is used and is too long, there may be a sudden loss of fixation as the leading thread passes through the isthmus into the softer and wider portion of the phalanx. Rotatory stability can be augmented by inserting a 0.028- or 0.035-inch Kirschner wire parallel to the screw. Intraoperative radiographs are obtained to confirm proper placement and screw length.

Dermadesis. Dermadesis is an operative approach that is rarely used for patients with type I swan neck deformities.[95] This procedure attempts to prevent PIP joint hyperextension by creating a skin shortage volarly. An elliptic wedge of skin (4–5 mm at its widest point) is removed from the volar aspect of the PIP joint. Care is taken to preserve the venous network just under the skin and to not open or disturb the underlying flexor tendon sheath. The skin is closed with the PIP joint in flexion. This technique is helpful only in mild cases and usually fails unless it is done in conjunction with other procedures (e.g., DIP joint fusion). When the PIP joint hyperextension is primary, we prefer to use a stronger checkrein against hyperextension. Our procedure of choice is flexor tendon tenodesis using one slip of the FDS.

Flexor Tendon Tenodesis ("Sublimis Sling"). Patients with PIP joint hyperextension maintain full passive motion but, as the hyperextension increases, begin to have difficulty initiating active flexion. These patients require restoration of strong volar support to the joint. We prefer the use of FDS tenodesis to prevent PIP joint hyperextension.[20]

A volar zigzag incision is made over the PIP joint to expose the flexor tendon sheath. The thin portions of the sheath on either side of the A3 pulley are excised while preserving the pulley. The flexor tendons are exposed, and care is taken to avoid injury to the vincula passing between the FDS and FDP tendons. One slip of the FDS is divided approximately 1.5 cm proximal to the joint. This portion is separated from its corresponding slip but is left attached distally. With the joint in 20 to 30 degrees of flexion, the detached slip is fixed proximally to act as a checkrein against extension. The proximal attachment can be made directly into the bone by using a bone anchor or pull-out wire, or it can be made at the thickened margin of the flexor tendon sheath (distal edge of the A2 pulley) with sutures (Figure 55.49).

We have found that the easiest technique is to use a small bone anchor with a 2-0 or 3-0 suture to attach the tendon

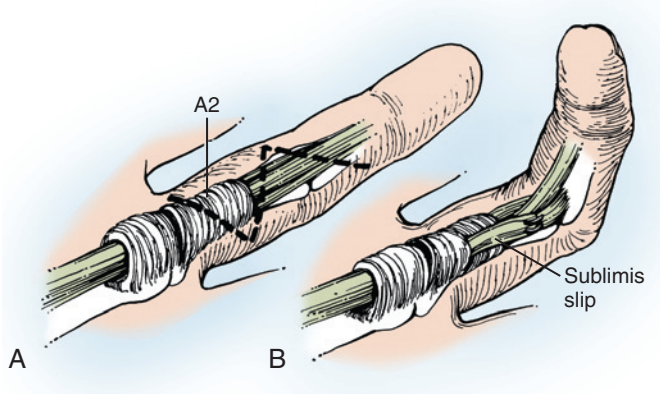

FIGURE 55.49 One technique for superficialis tenodesis to correct swan neck deformity. **A,** Zigzag incision used to expose the flexor tendon sheath. The incision should be extended far enough proximally to expose the A2 pulley. Tenosynovectomy is performed if necessary. **B,** A slip of flexor digitorum superficialis (sublimis) is sectioned proximally, passed through a slit in the A2 pulley, and sutured back on itself. (Copyright Elizabeth Martin.)

directly to the bone. To attach the tendon slip to the sheath, a transverse slit is made in the distal portion of the A2 pulley; the detached tendon slip is then passed through the pulley and sutured back onto itself. With both methods, the goal is to create a slight flexion contracture of the PIP joint. For greater purchase, the tendon slip can be attached through or adjacent to the A1 pulley in the distal part of the palm. Postoperatively, the joint is splinted in flexion at 30 degrees. We start flexion at 3 weeks to maintain PIP joint function but block hyperextension for at least 6 weeks.

A modified technique divides the FDS tendon more proximally with a distal palm incision. The FDS slip is then passed around the A1 pulley to prevent PIP joint hyperextension. This is simpler and faster and avoids an incision in the digit.

Retinacular Ligament Reconstruction. Littler devised a clever technique to prevent hyperextension while restoring DIP joint extension by reconstructing an oblique retinacular ligament with the ulnar lateral band.[126] In this procedure, the ulnar lateral band is freed from the extensor mechanism proximally but left attached distally. It is passed volar to Cleland's fibers to bring it volar to the axis of PIP joint motion. We pass the tendon slip to the opposite side of the finger and suture it to the fibrous tendon sheath under enough tension to restore DIP joint extension and prevent PIP hyperextension. In theory, this approach should solve both the DIP and PIP joint problems simultaneously. However, in a rheumatoid patient who has a primary mallet deformity with destruction of the terminal tendon, no amount of tension applied to the relocated lateral band can restore DIP joint extension. Thus, the net result of this procedure is restriction of PIP joint hyperextension. For patients with rheumatoid arthritis, it is an alternative to dermadesis or flexor tenodesis.

Type II: Limited PIP Joint Flexion in Certain Positions

Some rheumatoid patients with swan neck deformities have restriction of finger flexion only in certain positions. The deformity may appear similar to the type I deformity; however, on examination, PIP joint flexion is influenced by the position of the MP joint. With the MP joint extended and neutral in the anteroposterior plane, passive PIP joint flexion is limited. If the MP joint is allowed to flex or turn ulnarward, PIP joint flexion is increased. In such cases the swan neck deformity is secondary to MP joint involvement.

As the MP joints deviate and subluxate and the intrinsics become tight, a secondary swan neck deformity develops as the result of muscular imbalance. Initially, it is supple in most positions and becomes stiff only when the MP joint is in extension and the intrinsics are tightened further. Ultimately, however, the PIP joint becomes stiff regardless of the position of the MP joint. In these patients it is not sufficient to restrict PIP joint hyperextension. The intrinsic tightness must be relieved. Any MP joint disorder that initiates or aggravates the finger's muscular imbalance (i.e., subluxation or deviation) must also be corrected. This is accomplished by intrinsic release in patients with minimally involved MP joints and by combined MP joint arthroplasty and intrinsic release in the others.

Intrinsic Release. Intrinsic muscle release is performed through a dorsal ulnar longitudinal incision over the proximal phalanx, as described earlier. After release, PIP joint flexion with the MP joint extended or radially deviated should be improved. Intrinsic release can be combined with DIP or PIP joint procedures (or both) to restore balance.

In patients with an associated MP joint disease, MP joint alignment is corrected by implant arthroplasty. Although MP joint arthroplasty (Swanson) with resection of the metacarpal heads does lengthen the intrinsic tendon, we prefer to resect the ulnar intrinsic tendon as well to reduce the risk for recurrent intrinsic tightness and ulnar drift of the fingers.

Type III: Limited PIP Joint Flexion in All Positions

For patients with the type I and II deformities described earlier, there is only slight-to-moderate functional loss despite the finger deformity. However, patients with marked reduction of PIP joint motion in any position (type III) have significant loss of hand function because the ability to grasp objects is greatly reduced. Although it might seem logical to assume that patients with stiff swan neck deformities have advanced intraarticular changes that require either fusion to bring the finger into a functional position or arthroplasty to restore active motion, radiographic examination often reveals well-preserved joint spaces. In these cases, the structures that restrict passive motion include the extensor mechanism, the collateral ligaments, and the skin. The first step in surgical reconstruction of a stiff swan neck deformity is restoration of passive PIP joint motion. The procedures that we use to restore passive motion include joint manipulation, skin release, and lateral band mobilization. Correction of the deformity is delayed until passive motion is restored.

PIP Joint Manipulation. In patients with stiff swan neck deformities, the soft tissues have contracted about the joint. However, with the patient under anesthesia, it is sometimes possible to obtain 80 to 90 degrees of PIP joint flexion by gentle manipulation. PIP joint manipulation is rarely performed alone; it is usually done in conjunction with intrinsic release, MP arthroplasty, or flexor tenosynovectomy. If the joint is splinted in the flexed position, the tight soft tissues will stretch. After several weeks, the passive motion obtained by manipulation and splinting can be maintained as active motion, provided that the flexor tendons have not become adherent.

When done in conjunction with MP arthroplasty, temporary Kirschner wire fixation is used to hold the PIP joint in flexion. This concentrates the postoperative exercises on MP joint motion. After 10 days, the pins are removed and therapy is directed toward increasing PIP joint motion by using an extension block splint to prevent full extension of the joints. As stated previously, this method has restored 80 to 90 degrees of PIP joint flexion in joints that had been stiff.

When PIP joint manipulation is performed in conjunction with flexor tenosynovectomy, the joints are not pinned but are splinted in the flexed position postoperatively. Usually, after 24 to 48 h of splinting, therapy can be initiated with extension block splints. Therapy includes active PIP range-of-motion exercises with careful splinting in flexion between exercise periods. Initially, exercises are done for 5 minutes, 4 to 6 times daily, and increased as pain and endurance allow. Splinting is continued for 2 to 4 weeks, depending on the range of motion obtained. If an extensor lag of the PIP joint develops, extension splinting may be necessary.

Skin Release. The dorsal skin may limit the amount of passive flexion that can be achieved by manipulation. At some point

during the manipulation of long-standing fixed deformities into flexion, the dorsal skin blanches. If it is not relieved, skin necrosis occurs directly over the joint.

Dorsal skin tension can be minimized with an oblique incision just distal to the PIP joint, which allows skin edges to spread. The defect created is the result of skin contracture (not loss) and closes gradually in 2 to 3 weeks. Although initially we used skin grafts to cover these defects, satisfactory healing by secondary intention has convinced us that grafts are not needed. In fact, leaving this portion of the wound open allows drainage and reduces postoperative swelling and pain. It is important that the skin be released distal to the joint so that the extensor mechanism overlying the joint is covered (Figure 55.50).

Certain precautions must be observed when joint manipulation is performed. Minimal force should be used to bring the PIP joint into flexion; the soft tissues should stretch, not rupture. Fracture of osteopenic bone must be avoided. Therefore, if manipulation is difficult, we proceed to soft tissue release. The procedure used most often is lateral band mobilization.

Lateral Band Mobilization. With established swan neck deformities, the lateral bands are displaced dorsally. Their normal volar shift is lost, and the finger has limited flexion. We have found that freeing the lateral bands from the central slip with two parallel longitudinal incisions in the extensor mechanism allows the joint to be manipulated gently into full flexion without releasing the collateral ligaments or lengthening the central slip (Figure 55.51). Full passive flexion can often be achieved using this method. When the procedure is performed under local anesthesia, shifting of the lateral bands volarward on flexion, and relocation of them dorsally on extension, can be observed during active motion.

When this procedure was first used for stiff swan neck deformities in 1962, the greatest problem was loss of flexion after skin closure. Once the skin was sutured, the passive and active motion achieved by lateral band mobilization was lost. If the skin was allowed to heal before active motion was started, the amount of flexion obtained in the operating room was seldom maintained. We now use a curved dorsal incision with a short

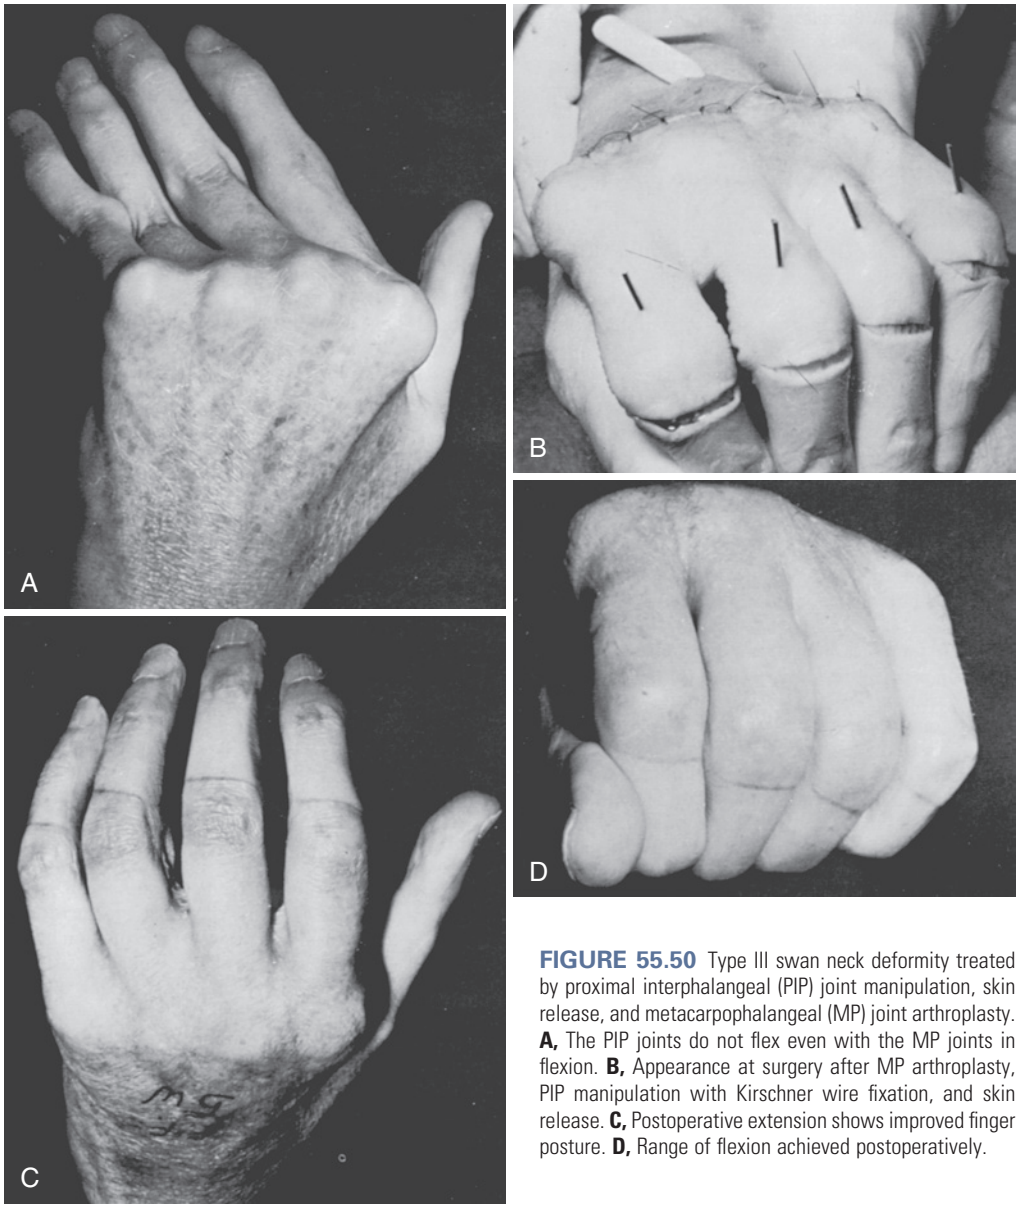

FIGURE 55.50 Type III swan neck deformity treated by proximal interphalangeal (PIP) joint manipulation, skin release, and metacarpophalangeal (MP) joint arthroplasty. **A,** The PIP joints do not flex even with the MP joints in flexion. **B,** Appearance at surgery after MP arthroplasty, PIP manipulation with Kirschner wire fixation, and skin release. **C,** Postoperative extension shows improved finger posture. **D,** Range of flexion achieved postoperatively.

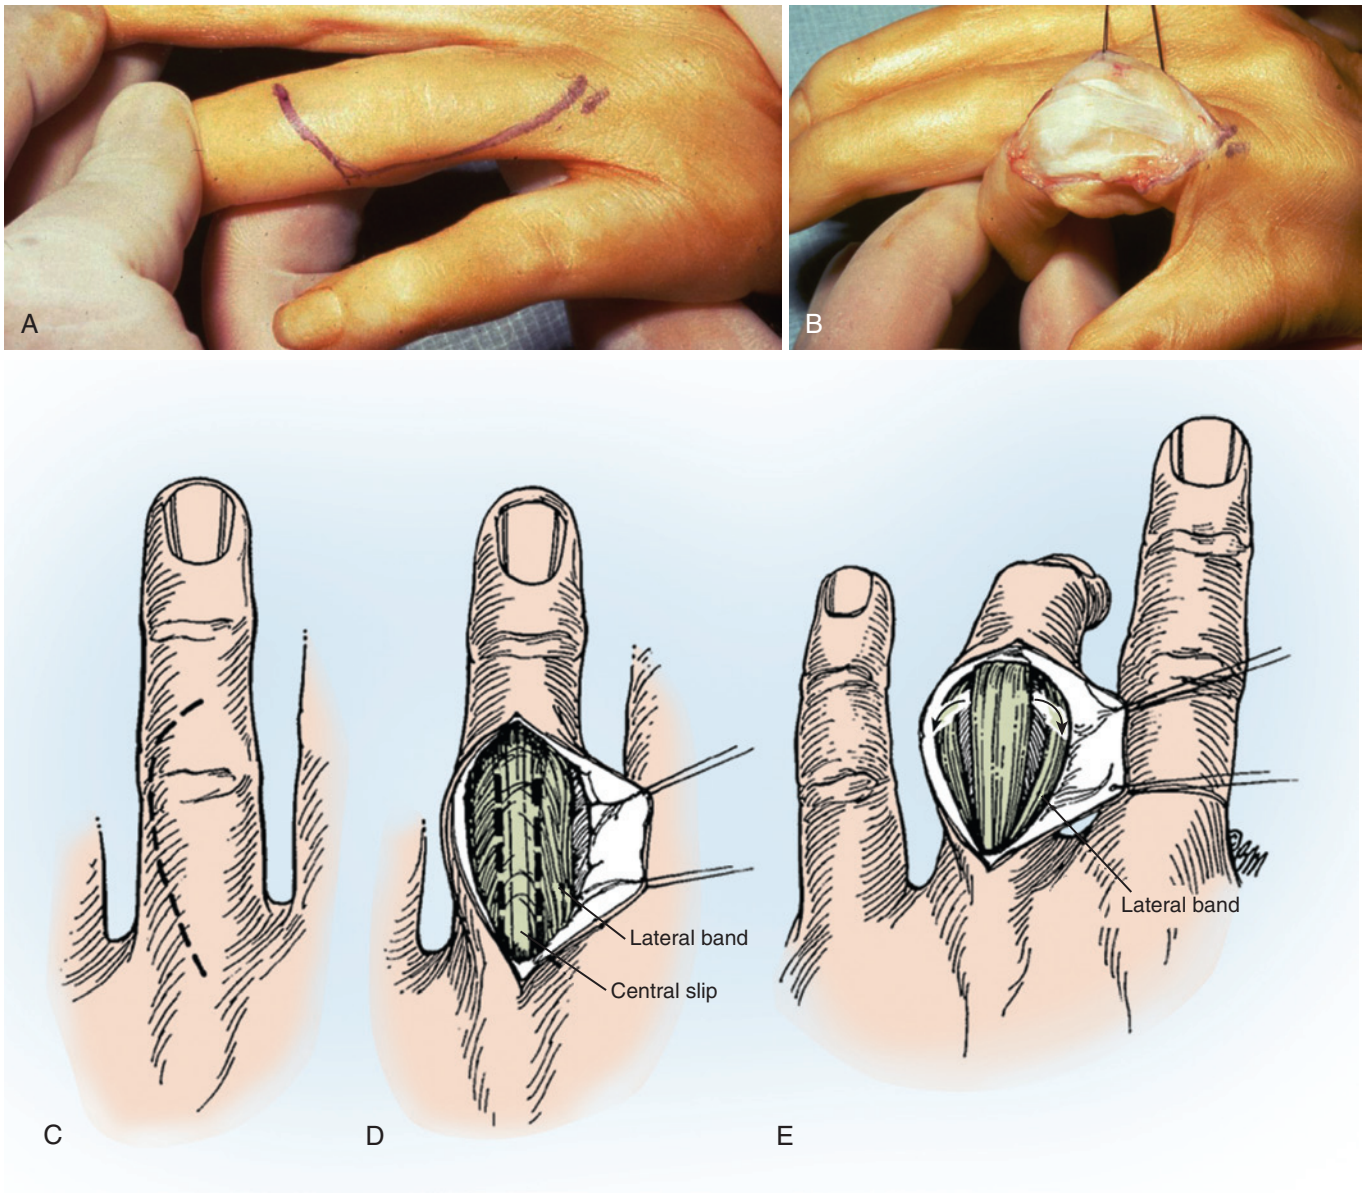

FIGURE 55.51 Type III swan neck deformity treated by lateral band mobilization. **A,** Incision used to expose the extensor mechanism over the proximal interphalangeal (PIP) joint. **B,** Parallel incisions separate the lateral bands from the central slip. Note the flexion obtained after manipulation of the PIP joint and volar shift of the lateral bands. **C-E,** Drawings of the technique for lateral band mobilization. (**C-E,** Copyright Elizabeth Martin.)

oblique limb across the middle segment. The proximal portion of the incision is closed with the finger held in flexion. The distal third of the incision is generally left open. The finger is splinted in flexion for 3 to 5 days to stretch the contracted collateral ligaments. Occasionally, however, it is necessary to release these ligaments, as well as lengthen the central slip with a step-cut. A dorsal extension block splint is used to prevent full extension of the PIP joints.[42,87]

Flexor Tenosynovitis and PIP Joint Stiffness

The flexor tendons must also be considered and assessed if optimal results are to be obtained from the procedures described earlier. Flexor tenosynovitis and secondary flexor tendon adherence are integral etiologic factors of stiff PIP joints and must be understood to provide adequate treatment. Flexor tenosynovitis or adhesions that limit active PIP joint flexion can result in stiff PIP joints. Conversely, stiff PIP joints can result in adherence of the flexor tendons. In either case, flexor tenosynovectomy or tenolysis must be a consideration in any treatment aimed at restoration of PIP joint motion.

Adhesions or rupture of the flexors obviate any passive motion gained by procedures directed at the extensor mechanism or the soft tissues surrounding the joint. However, preoperative assessment of flexor tendon function is limited if stiff joints are present. For this reason, we now determine the status of the flexor tendons in the operating room. If intravenous regional or local anesthesia has been used for either manipulation or lateral band mobilization, the tourniquet is released and the patient is asked to flex the fingers after muscle control has returned.

If active motion is not nearly equal to passive motion, anesthesia is reinstituted and the flexor tendons are explored. Tendon adhesions are released, and rheumatoid nodules within the tendon are removed. If regional block anesthesia has been used, the flexor tendons are exposed in the palm and traction is applied to test excursion. Occasionally, extensive flexor tenosynovectomy is required to improve flexor tendon excursion. Postoperatively, supervised splinting and active exercises are important in maintaining the motion ability gained at the time of surgery (see later).

Type IV: Stiff PIP Joints With Poor Radiographic Appearance

Patients with stiff PIP joints and radiographic evidence of advanced intraarticular changes require some type of salvage procedure, either fusion or arthroplasty. Factors that must be considered in deciding between procedures to use include the fingers involved, the status of adjacent joints, the status of supporting ligamentous structures, and the status of the flexor tendons. We tend to prefer fusion in the index finger, where lateral stability is particularly important. The status of adjacent joints is also essential. If the MP joints require arthroplasty, we favor fusion at the PIP joint level; however, experience shows that arthroplasty can be performed at both levels with good results. Although Adamson and colleagues reported less than optimal results with PIP arthroplasty in patients with inflammatory arthritis, their study combined the results of treating both boutonnière and swan neck deformities.[1] We believe that arthroplasty plays a limited role in the treatment of flexion boutonnière deformities because the extensor tendon is often compromised. With swan neck deformities, PIP arthroplasty works well as long as hyperextension is corrected; sublimis tenodesis can be performed at the same time if necessary. Inadequate lateral ligamentous support or associated flexor tendon ruptures, or both, are also relative indications for fusion.

PIP Joint Fusion for Swan Neck Deformity. After making a longitudinal skin incision, the extensor mechanism is split at the midline and the collateral ligaments are detached from the proximal phalanx. The joint is flexed to expose the articular surfaces, which are prepared for fusion by removing the articular cartilage and softening the subchondral bone with cup and cone reamers. Internal fixation can be achieved with crossed Kirschner wires, a tension band wire, or headless screws if the bone stock is adequate and the medullary canal is wide enough (see Figure 55.48).[63] A precise technique is needed to attain the desired angle of fusion if a screw is used. The position of fusion selected depends on the finger involved and the gender of the patient.

In general, the index finger PIP joint is fused in less flexion than the middle finger. The degree of flexion is greater in the ring and little fingers to facilitate grip. The amount of flexion chosen ranges from 25 to 45 degrees. When appearance is more important than strong grasp, less flexion than the so-called functional position is used. The patient's requirements must be discussed and determined preoperatively. It is helpful to have a small sterile goniometer on the instrument table because it is sometimes difficult to visually judge the angle of flexion of the PIP joint accurately. Usually, the joint is flexed more than anticipated. Measurement of the angle of flexion after the first pin is inserted allows easy correction before inserting the final pins.

PIP Joint Arthroplasty. Proximal interphalangeal silicone arthroplasty was originally used in 1966 in conjunction with silicone implants for the MP joints in rheumatoid arthritis.[118] Over the years the indicators have changed, and we now find the procedure most useful with degenerative arthritis and certain cases of traumatic arthritis.

Swanson's single-piece polymeric silicone spacer has been the arthroplasty implant of choice for several decades. The flexible silicone spacer was designed to facilitate the development of a fibrous capsule that would provide a pain-free and functional PIP joint.[65,121] The dorsal hinge design, as well as intramedullary stem pistoning, was thought to increase "in-plane" functional motion; however, only modest improvements in flexion arcs have been reported.[118] Other silicone implants include those made by DePuy and SBI (Figure 55.52). Although the material properties are essentially the same, the design features are slightly different. Both SBI and DePuy PIP implants have a more volar hinge, which may allow improved flexion arcs without volar impingement.

Even though silicone implant arthroplasty has been used clinically with success, complications occur and include hinge failure, angular deformities, bone erosion, and particulate synovitis.[118] Failure to replicate normal PIP motion may be a primary contributing factor to hinge joint implant failures. Recently, surface replacement arthroplasty of the PIP joint has been developed to improve joint biomechanics. These implants are designed to mimic the physiologic articulation of the PIP joints to restore normal motion based on a virtual axis rather than a fixed axis.[65,83] Minimal bone resection, preservation of the collateral ligaments, and implant design also may have a theoretic

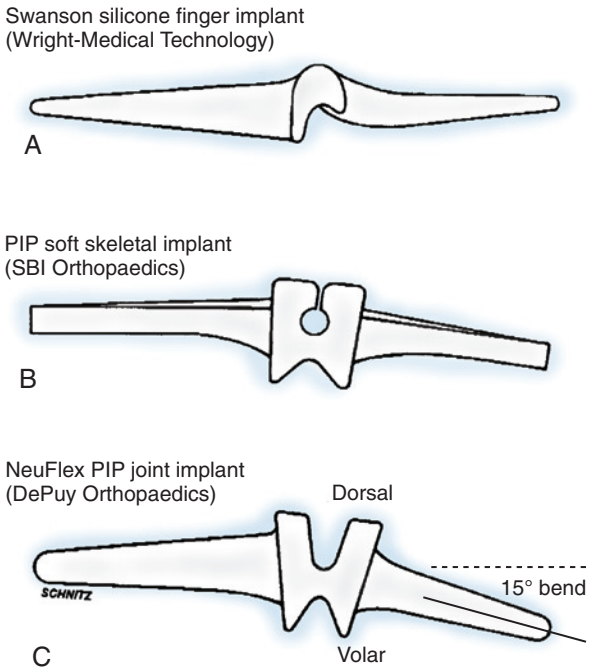

FIGURE 55.52 Silicone proximal interphalangeal (PIP) implants. **A,** Swanson silicone finger implants (Wright Medical Technology, Arlington, TN). **B,** PIP soft skeletal implant (Small Bone Innovations). **C,** NeuFlex PIP joint implant (DePuy Orthopaedics, Warsaw, IN). (From Kobayashi K, Terrono AL: Proximal interphalangeal joint arthroplasty of the hand. *J Hand Surg Am* 3:219–226, 2003, © 2003 by the American Society for Surgery of the Hand. Used with permission.)

advantage in improving "out-of-plane" stability when considering PIP joint arthroplasties on the hand's radial side; this is particularly so with the index finger, which must be able to resist the forces generated during pinch. Current surface replacement arthroplasty designs include an SBI metal-polyethylene prosthesis and a pyrolytic carbon prosthesis made by Ascension Orthopedics in Austin, TX (Figure 55.53).[14] However, the use of these implants for rheumatoid patients has been limited and outcomes have been variable.[14,27,55,134]

Indications. Arthroplasty of the PIP joint is primarily used for patients who have persistent pain that has been refractory to several months of intensive nonoperative therapy, including NSAIDs, occasional cortisone injections, temporary splinting, and carefully prescribed hand therapy focusing on modification of activity (no range of motion). If PIP motion is greater than 70 degrees or if the patient can touch the finger to the palm, we recommend PIP arthroplasty cautiously unless pain is an overriding factor.

The best candidate for PIP joint arthroplasty is a patient who has a painful PIP joint from degenerative or posttraumatic arthritis in one of the ulnar three digits and nearly full extension and limited (20–40 degrees) flexion. When there is good bone stock, minimal deformity, and a preserved extensor and flexor mechanism, the prognosis for eliminating pain and improving motion is good.

PIP arthroplasty is not usually recommended in painless conditions, especially if MP and DIP joint motion is good. However, occasionally patients with a single long, ring, or little finger that is stiff in an extended position are candidates for the procedure, even though the amount of flexion attained may be less than optimal. Silicone-rubber implants generally do not stand up to the repeated stress of pinch and are therefore not recommended for the index finger.

PIP joint arthroplasty is often unsuccessful in patients with severe rheumatoid involvement, particularly those with advanced boutonnière deformities. The results with swan neck deformities are much better. Combining PIP joint arthroplasty with MP joint arthroplasty, either as a combined procedure or in two stages, is not usually successful. We recommend PIP joint fusions combined with MP joint arthroplasty for combined involvement. However, in the unusual case of an isolated painful digit with little deformity, preserved bone stock, and functional extensor and flexor mechanisms, PIP arthroplasty may be appropriate.

Contraindications. The worst results after PIP joint arthroplasty have been in patients who have had PIP joint infections or previous failed attempts at tenolysis. The surgery generally fails because of recurrent scar formation. Massive bone loss, severe deformity, and repeated surgery, including initial extensive open reductions, are relative contraindications to the procedure, and arthrodesis should be considered in these cases.

We are cautious in recommending PIP arthroplasty for digits with significant fixed-flexion contractions in the range of 50 degrees or greater. In these cases, one must remove excessive bone to insert the implant, and extensive reconstruction of the extensor mechanism with prolonged postoperative splinting is required. The results after these procedures are not usually good. When surgery is indicated in such situations, it may be preferable to consider arthrodesis in a more functional position.

In general, we recommend PIP arthrodesis for the index finger because flexion is not as crucial, strong pinch is necessary, and lateral deviation occurs after PIP arthroplasty (Figure 55.54).[118] Volar plate arthroplasty may be a reasonable option for the radial digits given the lateral stability that can be obtained with this procedure. However, we would not absolutely exclude implant arthroplasty in the index finger PIP joint in certain cases.

Surgical Approaches. PIP arthroplasty can be done through either a dorsal or a volar approach. The original dorsal approach has some specific indications and advantages. It is useful if there is a significant flexion contracture that must be corrected or if reconstruction or tenolysis of the extensor mechanism is needed. With this approach, the extensor mechanism must be handled carefully, reattached, and then protected during the rehabilitation phase.

The volar approach spares the extensor mechanism, and for that reason it is now the preferred approach for patients with degenerative arthritis. It is simple and provides excellent exposure without interfering with the extensor mechanism. Swan

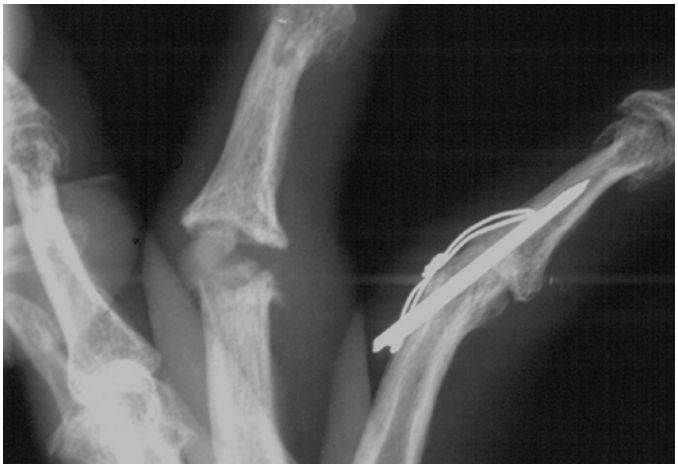

FIGURE 55.54 Status after arthrodesis of the index finger and arthroplasty of the middle finger proximal interphalangeal joint.

neck deformities can be corrected by repairing or reconstructing the volar plate. If flexor tendon adhesions are an additional issue, a volar approach allows easy access for tenolysis (Figure 55.55). However, this approach puts the digital nerves and vessels at risk and requires strict attention to orientation of the joint to ensure that the bone cuts are made appropriately and that the implant is inserted correctly.

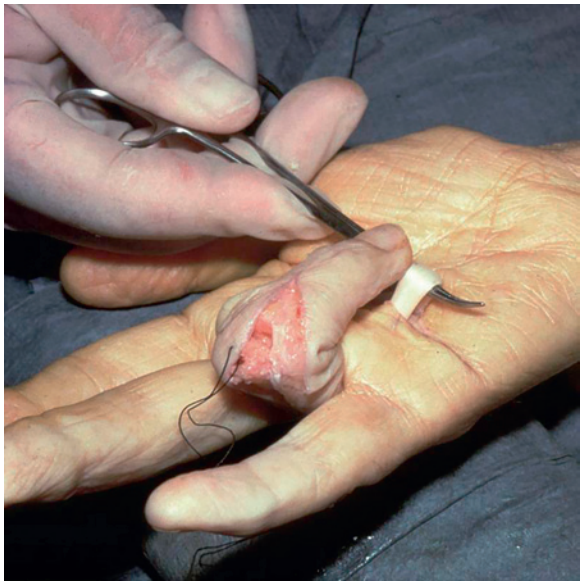

FIGURE 55.55 Flexor tendons can be assessed for adhesions by making a small incision at the proximal border of the A1 pulley. (From Kobayashi K, Terrono AL: Proximal interphalangeal joint arthroplasty of the hand. *J Hand Surg Am* 3:219–226, 2003, © 2003 by the American Society for Surgery of the Hand. Used with permission.)

Dorsal approach. A slightly curved dorsal incision is made to expose the extensor apparatus of the PIP joint. A midline incision is made through the extensor mechanism while protecting the insertion of the central slip. If adjustments in length are necessary to address boutonnière deformities, a distally based flap can be created. Alternatively, an incision can be made between the central slip and one of the lateral bands. The collateral ligaments can be released to allow adequate exposure of joint surfaces (Figure 55.56), which are prepared for arthroplasty with careful attention to preserving collateral ligament integrity. The head of the proximal phalanx is resected.

Preparation of the middle phalanx can be the most difficult part of the procedure depending on the amount of deformity at the base. When there are erosions with large lateral ridges on the sides of the middle phalanx, the ridges must be removed to prepare a flat surface to seat the implant. To do so, the assistant lifts the base and supports the phalanx while the surgeon carefully detaches the collateral ligament from the ridges, while being careful to not completely detach the entire ligament from the middle phalanx. A rongeur is used to remove the ridge. The medullary canals of the proximal and middle phalanges are opened with an awl and reamed to fit the selected size of implant by using the broaches supplied with each of the implant instrument sets. Occasionally, a high-speed bur with a blunt leading tip is used to shape the canal.

Trial components are inserted to assess motion and stability. It is sometimes necessary to repair the collateral ligaments to bone if laxity is present. The implant is inserted with the joint

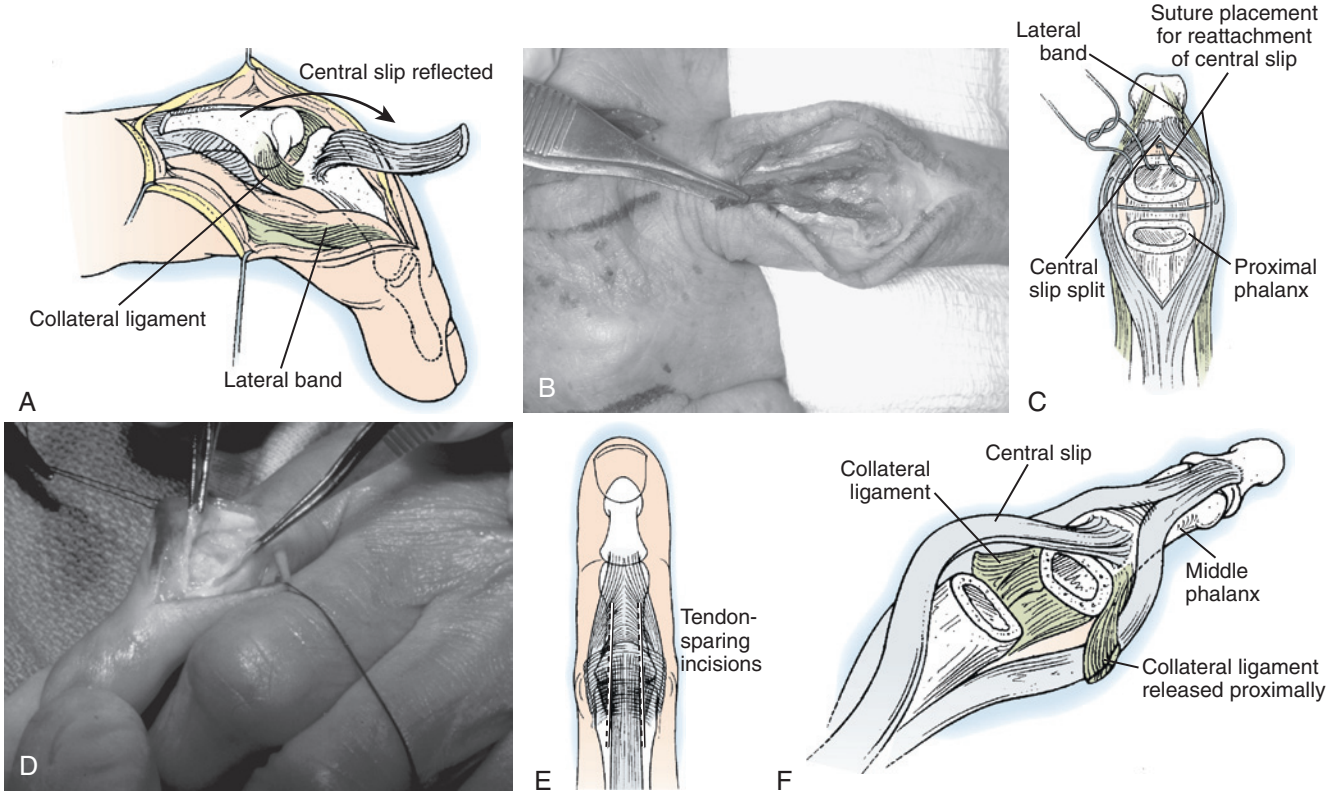

FIGURE 55.56 Dorsal approach to proximal interphalangeal arthroplasty. **A, B,** Distally based extensor flap technique. **C, D,** Central slip-splitting technique. **E, F,** Central tendon-sparing technique. (From Kobayashi K, Terrono AL: Proximal interphalangeal joint arthroplasty of the hand. *J Hand Surg Am* 3:219–226, 2003, © 2003 by the American Society for Surgery of the Hand. Used with permission.)

hyperflexed; it should be stable in the extended position. If the implant dislocates, buckles, or cannot be inserted, the space for it is usually too small and more bone must be resected. The extensor mechanism is repaired with either interrupted mattress sutures or a running suture. A monofilament absorbable suture is preferable for this but nonabsorbable sutures can be used.

The flexor tendon must be assessed if full active flexion was not present preoperatively. A trigger-finger incision can be used, and traction can be placed on the tendons to ensure full flexion. Alternatively, if local or intravenous regional anesthesia has been used, the tourniquet can be deflated and active flexion checked.

Volar approach. A generous volar zigzag incision centered over the PIP joint is made. The neurovascular structures are mobilized and protected. A 2- to 3-cm flap of volar pulley that includes the A3 pulley and a small portion of A2 and A4 is raised. This exposes the volar plate, which is detached from its membranous proximal origin and the accessory collateral ligaments; however, it is left widely attached to the base of the middle phalanx for later reconstruction. Penrose drains can be placed to retract each flexor tendon on either side of the joint. The joint is then carefully dislocated by hyperextension ("shotgun"), and the joint surfaces are prepared as described for the dorsal approach (Figure 55.57). Care must be taken to protect the attachment of the central slip, as well as to orient the bone cuts and insert the implant properly.

Closure is done by reattaching the volar plate to soft tissue or bone if necessary. If reattaching to bone, two drill holes are made in the base of the proximal phalanx. The suture should be placed before insertion of the implant. The flexor sheath can be used to reinforce the volar plate by placing it deep into the tendons, but it is generally placed in its anatomic position or excised. The tourniquet is deflated, and meticulous hemostasis is obtained because a postoperative hematoma or excessive swelling can jeopardize an early exercise program. A bulky dressing is applied with a volar splint holding the digits in extension.

Rehabilitation. If the condition of the extensor tendon is satisfactory, motion is started on the day of or day after the procedure regardless of the approach used. This can be modified if the extensor mechanism has been reconstructed. The dressing is changed 1 to 3 days after surgery. Rehabilitation protocols for dorsal approaches focus on maintaining the integrity of the extensor apparatus and prevention of adhesions. Early protected active PIP flexion and independent DIP flexion minimizes adhesions of the extensor apparatus.

Usually, the PIP joint is maintained in a neutral position (full extension) in between exercise periods and at night. A light dynamic extension splint can be used after the sutures are removed. If a significant extension deformity was present preoperatively, the patient is instructed to tape the finger in maximum flexion during the day and release the tape hourly for extension exercises. If the volar approach was used, active flexion and extension can be started immediately, usually with an extension block splint to maintain the PIP joint in 15 to 20 degrees of flexion for the first 2 weeks to protect the volar plate and prevent a hyperextension deformity.

Supervised hand therapy is generally prescribed, and the protocol is customized for each patient based on the preoperative deformity, the condition of the soft tissues, and the type of approach used. This therapy is continued for 4 to 6 weeks. Night or resting splints (or both) are used for protection after dynamic splinting is discontinued.

Outcomes. A large series of Swanson silicone PIP arthroplasties demonstrated an average range of motion of 45 to 60 degrees with approximately 70% of patients achieving more than 40 degrees.[118] Better results are obtained in patients with degenerative and posttraumatic arthritis. Our results for silicone PIP implant arthroplasty are similar to those reported in

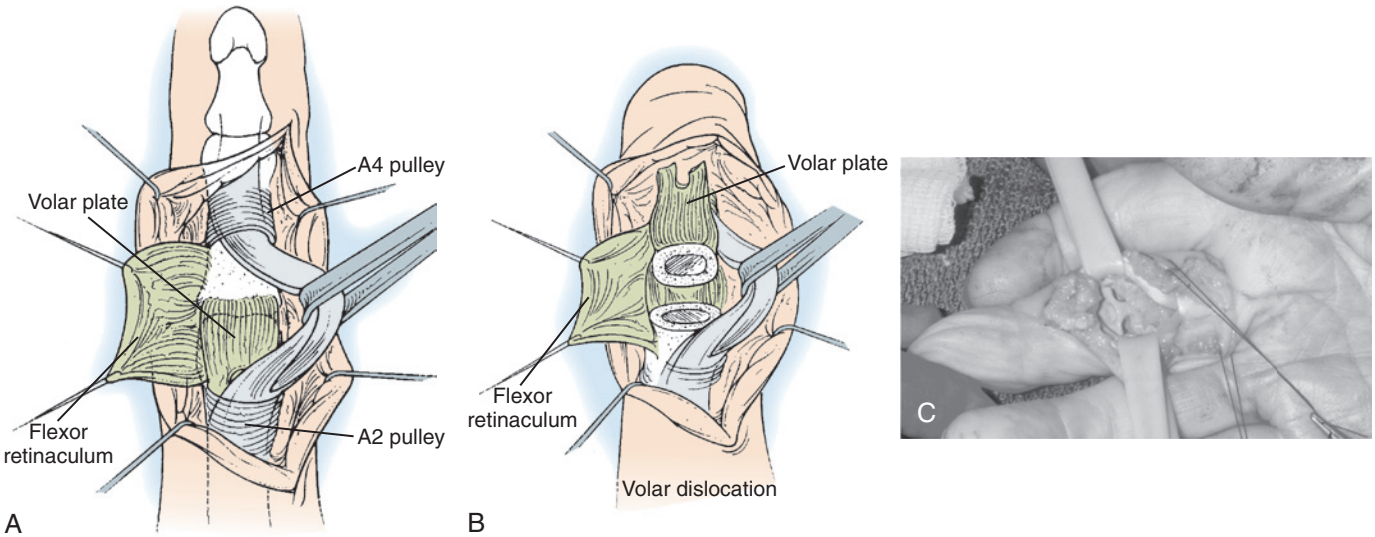

FIGURE 55.57 Volar approach to proximal interphalangeal (PIP) arthroplasty. **A,** An incision centered over the volar PIP joint exposes the volar plate, which is detached from the proximal phalanx. **B,** The flexor tendons are retracted with a Penrose drain to permit dislocation and preparation of the joint surfaces. **C,** Trial implant inserted to assess stability, appropriate size, and motion. the literature, with excellent pain relief, good motion, and stability. No fractures, dislocations, or infections have occurred. In our series, patients with posttraumatic arthritis demonstrated an average range of motion of 48 degrees without deterioration or pain at an average follow-up of 7 years (Figure 55.58). Iselin and Conti reported on 238 Swanson implants of the PIP joint between 1970 and 1990 and noted an average range of motion of −20 degrees of extension to 80 degrees of flexion (long, ring, and little fingers).[50] These authors concluded that results obtained at 12 months were likely to remain the same at 12 years.

The incidence of infection and dislocation in a large series was approximately 0.4%.[118] The implant fracture rate was about 6%, with an overall revision rate of 10%. Reports of bone resorption vary from 1.2 to 35% and may vary with the length of follow-up and person evaluating the radiographs. Foliart reviewed all the literature (70 articles, 15,556 small joint implants) pertaining to complications associated with silicone finger implants and reported very low complication rates.[41] Implant fracture and bone changes occurred in 2% and 4% of patients, respectively. Particulate synovitis and particle wear lymphadenopathy were noted in less than 1%.[41]

Little information is available for semiconstrained surface replacement PIP arthroplasty. In 2001, Johnstone reported his experience with 20 surface replacement PIP arthroplasty implants (CoCr/polyethylene), used primarily for osteoarthritis and posttraumatic pain.[56] The average follow-up was 14.6 months (range, 2–34 months). All patients noted pain reduction, with 90% reporting excellent pain relief. No patient lost movement, and 70% of them demonstrated an average arc of motion of 73 degrees. Poor results were associated with high levels of early postoperative pain and noncompliance with hand therapy.

CRITICAL POINTS *Proximal Interphalangeal Joint Arthroplasty*

Indications
- Persistent PIP joint pain.
- Swan neck deformity with joint destruction.

Contraindications
- Infection.
- Bone loss.
- Unstable joint.
- Severe flexion deformity.

Pearls
- Do not overbroach; stability provided by the implant will be lost.
- Splint the DIP joint in extension postoperatively to concentrate motion at the PIP joint.

Technical Points
- Use a dorsal approach if the extensor tendon requires reconstruction (i.e., boutonnière deformity).
- Use a volar approach if the extensor tendon is normal.
- Make a volar zigzag incision centered on the PIP joint.
- Mobilize and protect the neurovascular bundles.
- Open the A3 pulley and retract the flexor tendons.
- Detach the volar plate proximally.
- Detach the collateral ligaments from the proximal phalanx (if necessary).
- Perform synovectomy/debridement.
- Resect the condyle of the proximal phalanx perpendicular to the long axis.
- Square off the base of the middle phalanx.
- Broach the middle phalanx first, slightly dorsal to center.
- A rectangular broach provides stability and rotational alignment.
- Broach the proximal phalanx.
- Insert a trial implant; it should fit flush against the bone and extend just beyond the medial/lateral cortices.
- The implant should not buckle or dislocate.
- Check flexor tendon excursion (make a separate incision in the palm if necessary).
- Preplace a suture in the volar plate.
- Insert implant and then repair the volar plate if necessary.

Postoperative Care
- Splint for several days, then start active flexion/extension based on the condition of the extensor mechanism.
- Use an extension block splint that includes the adjacent digit or digits for 4 to 6 weeks when the volar approach is used.
- Buddy strap for 3 months.

Boutonnière Deformity

Boutonnière deformity occurs frequently in patients with rheumatoid arthritis. Like the swan neck deformity, it is not specific to this disease and represents an alteration in muscle and tendon

balance. The deformity has three components: flexion of the PIP joint, hyperextension of the DIP joint, and hyperextension of the MP joint. Although the swan neck deformity in a rheumatoid patient can originate at any of the finger joints, the boutonnière deformity begins with flexion of the PIP joint. Changes in the adjacent joints are secondary.

Synovial proliferation within the PIP joints stretches the extensor mechanism. As a result, the central slip is unable to maintain full extension of the joint. The lateral bands displace volarward and become fixed in this position. Shortening of the oblique retinacular ligaments results in hyperextension and limited active flexion of the DIP joint. As the flexion deformity of the PIP joint increases, the patient compensates by hyperextending the MP joint. When seen early, the deformities are correctable passively. Later, with fibrosis and contracture of the capsular tissues, the deformity becomes fixed. Functional loss as a result of the boutonnière deformity may remain minimal until the late stages. For this reason, the treatment of early boutonnière deformity should be simple and involve minimal risk.

Salvage surgery (fusion or arthroplasty) should be performed only for severe fixed deformities. Our operative approach to rheumatoid boutonnière deformities depends on the degree of severity. We classify boutonnière deformities as mild, moderate, or severe on the basis of the degree of flexion of the PIP joint, the presence of passive correctability of this joint, and the status of the PIP joint surfaces. This classification helps direct the type of treatment to use (Table 55.6).

Stage I: Mild Boutonnière Deformity

In the early stages of the boutonnière deformity, there is only a slight lag (10–15 degrees) in PIP joint extension. There may be active synovitis of the joint. The DIP joint may or may not be slightly hyperextended. The MP joint is usually normal during this early stage. The extensor lag of the PIP joint can be corrected passively; however, when such correction is done, there is limited flexion of the DIP joint. Flexion of the DIP joint improves as the PIP joint is flexed. The patient's functional loss is related as much to the lack of full DIP joint flexion as to the lack of PIP extension, but functional impairment is minimal at this stage.

Any operative treatment of this mild boutonnière deformity should not jeopardize existing function. We treat a mild deformity by extensor tenotomy to improve DIP joint flexion.[29] Dynamic splinting to extend the PIP joint is used postoperatively to restore the balance of the finger. This method does not risk loss of PIP joint flexion. If active PIP joint synovitis is present, we consider either local corticosteroid injection or synovectomy in a treatment plan.

Extensor Tenotomy. For this, we make a longitudinal incision over the dorsal aspect of the middle phalanx (Figure 55.59). The extensor mechanism is divided obliquely to allow the DIP joint to flex. The oblique tenotomy allows the tendon to be sutured

TABLE 55.6 Treatment Options for Boutonnière Deformity of Finger

Stage	PIP Joint	DIP Joint
I—Mild	Dynamic splinting Injection vs. synovectomy	Extensor tenotomy
II—Moderate	Correct any wrist flexion first Extensor reconstruction	Extensor tenotomy
III—Severe	Fusion (standard) Arthroplasty	Extensor tenotomy

DIP, Dorsal interphalangeal; *PIP,* proximal interphalangeal.

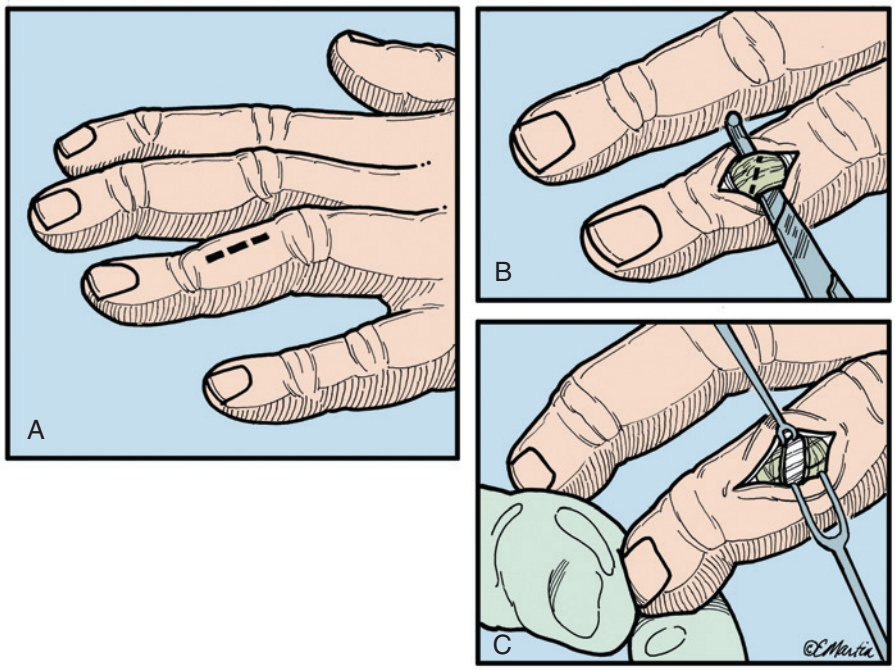

FIGURE 55.59 Technique of extensor tenotomy for a mild boutonnière deformity. **A,** Preoperative deformity of the ring finger. **B,** The extensor mechanism is isolated over the middle phalanx through a longitudinal incision. **C,** Tenotomy of the extensor mechanism can be performed transversely or obliquely, as shown. Note the flexion of the distal joint after tenotomy. (Copyright Elizabeth Martin.)

in the lengthened position and provides more tendon surface area for healing. Postoperatively, there may be a slight "droop" of the DIP joint, but a significant mallet deformity does not usually develop. This procedure is based on the concept that the oblique retinacular ligament acts to extend the DIP joint. However, the dorsal support provided by the extensor mechanism and joint capsule most likely plays a role in maintaining the normal posture of the joint.

It is preferable to perform extensor tenotomy under local anesthesia because this allows the alteration in finger stance as well as finger function to be observed at the time of surgery. Recently we have done these in the office using a percutaneous technique with a No. 18 needle. Any residual extensor lag of the DIP joint is treated with a brief period of postoperative external splinting, which generally corrects the problem. If the deformity is not corrected or if it progresses, the DIP joint can be fused in extension. For most patients, we do not splint the DIP joint postoperatively but encourage active flexion with the PIP joint supported by a dynamic extension splint. This is important in restoring proper balance between the two joints.

Stage II: Moderate Boutonnière Deformity

Loss of finger function becomes more significant as the flexion deformity of the PIP joint reaches 30 to 40 degrees. Patients usually compensate for this by hyperextending the MP joint. Although there are significant difficulties involved in reconstruction of a fixed moderate boutonnière deformity, we have found that satisfactory correction of the deformity with preservation of active PIP joint flexion can be achieved. All the procedures described for correcting an established boutonnière deformity attempt to restore extensor power to the PIP joint with local tissue. This is done by shortening the central slip and bringing the lateral bands dorsally. We believe that it is important to combine this procedure with extensor tendon tenotomy at the DIP joint. Unless this is done, there is a risk of restoring PIP extension but markedly limiting DIP flexion.

We recommend reconstruction of the extensor mechanism in patients with moderate progressive deformity if several criteria are met: good dorsal skin, relatively smooth joint surfaces, intact and functioning flexor tendons, and, of course, passive correctability of the PIP joint. We prefer to reconstruct the PIP joint extensor mechanism before or at the same time as MP joint arthroplasty because any residual flexion deformity at the PIP joint has an adverse effect on achieving MP joint flexion after arthroplasty.

Reconstruction of the Extensor Mechanism. A dorsal longitudinal curved incision is made over the PIP joint (Figure 55.60). A laterally based skin and subcutaneous flap is elevated to expose the extensor mechanism. This places the skin incision away from the site of the extensor tendon repair. The central slip is divided distally while leaving a cuff of tendon attached to the base of the middle phalanx and separated from the lateral bands proximally. Inspection of the undersurface of the central slip shows the changes that have occurred from gradual stretching. Approximately ½-inch (6 mm) of the central slip is excised. The remaining portion is reattached to the cuff of the central slip insertion, which was left intact at the base of the middle phalanx, with nonabsorbable sutures.

Two longitudinal relaxing incisions are made just volar to the lateral bands. The incisions divide the transverse retinacular

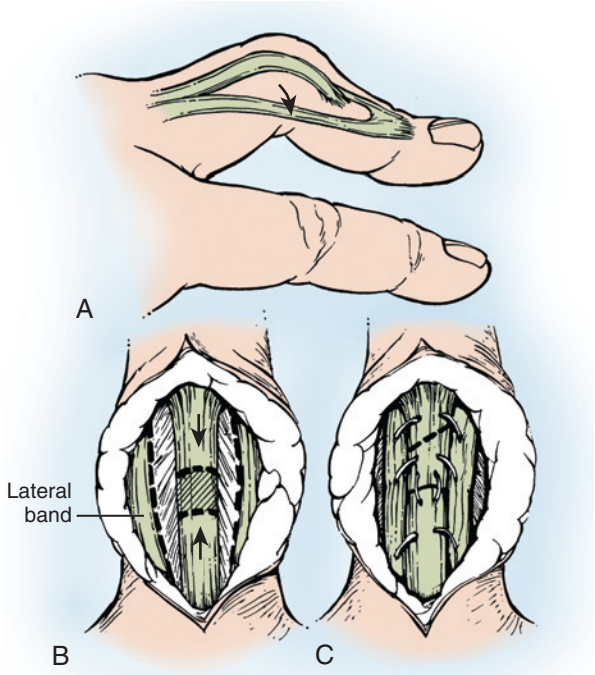

FIGURE 55.60 Reconstruction of the extensor mechanism for a boutonnière deformity. **A,** The fixed-volar position of the lateral band (*arrow*). **B,** Lateral bands mobilized. The portion of the central slip to be excised is shaded. **C,** The central slip is sutured in a shortened position, and the lateral bands are brought dorsalward and sutured to the central slip. (Copyright Elizabeth Martin.)

ligaments and allow the lateral bands to be brought dorsally. The lateral bands are sutured either to the central slip or to each other. The posture of the finger should be corrected now. However, there is usually increased resistance to passive DIP joint flexion, or even to hyperextension of this joint. The extensor mechanism overlying the middle phalanx is divided obliquely through the distal portion of the incision to allow the DIP joint to flex. This procedure allows all extensor mechanism force to be concentrated at the PIP joint level.

Adjustment of the tension of the central slip is very important. It should be possible to flex the PIP joint passively 70 or 80 degrees after the central slip has been reattached. The strong flexors act to increase the range of flexion after postoperative splinting has been discontinued.

A Kirschner wire is placed across the PIP joint to maintain full extension during the early postoperative period. The DIP joint is left free, and active motion of this joint is allowed. After 2 to 3 weeks, the wire is removed and the joint is protected for several weeks with a light dynamic extension splint during the day and a padded aluminum extension splint at night.

The postoperative program can be modified according to the finger involved and the amount of PIP joint flexion possible after the Kirschner wire is removed. If several fingers are reconstructed simultaneously, we remove the wire from the little finger first. For this finger we accept less correction of PIP joint extension to ensure maximal flexion. The reverse is true for the index finger, in which loss of some flexion is less significant.

If necessary, reconstruction of a moderate boutonnière deformity can be performed on all four fingers at the same time. In most patients, however, the criteria necessary for this

operation are present in only one or two fingers. Limiting the reconstruction to these fingers simplifies the operation, as well as the postoperative splinting and exercise program.

Stage III: Severe Boutonnière Deformity

In time, a boutonnière deformity progresses to the point where the PIP joint can no longer be extended passively. No attempt should be made to restore extensor mechanism function unless the joint can be extended passively without excessive force. In this case, restoration of passive motion by dynamic splinting or serial plaster casting is attempted. Occasionally, soft tissue release (i.e., dividing the transverse retinacular ligaments and the accessory collateral ligaments) is necessary to restore passive extension. This is combined with reconstruction of the extensor mechanism. Such extensive surgery is not often indicated.

In severe deformities with poor joint surfaces, the alternative treatment is fusion or arthroplasty. Fusion is the standard method used to correct severe fixed-flexion deformities in rheumatoid patients. It is used for those with finger extension that is so restricted that they are unable to grasp moderate-sized to large objects.

The position of PIP fusion is chosen so that a "functional" position of the involved finger is achieved. In the index or middle finger, loss of full flexion is not critical. In patients with severe bilateral boutonnière deformities, we have performed multiple fusions on one hand while leaving those on the other side untreated to maintain the ability to grasp small objects. However, the loss of PIP joint flexion after fusion is compensated, in part, by the gains in MP joint flexion.

PIP Joint Fusion. Technically, it is easier to perform PIP joint fusion to correct a fixed-flexion deformity than to correct a swan neck deformity because of the surplus skin on the dorsal aspect of the finger and the compression of the bone ends that occurs as the joint is straightened. We use a longitudinal curved incision over the PIP joint. The extensor mechanism is often nonexistent. The collateral ligaments are divided at their origin on the proximal phalanx. With the finger in maximal flexion, the distal end of the proximal phalanx is cut at a slight angle, directed volarly, and removed. The articular cartilage is removed from the base of the middle phalanx, and the subchondral bone is softened with a rongeur. As the finger is straightened, the bone ends are compressed. Bone grafts are not usually needed because of the excellent bone contact.

The position of fusion that we choose varies with the finger involved. We prefer 25 degrees of flexion for the index finger and gradually increase it to 45 degrees for the little finger. As mentioned previously, confirmation of the desired angle of fusion with a sterile goniometer is suggested. A Kirschner wire is passed longitudinally across the joint (Figure 55.61) and is supplemented by an obliquely placed wire. Wires can be cut off

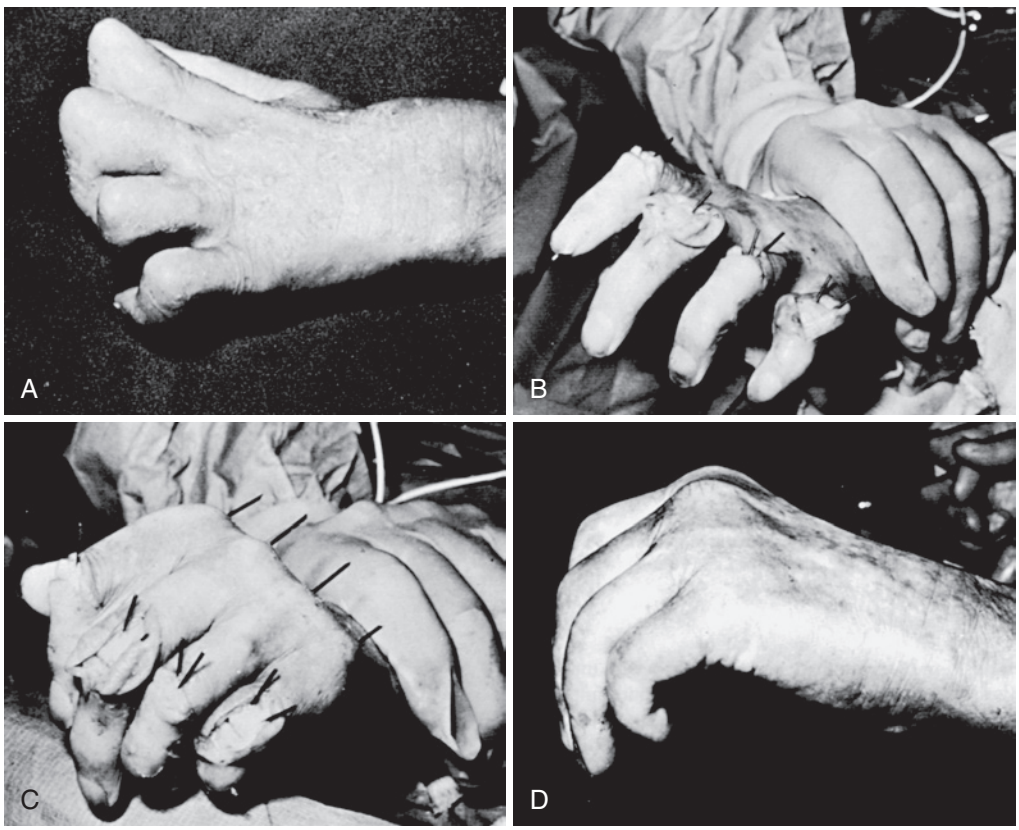

FIGURE 55.61 Severe boutonnière deformities treated by proximal interphalangeal (PIP) fusion. **A,** Severe fixed-flexion contractures of the PIP joints with the metacarpophalangeal (MP) joints fixed in extension. **B,** The degree of flexion for fusion increases from the index to the little finger. **C,** MP joints manipulated into flexion and held with Kirschner wires. **D,** Postoperatively, finger position is improved, and grasp of moderate-sized objects is possible. (From Nalebuff EA, Millender LH: Surgical treatment of the boutonnière deformity in rheumatoid arthritis. *Orthop Clin North Am* 6:753–763, 1985, with permission.)

flush to the bone and left in place permanently or left protruding through the skin to facilitate removal after fusion has occurred. A headless fusion screw can be used as described previously for internal fixation (see Figure 55.48).[37] External splints are used for the first 4 to 6 weeks until the fusion has started to consolidate. If the MP joints were fixed in hyperextension preoperatively, they are brought into flexion by manipulation, soft tissue release, or arthroplasty.

PIP Joint Arthroplasty. PIP joint arthroplasty using a silicone implant is an alternative method for treating a fixed rheumatoid boutonnière deformity. Because the goal of this procedure is to maintain motion, the extensor mechanism must be reconstructed as part of it. This is done by reattaching the central slip to the base of the middle phalanx. Relocation of the lateral bands dorsally is often also required to direct all the extensor force to the PIP joint.

This approach is particularly appropriate for patients whose deformity involves the ring and little fingers and whose MP joints are flexible because preservation of PIP motion in these fingers enhances the ability to grasp. However, we believe that it is not indicated for a severely flexed PIP joint because of the necessity of resecting excessive bone to provide enough space for the implant. PIP joint arthroplasty is discussed in more detail elsewhere in this text.

THUMB DEFORMITIES

Pathophysiology

The original classification of thumb deformities suggested by Nalebuff included four groups.[85] This classification has been revised to include a fifth and a sixth group. Type I deformity (boutonnière) is the most common, and type III deformity (swan neck) is the second most common. Type IV deformity is seen occasionally, and types II and V are rarer. Type VI is joint destruction and collapse associated with arthritis mutilans (Table 55.7). Surgical treatment must be individualized for each patient and each joint and includes synovectomy, tenodesis, tendon transfer, arthrodesis, and arthroplasty.

Type I Thumb (Boutonnière) Deformity

A type I deformity is characterized by MP joint flexion and distal joint hyperextension. It is usually initiated by proliferative MP joint synovitis, which bulges dorsally and results in attenuation of the EPB tendon insertion, stretching of the extensor hood, and displacement of the EPL tendon ulnarward and volarly. The collateral ligaments are stretched, and intraarticular joint destruction occurs to varying degrees. This loss of dorsal support results in proximal phalanx subluxation on the metacarpal and concomitant IP joint hyperextension from the altered pull of both intrinsic muscles and the EPL. The first metacarpal becomes radially abducted to compensate for MP flexion. The hyperextension of the IP joint and the flexion of the MP joint are accentuated when pinch forces are applied to the thumb and, with time, may become fixed. This particular deformity can be described as an "extrinsic-minus" deformity. Rupture of the EPL at the wrist level can therefore result in a similar deformity.

Distal joint hyperextension can be the primary disturbance, with MP joint flexion being secondary, although this is less common. This may be a result of attenuation of the volar plate of the IP joint because of synovitis or rupture of the FPL tendon, which generally occurs in the carpal tunnel. In these patients, IP hyperextension is greater than MP flexion. Metacarpal radial abduction is not usually a significant component because the MP flexion is less. Thus, when faced with a patient with a type I deformity, it is necessary to evaluate the MP and IP joints, as well as the individual flexor and extensor tendons that control them.

In the early stage, both MP and IP joint deformities are correctable passively (Figure 55.62); however, over time, fixed deformities develop, first of the MP joint alone and later of both the MP and IP joints.

Indications for Operative Treatment

There are three clinical stages in the development of type I deformity (Table 55.8). Each requires a different type of surgical

TABLE 55.7 Rheumatoid Thumb Deformities

Type	CMC Joint	MP Joint	IP Joint
I (boutonnière)	Not involved	Flexed	Hyperextended
I—Early	Not involved	Passively correctable	Passively correctable
I—Moderate	Not involved	Fixed contracture	Passively correctable
I—Severe	Not involved	Fixed contracture	Fixed contracture
II (uncommon)	CMC flexed and adducted	Flexed	Hyperextended
III (swan neck)	CMC subluxated, flexed, and adducted	Hyperextended	Flexed
III—Early	Minimal deformity	Passively correctable	
III—Moderate	CMC subluxated	Passively correctable	
III—Severe	CMC dislocated	Fixed contracture	
IV (gamekeeper's)	CMC not subluxated, flexed, and adducted	First degree, radially deviated, UCL unstable	Not involved
V	May or may not be involved	First degree, hyperextended, volar plate unstable	Not involved

treatment. In the early stages, there is MP joint flexion with IP joint hyperextension, but both joints are correctable passively. Surgical treatment at this stage includes synovectomy of the MP joint and reconstruction of the extensor mechanism. The original reconstruction of the extensor mechanism as described by Nalebuff is an EPL-rerouting procedure in which the long extensor tendon is rerouted through the dorsal capsule of the joint to provide additional extensor force at this level.[85] When this procedure is done, the intrinsic muscles of the thumb act as extensor forces for the distal joint. Synovectomy alone has not been shown to significantly alter the natural history of the disease, and synovitis recurs in 6 to 13% of patients after MP joint synovectomy. EPL rerouting corrects the MP joint deformity and helps prevent further collapse of the IP joint, but a review of this procedure by Terrono and colleagues revealed a high late recurrence rate; however, this procedure does improve function during that period.[124]

In the second stage, a fixed MP joint is present with or without intraarticular joint destruction. The IP joint deformity is correctable passively. Most patients are seen at this stage. Arthrodesis is recommended for the MP joint if it is totally destroyed and the two adjacent joints are minimally involved. However, if destructive changes are likely to develop at one of the adjacent (i.e., CMC or IP) joints, CMC joint arthroplasty or MP arthroplasty combined with EPL rerouting must be considered. Correction of the deformity at the second stage helps prevent the third stage from developing.

The third and most difficult stage consists of both a fixed MP joint flexion deformity and a fixed IP joint hyperextension deformity. Treatment is dependent on the status of each of the two joints. If the IP joint is not destroyed and can be released by a dorsal capsulotomy, some degree of IP joint motion can be preserved. However, the deformity usually recurs after release of the IP joint.

If the deformity is too severe, IP joint arthrodesis is indicated. MP joint surgery depends on the severity of the deformity, the status of the articular surfaces, and the surgery indicated for the IP joint. If the IP joint has been fused, it is best to try to preserve MP joint motion either with synovectomy and EPL rerouting or with silicone implant arthroplasty (Figure 55.63). However, in severely deformed or destroyed joints, combined MP and IP joint fusions are sometimes indicated. Although Ratliff stated that he had never found an indication for arthrodesis of both these joints,[102] others believe that this is

indicated occasionally. If the MP joint is only moderately stiff and has a salvageable joint surface, intrinsic muscle and ligament release with reconstruction of the extensor mechanism is indicated.

Type II Thumb Deformity

Type II deformity, which is seen rarely, is a combination of types I and III deformities. It consists of MP joint flexion with IP joint hyperextension and an associated subluxation or dislocation of the CMC joint. Treatment of this deformity is similar to that for types I and III deformities.

Type III Thumb (Swan Neck) Deformity

The second most common thumb deformity is type III, or swan neck deformity. It is characterized by MP joint hyperextension, IP joint flexion, and metacarpal adduction.[85] This deformity results from disease at the level of the CMC joint. Synovitis and erosion of the articular surfaces and capsular distention allow dorsal and radial subluxation of the CMC joint as the thumb is used for grasp. Repeated use can result in complete dislocation of this joint. As the joint subluxates, abduction forces are reduced and adduction contracture of the metacarpal develops (Figure 55.64).

Hyperextension of the MP joint develops secondary to the metacarpal adduction contracture if the volar plate is lax. As the patient attempts to open the first web space to grasp, the fixed-CMC joint deformity prevents metacarpal abduction and extension. The extension forces are transmitted to the MP joint, which results in hyperextension of it. Such patients can grasp moderate-sized objects only by hyperextending the MP joint.

Indications for Operative Treatment

Patients with type III deformities are also seen in three general stages (Table 55.9). In the first, a painful CMC joint, weak pinch, and various degrees of radiographic joint destruction are seen. At this stage there is minimal subluxation, minimal deformity, and no secondary MP joint involvement. Surgical treatment is indicated only for persistent pain after proper conservative therapy has failed. Such therapy consists of an adequate trial of systemic medications, 2 to 4 months of splinting, and occasional corticosteroid injections. The recommended surgical treatment is hemiarthroplasty. We no longer use implant arthroplasty at the thumb base but instead perform resection arthroplasty with ligament reconstruction and tendon interposition.[13]

Patients in the second stage show varying degrees of CMC joint deformity and mild, passively correctable MP joint hyperextension (Figure 55.65). Unless the pain is significant, these patients function quite well except for weakness of pinch. The recommended treatment of a CMC joint with mild MP joint deformity is resection arthroplasty and ligament reconstruction,[10] combined with volar tenodesis or sesamoidesis[127] of the MP joint. MP joint fusion is performed for advanced deformity or joint destruction or in patients with marked hyperextension but limited MP flexion.

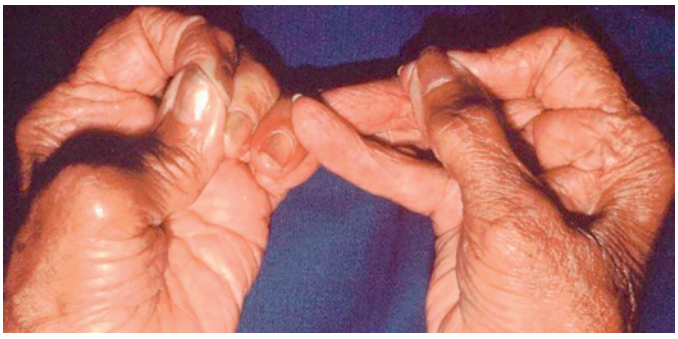

FIGURE 55.63 Type I thumb with impaired pinch function (*left*) is improved by interphalangeal joint fusion and extensor pollicis longus rerouting (*right*).

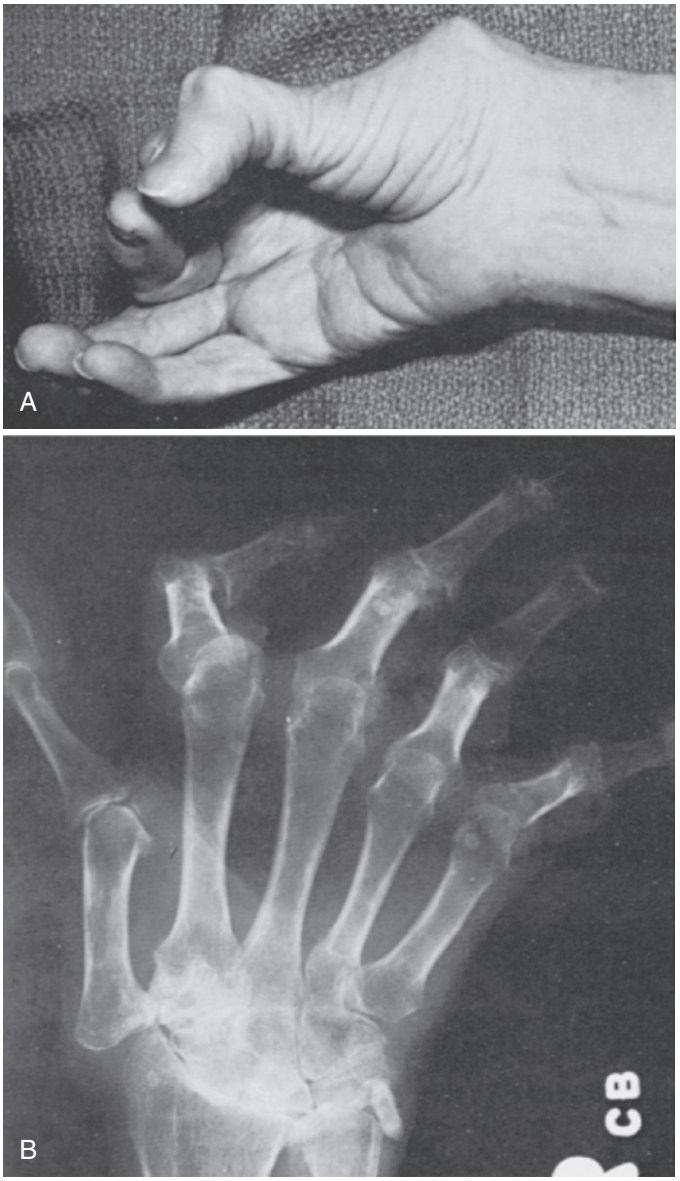

FIGURE 55.65 Advanced rheumatoid thumb deformity. **A,** Dislocated carpometacarpal joint with an adduction deformity of the metacarpal and hyperextension deformity of the metacarpophalangeal (MP) joint. **B,** Radiograph of the hand. Note the collapse deformity of the wrist, dislocation of the MP joints, and lateral dislocation of the index proximal interphalangeal joint. (From Nalebuff EA: Reconstructive surgery and rehabilitation of the hand. In Kelly WN, Harris ED, Ruddy S, et al., editors: *Textbook of rheumatology*, ed 2, Philadelphia, 1985, WB Saunders, pp 1818–1826, with permission.)

Advanced type III deformity includes complete CMC joint dislocation with a fixed-adduction contracture and a fixed-hyperextension deformity of the MP joint. These patients have significant disability as a result of the contracted first web space, which prevents grasp of moderate-sized objects. The zigzag collapse deformity precludes adequate pinch. CMC resection arthroplasty with ligament reconstruction and MP joint fusion is helpful in restoring function to these patients. MP arthroplasty is not performed for hyperextension deformity of the thumb. In a patient with SLE, CMC joint fusion should be done because of increased ligamentous laxity.

TABLE 55.10 Treatment Options for Type IV (Gamekeeper's) Thumb Deformity

Stage	MP Joint
Early	Synovectomy Reconstruction of the collateral ligament
Moderate	As for early (rare) Fusion Adductor fascia release
Advanced	Fusion Adductor fascia release

MP, Metacarpophalangeal.

Type IV Thumb (Gamekeeper's) Deformity

Type IV deformity is characterized by a radial deviation deformity of the MP joint with secondary adduction of the thumb metacarpal. This occurs as synovitis of the MP joint stretches the ulnar collateral ligament, thereby resulting in lateral instability of this joint. Secondarily, an adduction contracture of the thumb develops. In some cases, shortening and contracture of the adductor fascia similar to that seen in type III deformity can occur. The important aspect of type IV deformity is that there is no primary CMC joint disease; therefore, treatment is directed toward the MP joint.

Indications for Operative Treatment

For early deformity, MP joint synovectomy and collateral ligament reconstruction are performed (Table 55.10). In advanced cases, MP joint arthrodesis is done. If the metacarpal remains adducted after the fusion is completed, soft tissue release is added. After the MP joint is stabilized, the thenar muscles function to abduct and oppose the entire thumb ray more effectively and to prevent further adduction of the thumb metacarpal.

Type V Thumb Deformity

Type V thumb deformity results from stretching of the volar plate of the MP joint. It hyperextends, with secondary flexion of the IP joint as tension on the flexor tendon increases. In contrast to a type III deformity, the first metacarpal does not assume an adducted position.

Surgical treatment of a type V thumb deformity is simple; the MP joint is stabilized in flexion by volar capsulodesis, sesamoidesis, or fusion.

Thumb Deformities Secondary to Joint Destruction

These deformities are usually the result of the bone destruction and resorption associated with arthritis mutilans. In advanced cases they cause severe loss of hand function and disability.[91]

Operative Treatment Indications for Severe Joint Destruction and Arthritis Mutilans

Arthrodesis is the usual procedure of choice for severely affected joints. In patients with arthritis mutilans, arthrodesis should be performed early before marked bone resorption occurs. When arthritis mutilans has resulted in marked bone loss, bone grafts are required to restore or maintain length and to allow fusion to occur.[91]

Operative Techniques for Thumb Reconstruction

Surgery is based on which joint is involved. The classification of deformity by type improves the surgeon's understanding of the problem but is not important in the overall treatment chosen.

Interphalangeal Joint. Surgical techniques used for reconstruction of the IP joint are synovectomy, extensor tendon release (for fixed-hyperextension deformities), and arthrodesis of the IP joint.

Synovectomy. Synovectomy of the IP joint can be performed through a dorsal curved, a longitudinal, or a Y incision centered over the IP joint. Another incision that has been used is a longitudinal zigzag one centered over the IP joint. This protects the terminal branches of the dorsal sensory nerve. After the skin flaps are elevated, the proliferative synovium can be removed from either side of the joint with a small rongeur. A small portion of the extensor mechanism can be detached from the base of the distal phalanx which, combined with traction on the phalanx, allows easier access to the joint.

After IP joint synovectomy, the joint is splinted in extension for a few days before beginning exercises. It should be splinted between exercise periods for 2 weeks to prevent an extensor lag from developing.

IP Joint Release. This procedure is performed in conjunction with MP joint fusion or arthroplasty for a moderately severe type I deformity. The skin incision used is critical because the dorsal skin is contracted and thereby limits the amount of flexion that can be obtained. The usual approach involves a lateral incision on either side of the joint. Tenolysis of the extensor mechanism is performed. The dorsal capsule is incised by sliding the blade volar to the extensor mechanism and then rotating it 90 degrees. The dorsal portion of the collateral ligament is released through each incision, and the joint is manipulated into flexion. Usually, it can be held in 25 to 30 degrees of flexion without placing the dorsal skin under undue tension.

Alternatively, a "Z"-plasty can be used. A longitudinal incision is made over the midportion of the joint, which provides excellent exposure. The release is performed as described earlier. After the Kirschner wire has been inserted, the incision is converted into a Z-plasty. There is rarely sufficient skin to close the incision completely, and a portion of the wound is left partially open over the proximal phalanx. This epithelializes within 10 to 12 days, after which time the Kirschner wire is removed and exercises are initiated. For several days after the wire is removed, the joint is protected with a plaster or aluminum splint. Occasionally, an extensor lag develops; in such cases, the joint should be splinted in extension to allow the extensor mechanism to contract. After these procedures 10 to 25 degrees of active joint flexion can be expected; a large range of flexion is never obtained and the deformity often recurs.[124]

IP Joint Arthrodesis. This procedure was described earlier.

Metacarpophalangeal Joint. Operative procedures for a rheumatoid MP joint include synovectomy, synovectomy with reconstruction of the extensor mechanism, volar release in conjunction with reconstruction of the extensor mechanism for fixed-flexion deformities, arthroplasty, and arthrodesis.[46]

Synovectomy. A slightly curved, dorsal, longitudinal incision 3 to 4 cm in length is made over the MP joint. Radial and ulnar flaps are reflected to expose the extensor mechanism. The sensory branches of the radial nerve must be protected. The joint is exposed by a longitudinal incision between the EPL and EPB tendons, which are reflected ulnarward and radially, respectively. The synovium bulges dorsally, often having ruptured through the joint capsule. A synovectomy is performed with a small rongeur.

Traction applied to the joint gives additional exposure. Synovium should be removed carefully from the recesses on either side of the attachment of the collateral ligament to the metacarpal head. Synovitis in this area causes early bone erosions that can be seen radiographically. A small curet is helpful when entering the tight space between the ligament and the metacarpal head. After synovectomy is completed, the extensor mechanism is closed and tightened. The joint is splinted in extension to prevent a flexion deformity. Splinting is continued for 12 to 14 days before beginning exercises. In the thumb, MP joint stability is more important than motion; therefore, allow time for adequate soft tissue healing before motion is started.

MP Joint Synovectomy With Extensor Mechanism Reconstruction. These procedures are indicated for early type I deformity in which the joint is preserved and subluxation is correctable passively (Figure 55.66). Several different methods have been described, and in each the extensor mechanism is exposed as described for synovectomy. The EPL and EPB tendons are identified. The EPB is usually attenuated, and the EPL is often displaced ulnarly and volarly.

To perform the EPL rerouting described by Terrono and colleagues,[120,124] the interval between the EPL and the EPB is identified. The EPL is transected over the proximal third of the proximal phalanx and freed proximally. The attenuated EPB tendon is dissected from the base of the proximal phalanx and detached from the extensor hood. The joint is approached through a transverse incision in the thin portion of the capsule while leaving the thickened portion attached to the base of the proximal phalanx. A transverse incision is made in this thicker capsule distal to the joint, through which the EPL tendon is passed and pulled back over itself. Complete synovectomy of the joint is performed. With the joint held in full extension, the tendon is sutured tightly to itself or attached directly to bone with suture anchors or with sutures placed through drill holes. In a modified technique, the EPL tendon is transected more proximally and the EPB tendon sutured to the EPL stump to improve IP joint extension. An oblique Kirschner wire is used to hold the MP joint in extension. The thumb is splinted with the IP joint in extension.

IP joint flexion and extension exercises are started in a few days. The IP joint is protected in extension when not being exercised to prevent an extensor lag. The Kirschner wire across the MP joint is removed after 4 weeks. However, the MP joint is splinted in extension for an additional 1 to 2 weeks to allow complete healing of soft tissue. All splinting is discontinued 6 weeks after surgery.

MP Joint Ligament Reconstruction for Type IV Deformity. The skin incision described earlier is used. The interval between the EPL and EPB tendons is opened, and the EPL and dorsal expansion of the adductor pollicis are reflected ulnarward. The stretched ulnar collateral ligament is identified. This ligament is detached from the proximal phalanx or metacarpal, whichever end is more attenuated, and synovectomy of the joint performed. The attenuated portion of the collateral ligament is excised. The end of the collateral ligament is attached to bone

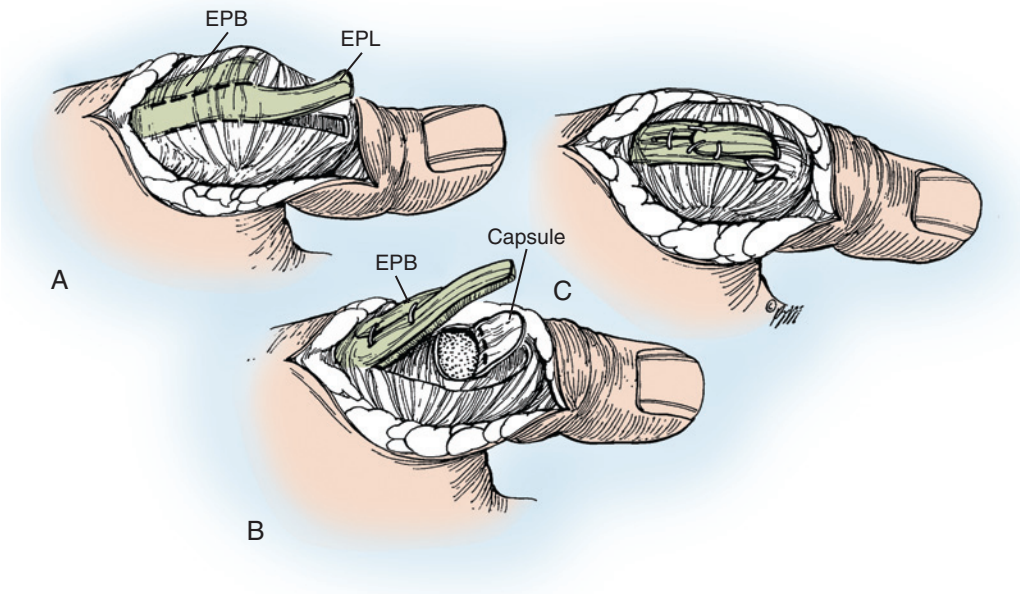

FIGURE 55.66 Extensor pollicis longus (EPL) rerouting for an early type I deformity. **A,** In the standard method of EPL rerouting, the tendon is transected between the metacarpophalangeal (MP) and interphalangeal joints and elevated proximally. **B,** With Nalebuff's modified technique, the EPL is transected more proximally and the distal stump is sutured to the extensor pollicis brevis (EPB) tendon. **C,** The proximal stump is passed through the MP joint capsule and sutured back onto itself in both methods. (Copyright Elizabeth Martin.)

with a pull-out suture or suture anchor. The adductor tendon is detached from the base of the proximal phalanx and advanced distally. Postoperative management is similar to that for the EPL-rerouting procedure.

Procedures for Fixed MP Joint Contractures. The procedures performed for fixed MP joint contractures are soft tissue release with extensor reconstruction (in mild-to-moderate cases) and arthroplasty or arthrodesis (for severe contractures with extensive cartilage loss). If the deformity is in the range of 25 to 35 degrees and the MP joint cartilage is involved minimally, soft tissue release may be preferable to arthroplasty or arthrodesis.

Arthrodesis of IP and MP joints without severe deformity or bone loss. Generally, the IP joint is fused in full extension or in very slight flexion. If necessary, also rotate the IP joint into slight pronation, particularly if the CMC joint is compromised. The technique is similar to that described for PIP joint fusion. A 0.045- or 0.062-inch guidewire is passed distally through the medullary canal of the distal phalanx to exit at the tip, just volar to the nail plate. The exit position of the wire on the fingertip is important. Placement too dorsal will damage the nail bed. With the joint held in the selected position, a self-compressing fusion screw is inserted in a distal-to-proximal direction through a small stab wound just below the nail at the level of the guidewire. A longitudinal or crossed Kirschner wire can also be used for internal fixation. The size of the wire is determined by the softness of the bone and the size of the medullary canal.

Several techniques for MP fusion are available. The MP joint is approached and prepared essentially as described earlier. In one technique, the joint is transfixed with two crossed Kirschner wires. Although the wires can be passed retrograde, they are inserted most easily directly across the joint from a dorsal approach and ulnarward on the metacarpal to dorsal and radial on the proximal phalanx, and vice versa. The wires should be directed so that they do not exit on the volar surface of the thumb, thereby putting the flexor tendon or digital nerves (or both) at risk. A single or dual parallel screws can be used for internal fixation of MP joint fusions.

Alternatively, a tension band technique can be used. It provides a more stable construct than Kirschner wires do, as well as earlier function and minimal immobilization. However, the tension band technique is more demanding (Figure 55.67), and the wires and pins frequently need to be removed after the fusion heals. The MP joint can be fused in 15 to 25 degrees of flexion. Slight pronation may facilitate pinch if the CMC joint is unstable, and the MP joint should be fused in more flexion, up to 25 degrees. It is advisable to measure the position of fusion accurately with a sterile goniometer before the final internal fixation devices are inserted. Intraoperative radiographs are also helpful in confirming the appropriate alignment for fusion.

If after obtaining stable fixation the position varies from that described earlier and is considered suboptimal, the joint can be bent into a better position if only one small-diameter Kirschner wire has been inserted. The second wire is inserted after the position is corrected.

Athrodesis for arthritis mutilans. Loss of bone stock is the major factor that makes fusion in rheumatoid patients difficult. The amount of loss ranges from thinned cortices and absent medullary cancellous bone to severe bone resorption with shortening, as seen in arthritis mutilans.[91,127] Joint exposure may be difficult because of the deformity or subluxation, and the soft, thin bone may not hold Kirschner wires well. In general, the technique is similar to that used for fusing any rheumatoid joint. However, certain points should be emphasized. Excellent exposure is mandatory. If "pencil-in-cup" deformities are present at the IP or MP joints, the bones are exposed by excising the capsule from the rim of the bone and the volar plate from

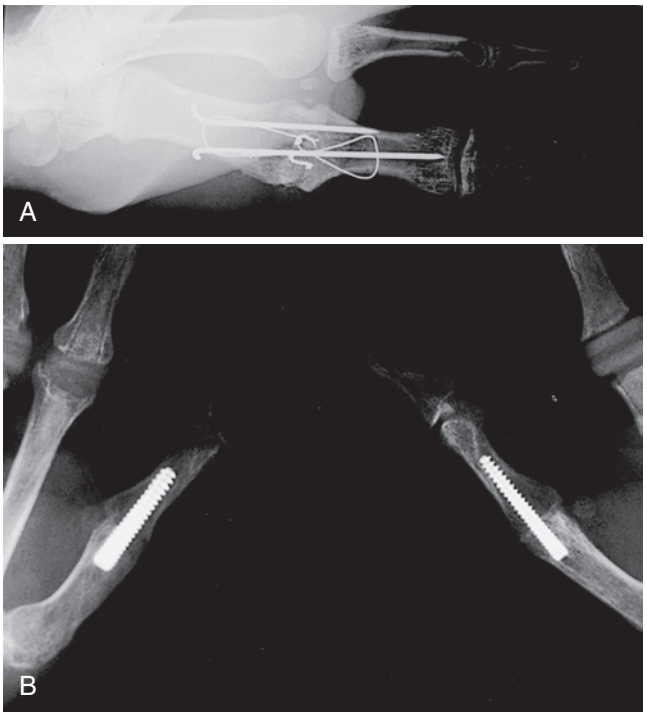

FIGURE 55.67 **A,** Thumb metacarpophalangeal (MP) joint fusion using the tension band technique. **B,** The left thumb MP joint was fused with a standard Acutrak screw, and the right thumb MP joint was fused with a Mini-Acutrak screw. Both fusions healed completely in 6 weeks.

the undersurface of the phalanx, then cut the cartilaginous and cortical rim transversely to obtain a flat surface.

After this has been accomplished, the joints can be apposed. However, adequate bone stock must be present. If bone stock is insufficient, cancellous bone from other areas (e.g., resected metacarpal heads) is helpful to fill the gap and increase stability. If the metacarpal heads from arthroplasty are devoid of cancellous bone, the cortical bone is crushed and used to fill the cavity. Wires are inserted as described earlier. A second longitudinal or crossed Kirschner wire may be needed for the IP joint.

Bone grafts are important in cases of arthritis mutilans. Shortening is accepted if the joints have fused spontaneously. However, iliac bone blocks are often needed to restore length and to obtain fusion (Figure 55.68).[91] The joints are exposed and prepared as described earlier. A bone block from the iliac crest or distal radius is fashioned, wedged into place, and fixed with longitudinal Kirschner wires. Cancellous bone is packed into the remaining space. These fusions are technically difficult and require 4 to 5 months of immobilization postoperatively.

Trapeziometacarpal joint anthroplasty. We now use the trapezium resection and tendon suspension/interposition method—that is, ligament reconstruction with tendon interposition (LRTI)—described by Burton and Pellegrini.[13] The APL should be advanced to ensure adequate postoperative abduction power. MP joint hyperextension or instability must be corrected at the same time, usually by arthrodesis. IP joint arthrodesis can also be performed at the same time if indicated.

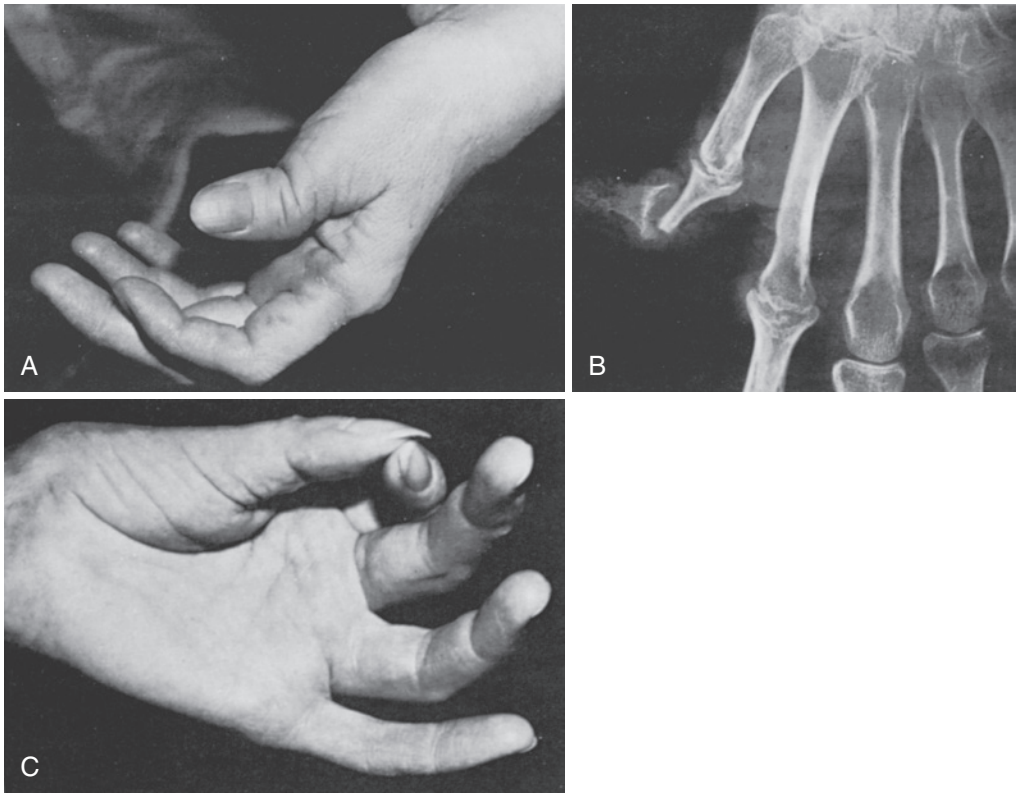

FIGURE 55.68 Unstable distal joint of the thumb fused with a bone graft. **A,** Clinical appearance of the thumb with collapse of the interphalangeal joint. **B,** Radiograph showing significant absorption of the distal end of the proximal phalanx. **C,** Note the stable pulp pinch between the lengthened thumb and index finger. The distal joint is fused in slight flexion. (From Nalebuff EA: Reconstructive surgery and rehabilitation of the hand. Tendinopathy is a term used to encompass painful conditions affecting the tendons of the wrist and hand and is perhaps the most common reason for a visit to a hand surgeon. Tendinopathy includes conditions such as tendon entrapment and stenosis (e.g., trigger finger, de Quervain disease), as well as inflammatory conditions (*tenosynovitis*). Strictly defined, *tenosynovitis* refers to inflammation of the synovial lining of a tendon sheath and is abundantly demonstrated by the diffuse, invasive synovitis associated with rheumatoid arthritis (RA) or other inflammatory arthropathies. Such proliferative tenosynovitis is relatively uncommon, is erosive, is not restricted to the retinacular thickenings of the tendon sheath, and may lead to tendon rupture. Other causes of inflammatory or proliferative tenosynovitis include deposition diseases such as amyloidosis, crystalline tendinopathy (e.g., calcific tenosynovitis or gout), and septic tenosynovitis, including bacterial, mycobacterial, and viral agents.

A far more common condition than proliferative tenosynovitis is *tendon entrapment* or *stenosing tendovaginitis*,[13] caused by narrowing or stenosis of a tendon's retinacular sheath. The two most common conditions are *trigger finger* and *de Quervain disease*. Because there is a paucity of inflammatory tissue associated with tendon entrapment,[36] the term *tenosynovitis*, when used to describe these conditions, is misleading and inaccurate from an etiologic perspective. Tendon entrapment occurs about the narrow fibroosseous canals that provide fulcrums for acute angulation of the digital and wrist tendons. Repeated motion of a tendon through such a narrow passageway can cause hypertrophy and fibrosis of the retinacular sheath[34] that results in an impediment to gliding, edema, and, ultimately, catching or locking of the tendon on either side of the sheath. Rarely, these conditions may be initiated by direct trauma. Tendon entrapment is initially characterized by local pain, swelling, and crepitus. Over time, the affected retinacular sheath responds by thickening (up to three times its normal diameter) and undergoes fibrocartilaginous metaplasia.[97] Pathologic examination rarely demonstrates hypertrophied synovium but rather thickening, nodularity, and attritional changes within the tendon, accompanied by gross thickening of the overlying sheath. These conditions as a group respond well in the early phase to conservative measures such as ice, splinting, and rest. Recalcitrant cases respond well to one or more corticosteroid injections. Surgical release of the retinacular sheath is definitive treatment because recurrence is rare.

PROLIFERATIVE TENOSYNOVITIS

Rheumatoid Arthritis

It has been estimated that tenosynovitis of the hand and wrist will develop in 64 to 95% of patients with RA.[9] The process may begin within the synovial lining of the tendon sheath, or it may invade the tendon from involvement of a contiguous joint. Rheumatoid tenosynovitis produces relatively painless bulky swelling along the entire extent of the synovial sheath and is most noticeable at the retinacular boundaries. Because of the thin, expansile dorsal skin of the hand, the disease may be quite prominent dorsally and produce noticeable swelling from the distal retinaculum to the metacarpal bases. The process can easily be differentiated from common wrist tumors such as ganglia or lipomas by the mobility of the mass with the extensor tendons and the tendency of the mass to bunch (the characteristic *tuck sign*) at the retinacular edge with active digital extension.[9] Tenosynovitis of RA is most common on the ulnar border of the wrist over the distal radioulnar joint and most frequently involves the fourth, fifth, and sixth dorsal compartments.

On the flexor surface, the earliest signs of considerable flexor tenosynovitis may be painful paresthesias caused by median nerve entrapment beneath the unyielding transverse carpal ligament. With time, palmar nodularity along the flexor tendons, crepitus, and frank triggering will develop in more than a third of patients with RA. Fusiform swelling of one or more digital flexor sheaths may cause a substantial impediment to flexion, pain, and stiffness mimicking rheumatoid arthropathy of the interphalangeal (IP) joints. Rarely, a finger may trigger in RA from entrapment of the profundus tendon by synovitis at the superficialis decussation (Camper chiasm). Helal described the cardinal sign of this syndrome as an inability to flex the distal interphalangeal (DIP) joint when the proximal interphalangeal (PIP) joint was held passively by the examiner in full flexion.[53]

For a more detailed discussion of rheumatoid tenosynovitis and the medical and surgical treatment options, the reader is referred to Chapter 55.

Crystalline Tendinopathy

Gout

Precipitation of crystalline material within the confines of an enclosed space (joint or tenosynovial space) incites an acute, fulminant inflammatory reaction marked by intense swelling, erythema, and pain. Gout is a disorder of urate metabolism in which the overproduction of uric acid causes hyperuricemia and hyperuricosuria.[25]

Gout affects over 6 million individuals in the United States and the incidence is reported to be rising.[21] The low solubility of monosodium urate is responsible for its crystallization and deposition in peripheral sites, including subcutaneous, intraarticular, and tenosynovial locations. Attempted phagocytosis by peripheral leukocytes releases lysosomal enzymes that produce an intense inflammatory synovitis. If left unchecked, the disease results in the formation of gouty *tophi*, which are large, lobulated subcutaneous deposits of monosodium urate crystals commonly seen in the pinna of the ear and the great toe.[107] Deposition in the hand occurs relatively late in the disease and is uncommon with good medical management.[79] Radiographic manifestations of gouty arthritis may precede symptoms in up to 25% of patients and precedes deposition of gouty tophi in up to 42%.[6] Gouty arthritis is manifested by acute and rapidly escalating joint pain over the first 24 hours, followed by spontaneous resolution over the next week to 10 days. Medical control of the disease is the mainstay of treatment. Gouty tenosynovitis in the hand can be present without visible tophi or previous involvement of the upper extremity. Often called "the great imitator," gout may masquerade as septic arthritis, RA, or neoplasm, and the diagnosis is often delayed by weeks or months. Initial signs of flexor tendon involvement include marked pain, erythema, acute swelling, and warmth suggestive of acute suppurative tenosynovitis.[1,11,43,79] Gouty flexor tenosynovitis within the carpal tunnel can compromise the median nerve and result in acute carpal tunnel syndrome.[43,79] In unsuspected cases, an intense exudative inflammatory reaction can occur after carpal tunnel release that mimics infection but responds well to antiinflammatory medications and uricosuric agents.[43] Gout can rarely coexist with RA, but it is perhaps more frequently misdiagnosed as RA because of its proliferative synovitis[1] and because 10% to 20% of patients with RA have elevated uric acid levels.[107]

Because hyperuricemia can be found in 5 to 7% of adult men, a diagnosis of gout should not be based on laboratory values alone. The combination of joint or tenosynovial aspiration, gram-stained smear results, and examination under polarized light is 85% sensitive for the diagnosis of gout and may be helpful in differentiating acute gouty tenosynovitis from RA or infection. Suspected pathologic material must be transported to the laboratory in ethanol rather than formalin to prevent degradation of the monosodium urate crystals. Compensated polarized light microscopy will demonstrate negatively birefringent (urate) crystals within the granuloma and histologic features otherwise typical of RA.

Other sites of gouty tenosynovial involvement in the hand include the extensor tendons at the dorsal retinaculum, a localized painful mass in the midpalm, and tophi over the dorsal aspect of the IP or metacarpophalangeal (MP) joints. Neglected cases can proceed to intratendinous infiltration,[1] flexion contractures,[107] tendon rupture,[79] and skin ulceration in extreme cases. Acute attacks are generally well handled by the administration of colchicine and antiinflammatory agents. Prophylactic perioperative treatment is recommended to reduce the chance of a postoperative flare-up.[79]

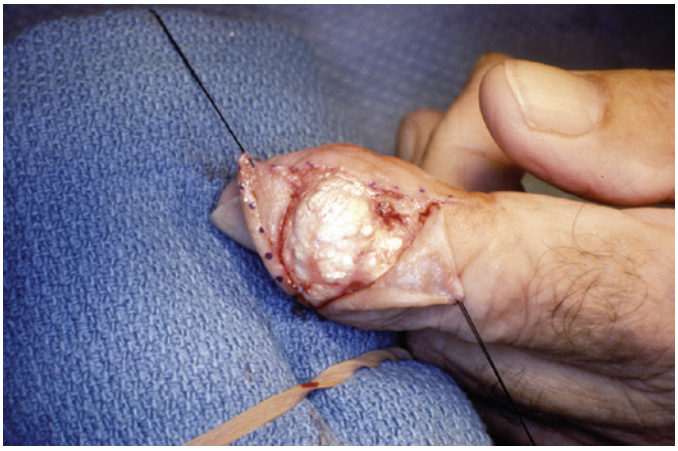

FIGURE 56.1 Excision of gouty tophus involving the extensor tendons and distal interphalangeal joint. Meticulous skin flap handling is necessary to avoid skin sloughing and wound breakdown.

Indications for operative management include synovectomy for restoration of mobility, tendon transfers for tendon rupture, decompression for median nerve compression, and removal of painful or disfiguring tophi to prevent skin breakdown and infection (Figure 56.1). When excising gouty tophi, care should be taken not to devascularize involved or compromised skin. Skin grafts are rarely necessary for coverage. Curettage is useful for bony involvement, and extensive stripping of periosteum is avoided. No attempt should be made to completely eradicate a tophus if excision would damage vital neurovascular structures or impair function. Bulky compression dressings are recommended to reduce dead space. Recurrence is rare after subtotal excision of gouty tophi and ample medical management.[107]

Calcific Tendinitis

An acute, intensely painful synovitis can accompany the release of calcium salts into the intrasynovial space in joints or tenosynovial sheaths and can resemble an infectious process.[18,80] The disease is not unlike the deposition of calcium about major joints in the body, as exemplified by calcific bursitis of the hip, knee, shoulder, and elbow. Hypercalcemia is neither necessary nor sufficient to produce ectopic calcifications, and elevated laboratory values and systemic signs are characteristically lacking.

The cause of calcific tendinitis of the hand and wrist is unknown. Neither trauma nor repetitive use can be implicated, and the disorder occurs more commonly in men (40 to 60 years of age) than women (5:1) and rarely in children.[50,75] The most common site is the flexor carpi ulnaris (FCU), although any of the flexors or extensors of the wrist may be afflicted. Histologic studies of crystalline material collected at surgery may demonstrate hydroxyapatite, which may induce the acute inflammatory reaction. As in other types of inflammatory synovitis, carpal tunnel syndrome has been reported to result from acute calcific tenosynovitis about the flexor tendons.[84]

The patient may present for treatment of a "septic" tendon or joint but demonstrates a striking lack of systemic findings.[18] The patient seldom has a history of penetrating trauma or previous infection. Although erythema is present, the pattern differs from that seen in cellulitis in that it seldom streaks proximally. The area of acute inflammation is typically more confined and localized. Radiographs should be carefully scrutinized for "fluffy" calcification in the area of symptoms or small soft tissue calcium deposits (Figure 56.2, *A* and *B*). Patients may recall similar events in the past. The diagnosis is frequently delayed, presumably because of confusion with infection.[80]

Treatment with oral nonsteroidal antiinflammatory agents for 5 to 7 days is usually successful. Symptoms often subside within 24 hours. For patients who may not take these agents, a prepackaged tapered methylprednisolone oral dose pack (Medrol Dosepak) can be used. Splinting the afflicted joint may also lessen the pain. Although direct aspiration and injection of corticosteroids with lidocaine can be performed, this is seldom needed. Follow-up radiographs will generally show complete disappearance of small deposits in 2 to 4 weeks. Resistant or chronic cases with large calcific deposits may require surgical excision, but this is an exception. Incision of the affected tendon will allow extrusion of the material, which resembles "toothpaste."[18]

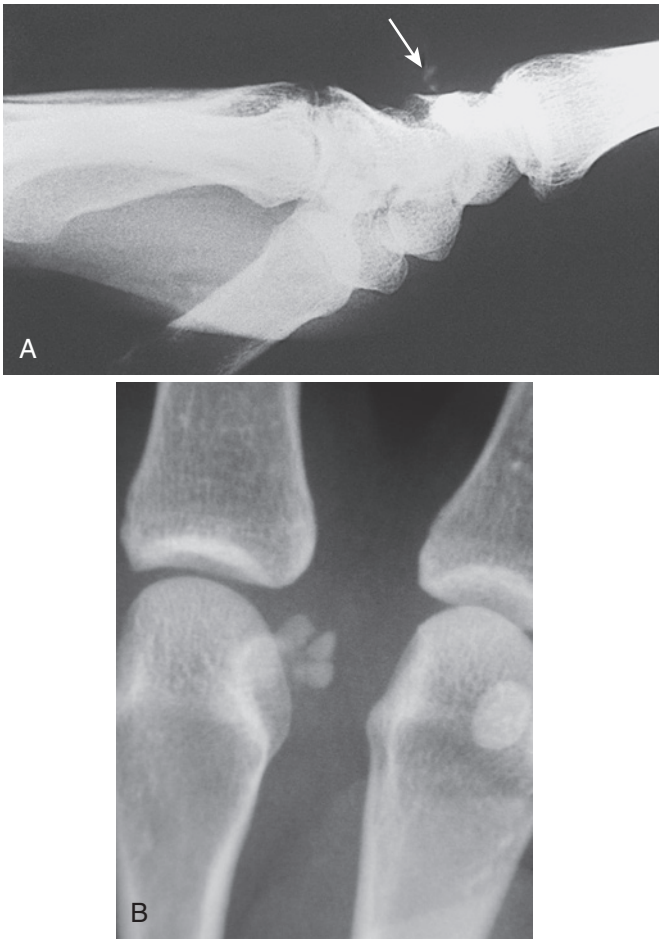

FIGURE 56.2 **A,** A small calcific deposit within the extensor carpi ulnaris tendon sheath (*arrow*) explained the extreme pain and loss of motion experienced by this 28-year-old businessman. **B,** Fluffy calcifications at the level of the A1 pulley appeared 1 week after the onset of excruciating pain along the flexor sheath that mimicked acute septic flexor tenosynovitis in this 38-year-old woman with no history of penetrating trauma. The symptoms resolved with antiinflammatory agents and splinting.

Other Crystalline Tendinopathies

Pseudogout. Rarely, calcium pyrophosphate dihydrate (CPPD, or pseudogout) can precipitate within the carpal tunnel and cause an acute fulminant inflammatory tenosynovitis with resultant carpal tunnel syndrome.[11,22] Radiographs may reveal fluffy soft tissue calcifications within the carpal tunnel and often show calcifications within the triangular fibrocartilage complex (TFCC). Pathologic examination reveals rhomboid-shaped crystals with faintly positive birefringence under polarized light.

Hydroxyapatite Deposition. Deposition of hydroxyapatite has also been reported to cause an acute carpal tunnel syndrome that is recalcitrant to antiinflammatory agents and rest.[114] Both conditions are best treated by early decompression and excision of the crystalline material.

Amyloid Deposition

Amyloidosis is a condition resulting from the deposition of a low-molecular-weight serum protein, β_2-microglobulin, in the bones and soft tissues. Excess protein accumulation can result from a rare primary enzymatic defect (Meretoja syndrome)[93] but more commonly occurs in patients with renal failure who are undergoing peritoneal dialysis or hemodialysis. The protein is not filtered by standard dialysis membranes, and the severity of the disease is proportional to the age at initiation of hemodialysis and the duration of treatment.

Hand involvement in amyloidosis is usually characterized by cystic lesions in the carpal bones and destructive arthropathy involving the wrist and IP joints. Thick, plaquelike accumulations along the flexor tendons can cause trigger fingers, carpal tunnel syndrome, flexion contractures, and tendon rupture, usually without signs of inflammation. In a patient undergoing renal dialysis, paresthesias in the median nerve distribution and diminished active motion are strongly suggestive of amyloid deposition within the carpal canal. Surgical decompression along with débridement and complete removal of amyloid "tenosynovium" is effective in relieving symptoms, which usually do not recur (Figure 56.3). Trigger fingers should be

FIGURE 56.3 The more extended operative exposure required for amyloid-induced carpal tunnel syndrome. Note the extensive hypertrophied synovium excised from around the flexor tendons.

approached through standard incisions in the midpalm, and complete tenosynovectomy and division of the A1 pulley should be performed. Digital tenosynovitis may be excised through Bruner incisions, with retention of all other annular pulleys.

Ochronosis

Alkaptonuria is an extremely rare autosomal recessive defect of tryptophan metabolism caused by a deficiency in the enzyme homogentisic acid oxidase. As a result, unmetabolized homogentisic acid is excreted in urine and deposited in the joints and soft tissues (ochronosis). The protein deposits have a characteristic dark pigmentation that causes darkened urine and deep staining of collagenous tissue. Joint deposition or accumulation in the intervertebral disk can lead to severe destructive arthropathy. The protein may be deposited within tendons[70] and has been demonstrated to cause stenosing tenosynovitis. Seradge reported a case involving multiple digits of both hands that was unresponsive to corticosteroid injection. Surgical release of the A1 pulley was successful at eliminating the symptoms.[102]

Septic Tenosynovitis

Acute suppurative flexor tenosynovitis is covered in Chapter 3.

Chronic Tenosynovitis

Certain indolent infections can be manifested as subacute tenosynovitis and must be included in the differential diagnosis. Such infections include tuberculosis,[15] atypical *Mycobacterium* infection,[62] gonococcal tenosynovitis, and fungal infections. These chronic infections are discussed in detail in Chapter 3.

Sarcoid

On occasion, sarcoidosis can be manifested as digital flexor tenosynovitis and must be included in the differential diagnosis of isolated, inflammatory tenosynovitis.[38,74] Sarcoidosis is a systemic, immune-mediated granulomatous disease that primarily affects the lungs, spleen, and lymph nodes but may be manifested as bone, joint, or tenosynovial involvement in approximately 25% of patients. Radiographs of affected hands typically reveal well-defined cystic granulomatous lesions in the phalanges. The causative agent that triggers sarcoidosis has not been identified. Its progression is variable, with spontaneous regression in some but progression to a chronic fibrotic state in others.[35] The disease is more common in women than men and affects blacks 10 times more frequently than whites in the United States. Sarcoidosis may precipitate secondary gout because of an overproduction of purines in the proliferative granulomas. Treatment includes surgical tenosynovectomy and systemic corticosteroids.[74] Histopathologic examination of the excised material demonstrates noncaseating granulomas, as well as epithelioid and multinucleated giant cells.

Tendon Entrapment

Tendon entrapment (formerly known as *stenosing tenosynovitis*) refers to mechanical impingement of a tendon in the hand or wrist caused by narrowing of its retinacular sheath. Unfortunately, tenosynovitis is generally very broadly defined and has been used to describe a heterogeneous collection of vague aching conditions of the upper extremity. *Tendovaginitis* (Latin for "tendon sheath" and Greek for "inflammation") may be a more precise term than *tenosynovitis* to describe the thickened retinacular sheath that characterizes these conditions. In 1952, Burman[13] tried to clarify the definition as follows: "Tendovaginitis is not tenosynovitis. Before there is stenosing tendovaginitis, there must be nonstenosing tendovaginitis. It takes time to make a sheath stenotic. The latter is reversible, the former is not." As the term *tendovaginitis* is considered archaic, this group of conditions is best simply described as *tendon entrapment*.

Histologic Findings

The most common types of tendon entrapments are de Quervain disease and trigger digits, although the process has been reported to affect each of the tendons of the hand and wrist. Inflammation has been cited as the common denominator of a number of affectations of the upper extremity, including de Quervain disease, trigger digits, and carpal tunnel syndrome. In patients without a known history of inflammatory disease, several studies have failed to detect acute or chronic inflammatory cells in tenosynovial biopsy samples taken from patients undergoing carpal tunnel release.[40,58,100] Similarly, in Fahey and Bollinger's pathologic analysis of synovium from adults and children who underwent trigger release, synovial proliferation was uncommon (one case), and pathologic findings of degeneration, vascular proliferation, and cartilage formation were limited to the retinacular sheath.[34] Similar histologic analysis of tissue removed during tenolysis for de Quervain disease or stenosis of the flexor carpi radialis (FCR) tendon documented perisynovial fibrous tissue and endothelial proliferation with a paucity of inflammatory tissue. The lack of pronounced inflammatory findings within the tenosynovium and the demonstration of fibrotic thickening in the retinacular ligament prompted Garsten in 1951 to coin the term *peritendinitis stenosans* and to suggest that the conditions may be related more to intrinsic anatomic and degenerative changes than to occupational factors.[41]

Causative Factors

Although the cause of tendon entrapment is disputed, certain epidemiologic factors are apparent. These conditions tend to cluster in certain patients, with coexistence of carpal tunnel syndrome, trigger digits, de Quervain disease, epicondylitis, and subacromial bursitis implicating a more systemic yet undefined predisposition.[44,85] A recent study demonstrated a three-fold incidence of carpal tunnel syndrome in patients with multiple trigger digits.[117] Each condition is far more common in women than men,[85,87,116] and the peak incidence of trigger digits averaged 55 to 60 years of age in several series.[34] The age distribution of trigger digits has not changed appreciably in more recent series despite an increase in the use of computer keyboards, personal digital assistants, and other "repetitive" tools and tasks in younger individuals.[85,87,97] Bunnell proposed anatomic factors to explain the pronounced difference in prevalence among men and women.[12] Degenerative factors may have an etiologic role in the development of flexor tendon entrapment of the digits, as evidenced by the increased incidence of these disorders in the dominant hand.[85,87,97] Several studies point to a relationship between activities that require exertion of pressure in the palm while performing forceful grip or repetitive digital flexion, such as arc welding, use of heavy shears, or constant handheld tool

work.[13,34] Forceful use is unlikely to be the sole etiologic factor, however, as evidenced by the strikingly low incidence in males and athletes and an age distribution that peaks in the sixth decade. Trezies and colleagues demonstrated no significant difference between the occupational distribution of patients with trigger digits and that of the general population.[111] A recent systematic review of 179 studies could find no causal link between de Quervain disease and occupational risk factors.[104] Other anatomic and intrinsic factors undoubtedly contribute to a predisposition for the development of tendon entrapment in the hand and wrist.

Trigger Digits

Tendon entrapment of the fingers and thumb is one of the most common causes of hand pain and disability. The condition causes painful catching or popping of the involved flexor tendon as the patient flexes and extends the digits. On occasion, the digit will lock in flexion and require passive manipulation of the digit into extension. Rarely, a digit may be locked in extension. Over time, guarding and reluctance on the part of patients to fully range the digit can lead to secondary flexion contractures at the PIP joint.

Pathologic Findings

Twenty-two extrinsic tendons cross the wrist and provide a unique combination of power and dexterity in the hand. Each tendon passes through a series of tight fibroosseous canals designed to optimize the balance between motion and production of force by maintaining the tendon in close apposition to the joint or joints that it controls. Division, attenuation, or rupture of a critical retinacular ligament, or *pulley*, will allow the tendon to drift away from the joint's center of rotation and consequently increase its moment arm for production of force and lead to tendon imbalance and flexion contracture. Pulley disruption also effectively lengthens the tendon and limits its excursion.

The phenomenon of trigger finger is due to mechanical impingement of the digital flexor tendons as they pass through a narrowed retinacular pulley at the level of the metacarpal head.[85,87,97] Proximal phalangeal flexion, particularly with power grip, causes high angular loads at the distal edge of the first annular (A1) pulley. Hueston and Wilson suggested that "bunching" of the interwoven tendon fibers occurs, akin to the effect of pulling a multifilament strand through the eye of a needle[55]; this may be responsible for the reactive intratendinous swelling sometimes noted at surgery.[34] The most remarkable pathologic changes are seen in the pulley itself, which demonstrates gross hypertrophy, described by Bunnell as a "whitish, cicatricial collar-like thickening."[12] Microscopic examination demonstrates degeneration, cyst formation, fiber splitting, and lymphocytic or plasma cell infiltration.[34] Ultrastructural studies comparing normal and trigger A1 pulleys have demonstrated the presence of chondrocytes in the normal innermost, or *friction*, layer of normal A1 pulleys and chondrocyte proliferation and the presence of type III collagen in pathologic pulleys.[97] It is thought that the A1 pulley and the corresponding surface of the flexor tendon undergo fibrocartilaginous metaplasia under the influence of repetitive, compressive loads. A recent study by Miyamoto and colleagues in which a specialized ultrasonographic compression technique was used documented increases in both stiffness and thickness of the A1 pulley in patients with symptomatic triggering; notably, corticosteroid injection reversed these changes within 3 weeks of injection.[76]

Demographics

The most common form of trigger finger is the primary type, which is found predominantly in otherwise healthy middle-aged women with a frequency of two to six times that seen in men.[34,85,87,71] Involvement of several fingers is not unusual; in patients with multiple trigger digits, the most commonly affected digit is the thumb, followed by the ring, long, little, and index fingers.[34] Secondary trigger finger can be seen in patients with diabetes, gout, renal disease, RA, and other rheumatic diseases and is associated with a worse prognosis after conservative or surgical management.[20,44,103] The lifetime incidence of trigger digits has been reported to be 2.2% in nondiabetic adults older than 30 years and up to 10% in patients with insulin-dependent diabetes mellitus.[103]

Although the flexor tendon sheath is constricted at the MP joint, the patient or examining physician often localizes the phenomenon incorrectly to the PIP joint. A locked trigger digit can lead to an incorrect diagnosis of dislocation, Dupuytren disease, and even focal dystonia or hysteria. A locked trigger digit can be confused with so-called *true locking* of the MP joint (see Chapter 8). Except for rare instances of locking caused by a tumor of the tendon or sheath, a loose body in the MP joint, anomalies of the sesamoids, or entrapment of an intrinsic tendon on an irregularity of the metacarpal head,[89] the diagnosis should be straightforward and can be confirmed with a simple lidocaine injection into the flexor sheath to unlock the digit. On occasion, de Quervain disease[115] and tendon entrapment of the extensor pollicis longus (EPL) have been demonstrated to cause triggering of the thumb and may lead to an error in diagnosis. Rarely, localized enlargement of the flexor digitorum profundus can trigger at a stenotic A3 pulley and lead to persistence of symptoms after routine surgical incision of the A1 pulley. Up to a quarter of trigger digits in patients with RA may be due to profundus entrapment by synovitis at the superficialis decussation.

Classification

Attempts have been made to classify triggering, but in one such report by Newport and colleagues,[85] no correlation was found between their grading scheme and outcome after injection therapy. I believe that some type of simple classification is useful if for no other purpose than to provide the clinician with a way to record notes in the patient's chart for retrospective review. Several authors have used a scheme such as the following, originally proposed by Quinnell[90] and modified by David Green (Green DP, personal communication, 1997):[31,48,83,87]

- Grade 1 (pretriggering)—Pain; history of catching, but not demonstrable on physical examination; tenderness over the A1 pulley
- Grade II (active)—Demonstrable catching, but the patient can actively extend the digit
- Grade III (passive)—Demonstrable catching requiring passive extension (grade IIIA) or inability to actively flex (grade IIIB)
- Grade IV (contracture)—Demonstrable catching with a fixed flexion contracture of the PIP joint

Treatment

Nonoperative Management. Most primary trigger digits in adults can be successfully treated nonsurgically with corticosteroid injection or splinting. Early series recommended surgical treatment as straightforward and highly effective and regarded prolonged conservative treatment as "unreliable and expensive."[34] Subsequent follow-up series documented poor results in 7 to 9% of patients after surgical treatment, with complications including reflex sympathetic dystrophy, infection, persistent triggering, stiffness, and nerve injury. More recent reports continue to document infrequent but serious complications, including nerve transection, infection, incisional pain, flexion deformity, pulley rupture, flexor tendon bowstringing, and recurrence.[19,44,52,83,85] The small but finite risk for complications from open trigger release warrants an initial attempt at splinting or corticosteroid injection, or both.

The popularity of corticosteroid injection has waxed and waned over the years. In primary trigger finger and thumb, corticosteroid injection has a highly satisfactory rate of success, particularly in nondiabetic patients with involvement of a single digit, a discrete palpable nodule, and a short duration of symptoms (Table 56.1). Although several authors have demonstrated that improvement after injection is less likely in diabetic patients than in nondiabetic patients, the treatment is not ineffective in diabetic patients, and it is associated with a low complication rate. Rarely, tendon ruptures have been reported after corticosteroid injection, and the cause is difficult to discern. In one case, the flexor pollicis longus (FPL) ruptured in a 62-year-old patient who was opening a file drawer 4 years after two corticosteroid injections for trigger thumb.[109] In a second case, both the superficialis and profundus tendons ruptured in a 77-year-old patient approximately a year after two steroid injections with triamcinolone acetonide (40 mg/mL).[37] In a recently reported case, Gyuricza and colleagues described rupture of multiple flexor tendon pulleys and severe bowstringing after a series of corticosteroid injections for trigger finger.[47] Even though a causative link between a particular corticosteroid preparation and tendon or pulley rupture cannot be made, all authors recommend that intratendinous injection be avoided given the known attritional effects of corticosteroids on collagen. No other serious complications of this technique have been reported. A transient rise in blood and urine glucose levels is common in diabetics,[44] and these patients should be advised that this is likely to occur. Because of the theoretical chance of inhibition of wound healing, it is prudent to wait at least 6 weeks after corticosteroid injection before consideration of open surgical release.

In a novel evidence-based study of cost-effectiveness, Kerrigan and Stanwix investigated five strategies of treatment ranging from one or two corticosteroid injections, followed by surgical release, to immediate open or percutaneous release. They concluded that the strategy of two corticosteroid injections followed by surgery in nonresponders was the least costly algorithm and was 250 to 340% less expensive than immediate surgical release.[59]

Technique of Corticosteroid Injection. There are many different techniques for injection of trigger fingers, but the following is my preferred method. A 3-mL syringe is loaded with 0.9 mL of plain lidocaine (no epinephrine) and 0.1 mL of sodium bicarbonate. Sodium bicarbonate, in a 1:10 mixture, neutralizes the acidity of lidocaine and effectively reduces the pain of injection. (Bupivacaine [Marcaine] should not be used

TABLE 56.1 Outcomes of Steroid Injection for Trigger Digits

Author	Year	Cortisone Preparation	Findings	Number of Digits	Notes
Kolind-Sorensen[61]	1970	Hydrocortisone	67% success overall; 78% for "primary" trigger digits	106	Only 50% success rate with trigger digits secondary to rheumatoid arthritis, diabetes
Lapidus and Guidotti[64]	1972	Methylprednisolone	"Uniformly good results"	41	Follow-up unspecified
Rhoades et al[91]	1984	Methylprednisolone	72% resolution overall; 93% resolution if <4 months	53	Favorable prognosis: single digit, short duration
Freiberg et al[39]	1989	Triamcinolone acetonide	79% resolution overall: 93% for "nodular," 48% for "diffuse"	101	Improved prognosis: nodular vs. diffuse type, shorter duration of symptoms
Marks and Gunther[71]	1989	Triamcinolone acetonide	Single injection: 84% Two injections: 91%	108	Average 44-month follow-up; better outcomes in female patients
Newport et al[85]	1990	Betamethasone sodium phosphate	One to three injections: 77%	338	Favorable prognosis: single digit, <6 months' duration; trigger grade had no effect on outcome
Griggs et al[44]	1995	Betamethasone sodium phosphate	50% success in diabetics: 72% for NIDDM, 44% for IDDM	121	Incidence of multiple trigger digits and failure of injection statistically increased in IDDM population
Murphy et al[82]	1995	Betamethasone sodium phosphate	64% resolution in steroid group, 20% placebo response	24	Sheath distention alone unsuccessful
Stahl et al[103]	1997	Methylprednisolone	Diabetics: 49%	60	Diabetics: higher incidence of diffuse type, multiple digits; 7% complication rate in diabetics
			Nondiabetics: 76%	60	
Ring et al[92]	2008	Triamcinolone vs. dexamethasone	6 weeks: 63%, 3 months 66% 6 weeks: 38%, 3 months: 71%	84 PRCT	Significant improved satisfaction in triamcinolone group at 6 weeks, not sustained at 3 months.

IDDM, Insulin-dependent diabetes mellitus; *NIDDM*, non–insulin-dependent diabetes mellitus; *PRCT*, prospective randomized controlled trial.

when mixing with bicarbonate because precipitation may occur.) One milliliter of soluble corticosteroid solution is added to the mixture; I prefer betamethasone sodium phosphate or acetate, but other preparations such as dexamethasone or triamcinolone hexacetonide are equally satisfactory. A short 25- or 27-gauge needle is applied to the syringe. The hand is prepared with a povidone-iodine or alcohol solution and the digits slightly hyperextended. The metacarpal head is palpated, and the skin sprayed with ethyl chloride solution for a few seconds as a local refrigerant/anesthetic. The needle is introduced through the frosted skin and directly into the flexor tendon over the metacarpal head (Figure 56.4). Needle placement can be confirmed if necessary by disengaging the syringe from the needle and asking the patient to bend the digit gently; however, injection studies have demonstrated similar outcomes in patients with extrasynovial injection of corticosteroid.[57] Light pressure is applied to the plunger while simultaneously withdrawing the needle slowly. When the needle tip emerges from the tendon substance, dramatic relief of resistance is felt, and a fluid wave may be palpated throughout the tendon sheath proximal and distal to the injection site. Generally, no more than 1 to 2 mL of the solution can be injected. The needle is withdrawn and slight digital pressure applied. As an alternative to midline injection, Carlson and Curtis prefer a midaxial injection site at the level of the midproximal phalanx.[17]

Splinting. For those who decline injection, some consideration should be given to splinting the involved digit. To test the efficacy of simple splinting for trigger digits, Patel and Bassini compared the outcomes of splinting the MP joint in 15 degrees of flexion with a single injection of betamethasone.[87] At a 1-year follow-up, 66% of all digits splinted were symptom free versus 84% of the injected digits. The authors concluded that splinting is an efficacious alternative for patients who are reluctant to consider corticosteroid injection. Rodgers and associates demonstrated 55% resolution of early trigger digits in 31 workers after splinting the DIP joint in full extension for 6 weeks.[94] They proposed that limitation of profundus gliding, decreased differential gliding of the flexor tendons within the sheath, decreased overall use of the digit, or a combination of these factors were responsible for resolution of the symptoms in this manual laborer population.

Surgical Treatment

PERTINENT ANATOMY

The flexor digitorum profundus and superficialis tendons enter a narrow fibroosseous tunnel formed by a groove in the palmar surface of the metacarpal neck and the annular ligament. Doyle and Blythe demonstrated that the flexor sheath in the finger is a double-walled, hollow, synovial-lined, connective tissue tube that encloses the flexor tendons.[28,29] These authors identified four annular and three cruciform pulleys (Figure 56.5). The annular pulleys are thick and rigid. The second pulley (A2), attached to the proximal phalanx, and the fourth pulley (A4) are the most important functionally. It has been shown experimentally that section of only the first annular pulley (A1), as done for surgical release of trigger finger or thumb, produces no loss of flexor function. However, division of both the A1 and A2 pulleys causes substantial postoperative bowstringing and limitation of full active flexion to the distal palmar crease.

The FPL passes through a narrow tunnel formed by the grooved palmar surface of the first metacarpal neck and the transverse fibers of the annular ligament of the flexor sheath (Figure 56.6). The thumb is enclosed in a similar double-layered synovial sheath, and its pulley system consists of one oblique and two annular pulleys.[29] The first annular pulley is 7 to 9 mm wide and located palmar to the MP joint. Embedded on either side of the capsule of the MP joint is a sesamoid bone into which a tendon of one head of the flexor pollicis brevis inserts. This locale is the narrowest point in the FPL sheath and the point at which the constriction develops. Overlying the proximal phalanx is a second pulley that has variably been described as oblique[29] or transverse[7] but is critically important to prevent bowstringing of the FPL. The pulley is 9 to 11 mm wide and is continuous with a slip of the tendon of insertion of the

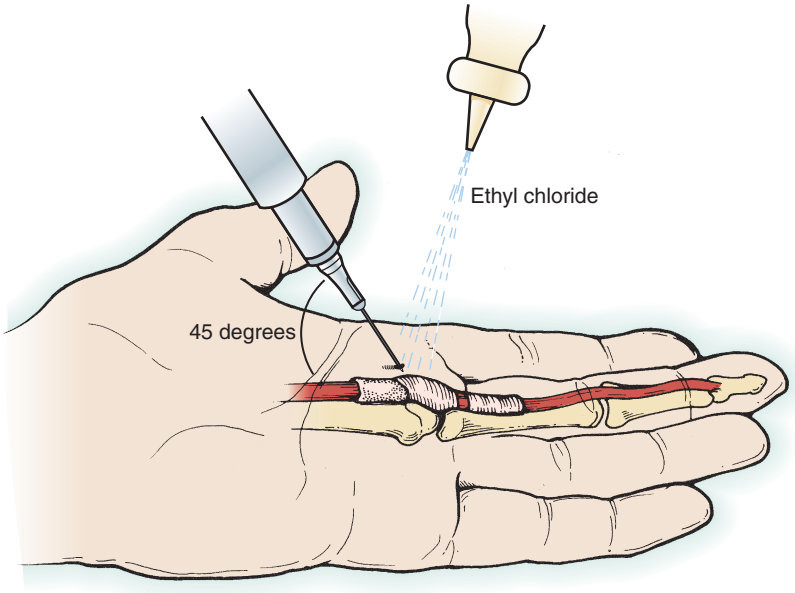

FIGURE 56.4 The author's preferred technique of trigger finger injection (see text).

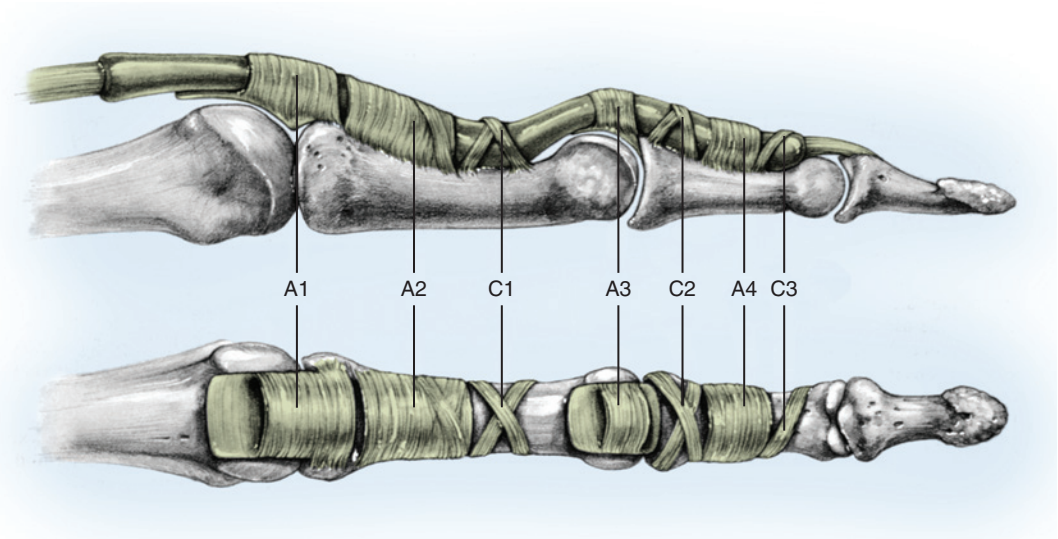

FIGURE 56.5 Doyle and Blythe have identified four annular and three cruciform pulleys in the fingers. (Adapted from Doyle JR, Blythe W: The finger flexor tendon sheath and pulleys: anatomy and reconstruction. In *AAOS Symposium on Tendon Surgery in the Hand*, St. Louis, 1975, CV Mosby, pp 81–87, with permission. Redrawn by Elizabeth Martin.)

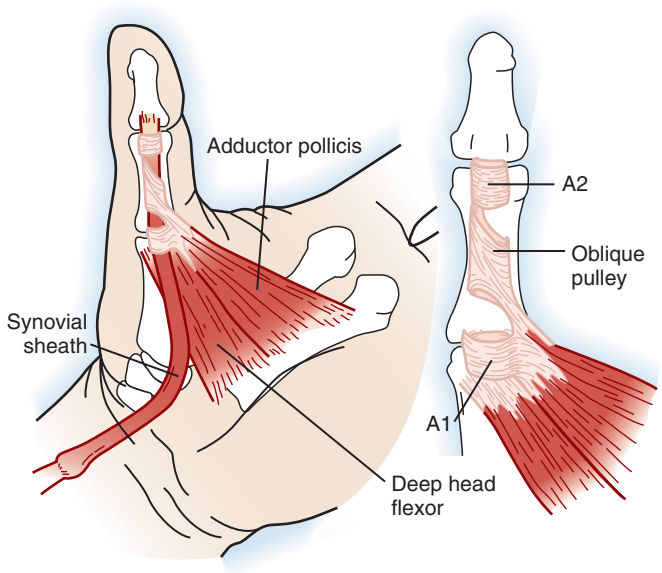

FIGURE 56.6 The flexor pollicis longus passes beneath a similar system of pulleys. Note the important *oblique* pulley just distal to the first annular pulley. FIGURE 56.7 Incisions for release of trigger fingers and thumb. The leading edge of the A1 pulley is identified on the middle digit. Typical transverse incisions are demonstrated on the thumb, index, and small digits. Oblique and longitudinal incisions are illustrated on the long and ring digits. (Copyright © Elizabeth Martin.)

adductor pollicis and courses in an ulnar-proximal to radial-distal direction. The oblique pulley must be preserved during trigger thumb release. Bayat and colleagues have called our attention to considerable variability of the thumb pulley system, with three distinct types of "Av" pulleys located between the oblique and first annular pulleys.[7] The exact significance of the Av pulley and consequences of sectioning have not been elucidated; consequently, it is recommended that these fibers are left intact. The second annular pulley overlies the volar plate of the IP joint, just proximal to the insertion of the FPL on the distal phalanx.

Topographic Anatomy and Skin Incisions. The proximal edge of the first annular pulley roughly coincides with the distal palmar crease in the fourth and fifth rays and the proximal palmar crease in the index finger and is halfway between the two creases in the middle finger (Figure 56.7). An anatomic study of 256 cadaveric digits demonstrated that the palmar-digital skin crease lies midway between the proximal edge of the A1 pulley and the PIP flexion crease, thus allowing the examiner

to precisely identify the A1 pulley's leading edge.[118] This study has practical surgical implications; with surprising accuracy, the surgeon can topographically identify the leading edge of the A1 pulley by first measuring the distance between the PIP flexion crease and the palmar-digital crease and then measuring the same distance proximally from the palmar-digital crease. The proximal edge of the FPL sheath annulus is directly deep to the MP flexion crease of the thumb and lies directly over the volar plate.

Short transverse incisions placed adjacent to the proximal or distal palmar crease—or for the middle finger, halfway between the two creases—thus provide excellent exposure of the A1 pulley to be divided. This site also positions the healed incision away from the underlying bony prominence of the metacarpal head, thereby lessening direct pressure on the scar in grasping spherical or cylindrical objects. Longitudinal incisions are favored by several authors because this extensile approach allows rapid and safe visualization of a longer segment of the flexor tendon and the leading edge of the A2 pulley.[105] It is important to avoid crossing the palmar or digital creases with a longitudinal incision to prevent a painful scar contracture. In either approach, the location of the digital nerves and arteries that closely parallel each flexor sheath in the fingers must be understood and the bundles protected. In particular, the radial digital nerve of the thumb is vulnerable because it lies quite close to the deep layer of dermis at the flexion crease and will be lacerated if the initial incision is carried too deeply.[19] The same nerve can also be injured by blind scissors dissection more proximally where it crosses the thumb flexor sheath diagonally (Figure 56.8).

Operative Technique of Open Trigger Digit Release. A padded pneumatic forearm tourniquet is applied to the awake patient, and 3 to 5 mL of 1% lidocaine (neutralized with sodium bicarbonate in a 10:1 lidocaine:bicarbonate solution) anesthetic is used to infiltrate the skin overlying the A1 pulley. It is not generally necessary to fill the flexor tendon sheath with anesthetic. The distance between the palmar-digital crease and the PIP crease is measured, and the leading edge of the A1 pulley is identified by the technique of Wilhelmi and associates,[118] as described above. A 1- to 1.5-cm transverse, oblique, or longitudinal incision is made directly over the involved A1 pulley as dictated by local skin creases. In the thumb, the flexor pollicis tendon is approached through a 1.5-cm transverse incision in the MP flexion crease. Immediately after the skin has been incised, blunt dissection is used to spread the subcutaneous tissues and the palmar fascia to expose the flexor sheath. The digital nerves and vessels are retracted with small right-angled retractors and are not subjected to extensive dissection. The proximal edge of the thickened flexor sheath (proximal side of the A1 pulley) is identified, and a scalpel blade is used to divide the entire A1 pulley under direct vision (Figure 56.9). Anatomic studies have demonstrated apparent continuity between the first and second annular pulleys in up to 40 to 60% of digits. Care is taken to avoid division of the A2 pulley and consequent bowstringing, although it has been demonstrated that up to 25% of either end of the A2 pulley can be divided without any detrimental mechanical effect on digital flexion. In the thumb, care is taken to preserve the oblique pulley in its entirety to prevent bowstringing. After release, the patient is asked to actively move the digit to confirm complete relief of the triggering. Meticulous hemostasis is obtained via electrocautery, and the wound is closed with one or two monofilament sutures.

A small hand dressing is applied, with all digits left free, and motion is encouraged on the day of surgery. The patient is counseled to use the hand for light activities, and supervised hand therapy is usually necessary only for patients with preoperative fixed flexion contractures. Sutures may be removed 7 to

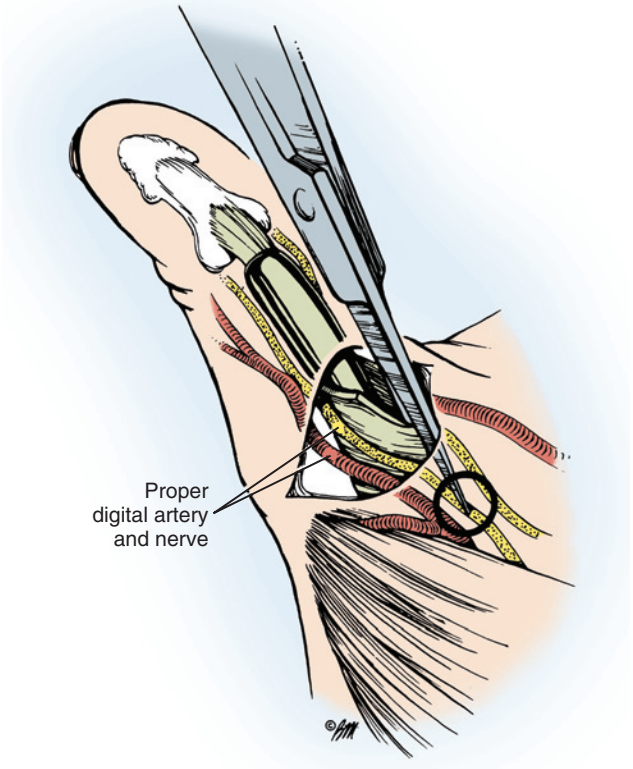

FIGURE 56.8 The digital nerves are vulnerable to injury if the skin incision is deepened too quickly or if a knife or scissors are inserted too far proximally without visualizing the nerves (*circle*). (Copyright © Elizabeth Martin.)

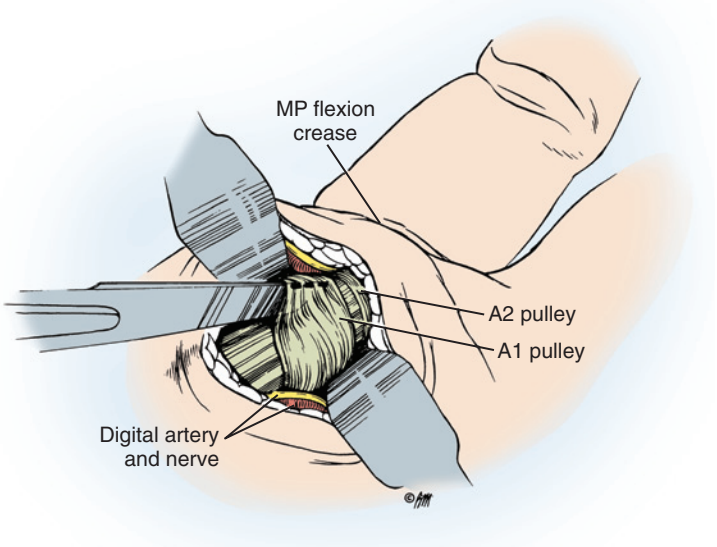

FIGURE 56.9 A No. 11 knife blade is used to divide the first annular pulley to relieve triggering in the finger. *MP,* Metacarpophalangeal. (Copyright © Elizabeth Martin.)

10 days postoperatively. Most patients can resume full hand use within 3 to 4 weeks of surgery.

CRITICAL POINTS *Open Trigger Finger Release*

- For the index through small digits, measure the distance between the palmar digital and PIP flexion creases, and measure this distance again proximal to the palmar-digital crease to identify the leading edge of the A1 pulley.
- Make a transverse, oblique, or longitudinal incision directly over the A1 pulley.
- Do not cross flexion creases with a longitudinal incision.
- Spread down to the flexor sheath; retract the neurovascular bundles.
- Sharply divide the A1 pulley fibers to expose the flexor tendons.
- Preserve the A2 pulley in the fingers; preserve the oblique fibers in the thumb.
- Confirm complete release by active flexion.
- Use a small conforming bandage and advise immediate motion. Perform early therapy for fixed flexion contractures.

Percutaneous Trigger Finger Release (Video 56.1). Open surgical release of trigger digits is not without complication; in fact, some authors report a dissatisfaction rate as high as 26%.[110] Percutaneous trigger release has been reported by several authors to be a safe alternative to traditional open methods using a variety of instruments (Table 56.2).[31,67,69,108] Reported results have been encouraging, with success rates of 74 to 94% at medium-term follow-up and few reported complications. Incomplete relief of triggering has been reported in a higher percentage of patients with grade 4 trigger digits and fixed flexion contractures[48] and in those undergoing hemodialysis.[83] All authors agree that practice on cadaveric hands is recommended before attempting the procedure in patients.

This procedure is done in the office.[31,88] The palm and affected digit are prepared with antiseptic solution and the digit exposed with a fenestrated drape. The MP joints are hyperextended over a rolled towel to displace the neurovascular structures dorsally. The A1 pulley is palpated directly over the metacarpal head. Ethyl chloride is sprayed by an assistant as a topical anesthetic, and the skin and flexor tendon sheath are

TABLE 56.2 Percutaneous Trigger Finger Release

Author	Year	Number of Digits	FINDINGS		Follow-up (months)	Notes
			Instrument	Success Rate		
Lorthioir[67]	1958	52	Custom "tenotome"	100%		Longitudinal tendon scoring well tolerated
Tanaka et al[108]	1990	210	4-mm scalpel blade	74%	24	29% poor results in fingers; best results in thumbs
Eastwood et al[31]	1992	35	21-gauge needle	94%	13	1 repeat release; discouraged for thumbs
Lyu[69]	1992	63	Custom hook device	88%	11	11% conversion to open release; no complications
Stothard and Kumar[106]	1994	18	18-gauge needle	94%		One recurrence; several patients with temporary flexion contractures; superficial tendon scoring
Pope and Wolfe[88]	1995	25 (cadaveric)	19-gauge needle	90%	N/A	Superficial scoring of tendon; not recommended for the thumb or index finger because of the proximity of digital nerves
	1995	13	19-gauge needle	100%	N/A	5 of 13 pulleys incompletely divided distally; active trigger necessary to confirm release
Bain et al[5]	1995 (cadaveric)		14-gauge angiocatheter	68% for digits, 58% for thumb	N/A	Five missed releases; not recommended for the thumb or little finger
Nagoshi et al[83]	1997	67	18-gauge needle	78% idiopathic, 62% hemodialysis	9	Active triggering necessary at the time of release; higher grades and digits locked in extension do less well with the percutaneous method
Cihantimur et al[23]	1998	34	16-gauge angiocatheter	100%	12	No complications
Bain and Wallwork[5a]	1999	31	14-gauge angiocatheter	97%	2	Active triggering at the time of release; not recommended for locked digits, tenosynovitis
Dunn and Pess[30]	1999	52 (cadaveric)	Custom push knife	98%	N/A	No nerve or vessel injury; complete release
		26	19-gauge needle	38%		Superficial scoring of tendons
Ha et al[48]	2001	185	Custom hooked blade	94%	12	No complications; effective for locked digits
Guler et al[46]	2013	87	18-gauge needle	98% open 97% percutaneous	23	5.7% digital nerve injury in percutaneous group

N/A, Not available.

infiltrated with 1 to 2 mL of neutralized 1% lidocaine solution using a 27-gauge needle. A 19-gauge needle is placed percutaneously through the annular pulley, and placement within the flexor tendon is confirmed by asking the patient to slightly flex the digit (Figure 56.10). The needle is withdrawn slowly and rotated to align the bevel of the needle along the longitudinal axis of the tendon. A sweeping motion is used to score and section the A1 pulley proximal and distal to the site. Disappearance of a grating sensation indicates complete sectioning of the annulus. The needle is withdrawn and the patient is asked to flex and extend the digit several times. On occasion, a second needle stick is necessary to complete the release. An adhesive bandage is applied, and the patient is instructed to use the hand for activities as tolerated. Patients should be advised to expect a mild to moderate degree of discomfort for several days; ice and antiinflammatory agents are helpful in the immediate 48 to 72 hours postoperatively.

CRITICAL POINTS *Percutaneous Trigger Finger Release*

- Release is indicated for recalcitrant digits that have failed one or two corticosteroid injections.
- Actively triggering digits may be candidates for percutaneous release.
- A 19-gauge needle is used according to the technique of Eastwood and colleagues.[31]
- Do not use for the thumb and index finger because of the proximity of crossing nerves.
- Hyperextend the digit over a rolled towel at the MP joint to retract the nerves.
- Insert the needle into the tendon; confirm placement by active tendon motion.
- Withdraw the needle slowly out of the tendon.
- Rotate the needle to align the bevel with the tendon; sweep back and forth with the tip.
- One or two needle placements may be necessary to complete division of the pulley.
- Confirm complete release by active flexion of the digit.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

All patients with trigger digits are offered one to two trials of corticosteroid injection. Patients with trigger digits secondary to RA or diabetes are counseled about the reduced success rate with this form of treatment and are not generally offered a second attempt at injection. Resistant primary trigger digits that actively trigger (grade II or III) at the time of the office visit may be considered for percutaneous release; active triggering is necessary at the time of release to confirm complete sectioning of the annular pulley. The technique is not used in the index finger and thumb or for digits with PIP joint contractures. Open release is performed through a 1-cm longitudinal or oblique incision placed in the skin lines and directly over the A1 pulley. The thumb is released through a 1.5-cm transverse incision at the level of the MP flexion crease.

Complications

There have been no reported nerve or vascular complications with steroid injection or percutaneous trigger finger release in

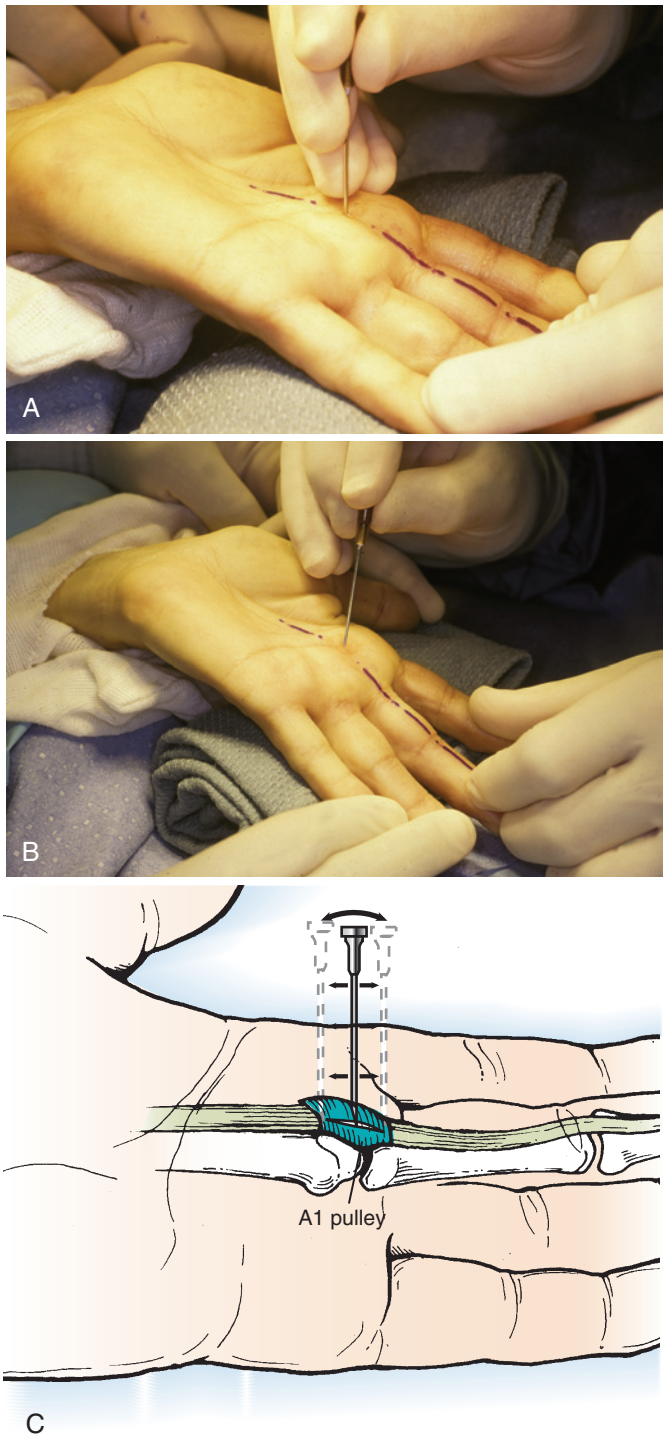

FIGURE 56.10 **A,** Percutaneous release of a long finger A1 pulley. The metacarpophalangeal joint is hyperextended and a 19-gauge needle inserted just distal to the palmar crease. The bevel of the needle is oriented longitudinally with the tendon. The skin markings indicate the path of the flexor tendons. **B,** The needle is stabilized and the pulley is released in a proximal to distal direction. Elimination of a grating sensation as the pulley is cut indicates completion of the release. **C,** A proximal to distal sweeping motion of the needle is used to lyse the annular pulley. (**A** and **B,** From Pope DF, Wolfe SW: Safety and efficacy of percutaneous trigger finger release. *J Hand Surg [Am]* 20:280–283, 1995, with permission.)

the index through small fingers. Authors have identified digital nerve injury of up to 5.7% following percutaneous trigger thumb release[46] because of the crossing radial digital nerve. Hence, the release is not advised in affected thumbs. There is a finite rate of incomplete release or recurrence following percutaneous trigger release; open release is indicated in persistently symptomatic patients.

Reported rates of complication following open trigger release range widely from 3 to 31%,[10,119] depending in large part on the definition of "complication" and the severity of the adverse events noted. In a retrospective study of 1598 patients at a single institution, 5% of operated digits had an adverse event, and less than 1% required additional surgery. The majority of adverse events were wound-related problems, surgical site tenderness, or digital stiffness requiring therapy, and complications were higher among patients with diabetes mellitus.[10] Chronically locked trigger digits may require hand therapy and dynamic splinting to overcome PIP joint flexion contractures. Digital nerve injury is an infrequent but serious complication of trigger release by the open method.[31] Prompt exploration and repair or reconstruction is indicated. Rarely, persistence or recurrence requiring reoperation has been reported.[112] Inadvertent sectioning of all or a portion of the A2 pulley can cause bowstringing with resultant loss of full finger flexion.[47] If bowstringing does not resolve, pulley reconstruction with a tendon graft may be required (see Chapter 6).

Congenital Trigger Thumb

When a child is seen with a thumb locked in flexion, a variety of diagnoses must be entertained, including congenital clasped thumb, absent or aberrant extensor tendons, arthrogryposis, or spasticity (see Chapter 37). The most common cause of abnormal thumb posturing in flexion or extension is termed *congenital trigger thumb*, although the digit is rarely seen to trigger or catch as occurs in the adult equivalent.[26] Pathologic specimens document more frequent thickening and synovial proliferative changes in the tendon itself rather than in the annular sheath, as opposed to adult cases, which show characteristic thickening and degeneration within the tendon pulley.[34] A frequent pathologic finding at surgery is nodular thickening in the tendon, referred to as a Notta node after the individual who reportedly first described the trigger phenomenon in 1850 (Figure 56.11). The eponymous designation is not entirely appropriate (or accurate), as Alphonse Notta described the nodular palmar thickening of trigger finger in four adult patients and did not actually visualize the tendon in these cases.[24] The node of Notta can be palpated just proximal to the proximal border of the A1 pulley, confirming the diagnosis.

Although the condition is rare, the true incidence of trigger thumb is unknown. Among all children seen at a major pediatric hospital, the condition was diagnosed in 0.05%.[42] Whether the condition is truly congenital or acquired is of some controversy because it is rarely diagnosed at birth.[26,27,81] Some authors contend that the condition is overlooked until at least 6 months of age because of characteristic flexion posturing of the thumb in newborns. Of 70 congenital trigger digits treated by De Smet and colleagues, only 3 were reported by the parents as being present at birth and only 9 before the age of 6 months.[26] In two prospective series involving a total of 8746 newborns, no trigger thumbs were demonstrated in the nursery, and the authors

FIGURE 56.11 Inspection of the flexor pollicis longus after release of the first annular pulley reveals the characteristic "Notta node" (*arrow*) seen in congenital trigger thumbs.

contended that the condition is acquired rather than congenital.[78,95] Within a cohort of 78 children treated surgically for trigger thumb, none was initially seen before 3 months of age.[95] Current consensus favors the acquired versus congenital disorder. The condition has a bilateral incidence of 25% to 33%,[27,34,42] and no association with specific congenital anomalies has been demonstrated.[42] Trigger thumbs have been reported in monozygotic twins,[34] thus raising the question of a genetic predisposition.

Treatment

Early authors found conservative measures such as observation and splinting to be "uniformly unsuccessful"[34] and perhaps causative of deleterious MP hyperextension deformities or fixed IP contractures. A later study of 26 trigger thumbs diagnosed in early infancy by Dinham and Meggitt documented a 31% rate of spontaneous resolution.[27] In children aged 6 to 30 months at diagnosis, however, the same authors cited a recovery rate of just 12% after a 6-month observation period. Ger and coworkers reported no spontaneous resolution in 19 trigger thumbs diagnosed in children younger than 6 months of age and monitored for an average of 44 months.[42] Similarly, Wood and Sicilia found no spontaneous resolution in 37 digits monitored for an average of 9 months.[120] Baek and colleagues recently demonstrated a 63% spontaneous resolution rate in a cohort of 71 thumbs monitored for a longer period averaging 48 months.[4] Splinting is difficult to maintain, particularly in infants and toddlers. It is unlikely that a period of observation, with or without stretching or splinting, will result in any permanent deficit or flexion contracture. If the triggering or deformity does not resolve, surgical release can be performed before the age of 5 years to prevent permanent contracture of the IP joint.

Surgical Technique. The procedure is generally performed under a general anesthetic, supplemented with local lidocaine (see the section on Trigger Thumb, Chapter 37, for operative details). A well-padded tourniquet is applied to the arm, and the arm is exsanguinated with an Esmarch bandage. A small transverse incision is made over the palpable nodule at the MP flexion crease. Blunt dissection is performed to identify both digital nerves, which lie immediately beneath the skin at this

level. Right-angled retractors are used to retract the neurovascular bundles, and the transverse retinacular A1 pulley is divided to expose the flexor tendon and associated nodule. The oblique fibers of the retinacular pulley system are carefully preserved.[7,29] No attempt is made to excise or reduce the tendon nodule. The flexor tendon should be lifted out of the wound with a blunt instrument to ensure unrestricted range of thumb motion.

Outcomes of surgical release for congenital trigger thumb have been excellent, with no reports of recurrence and few complications.[42] McAdams and associates performed a long-term study of 21 patients for an average of 15 years and demonstrated minor deficits in IP extension in 23% of their patients but no functional deficit.[72] Longitudinal incisions in a third of their patients resulted in unsatisfactory scarring and contracture. The authors underscored the importance of a transverse incision and careful preservation of the oblique pulley fibers to prevent alterations in tendon mechanics and the development of a flexion contracture.

Trigger Digits in Childhood

Rarely, triggering can occur in other digits in childhood.[16,34] Surgical release of the A1 pulley is not as universally successful as it is with childhood trigger thumbs, thus suggesting a different cause of the condition. In a series of 16 children with 18 trigger digits, Cardon and colleagues demonstrated resolution of triggering in only 10 after division of the A1 pulley alone. In 6 others, abnormalities of the flexor digitorum superficialis decussation necessitated excision of one or both of its slips.[16] The authors recommended the use of an extensile approach to the flexor tendons so that additional surgery can be performed if division of the A1 pulley does not resolve the triggering (see section on Trigger Thumb, Chapter 37, for operative details). Children with storage diseases, such as Hurler syndrome, can acquire trigger digits and carpal tunnel syndrome as a result of abnormal collections of mucopolysaccharide within and around the flexor tendons. Surgical decompression has been demonstrated to be successful in improving hand function.[16,113] Seiler and Kerwin reported trigger finger in an adolescent secondary to a painless calcific nodule in the substance of the flexor profundus tendon.[101]

De Quervain Disease

There are six separate compartments under the dorsal carpal ligament, each lined with a separate synovial sheath membrane. The first of these, which is over the styloid process of the radius, contains the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons. These tendons pass through an unyielding osteoligamentous tunnel formed by a shallow groove in the radial styloid process, covered by a tough overlying roof composed of the transverse fibers of the dorsal ligament, and bordered by vertical septa between the retinaculum and radius. This fibrous tunnel is about 2 cm long, but the synovial sheath extends from each musculotendinous junction proximally to the tendon insertions well beyond the tunnel itself.

Tendon entrapment of the first dorsal compartment of the wrist is a common cause of pain and disability of the wrist and hand. Fritz de Quervain has been credited with the description, in 1895, of a specific entity involving the APL and EPB tendons at the radial styloid process. A similar entity had been reported in the 1893 edition of *Gray's Anatomy* and named "washerwoman's sprain." The process is attributed to activities requiring frequent abduction of the thumb and simultaneous ulnar deviation at the wrist. Tension on the tendons of the first dorsal compartment, if sustained and repeated, is said to produce friction at the rigid retinacular sheath, with subsequent swelling or narrowing of the fibroosseous canal. Acute angulation of the tendons at the retinaculum occurs with wrist extension, and increased anatomic angulation of the tendons in women was suggested by Bunnell to help explain their markedly increased prevalence of the disease.[12] Aberrant tendons and variations in anatomy of the tendons and their sheaths have been thought by several authors to contribute to the process and help explain the poor response to conservative treatment in certain individuals.

The diagnosis is usually made without difficulty after eliciting a complaint of several weeks or months of pain localized to the radial side of the wrist and aggravated by movement of the thumb. The average age in most series is in the fifth and sixth decades, and the syndrome may be up to six times more common in women.[116] The disease also peaks among recent postpartum and lactating females.[3] Findings of local tenderness and swelling 1 to 2 cm proximal to the radial styloid and knife-like pain when the thumb is clasped in the palm and the wrist forced into ulnar deviation (*Eichhoff maneuver*)[32] are diagnostic of the disease. Harry Finklestein subsequently described the pathognomonic examination maneuver that bears his name: "On grasping the patient's thumb and quickly abducting the hand ulnarward, the pain over the styloid tip is excruciating."[36] Both tests should be performed in patients with suspected de Quervain disease.

de Quervain disease must be differentiated from the less common condition of *intersection syndrome*, in which pain, swelling, and, in severe cases, crepitus are found over the second dorsal compartment tendons more proximally. The condition has also been confused with trigger thumb,[36] and this may be related to the presence of a separate fibroosseous tunnel and "pseudotriggering" of the EPB tendon.[115] de Quervain disease should also be differentiated by radiography and physical examination from arthritis of the thumb carpometacarpal (CMC) or scaphotrapezial-trapezoid joints (or both), although these lesions may coexist because of their similar demographics. Radiographic study also excludes scaphoid fracture and arthrosis involving the radiocarpal or intercarpal joints. Occasionally, radiographs show localized osteopenia or spurring at the radial styloid (Figure 56.12). Advanced imaging modalities are rarely helpful for diagnosis.

Treatment

Nonoperative Treatment. In acute cases, some success has been reported after immobilization in a cast or splint with the wrist gently extended and the thumb abducted, but in my experience, symptoms tend to recur shortly after removal of the cast when the inciting activity is resumed. In a prospective study, splint immobilization alone led to a 70% failure rate in 37 wrists and was shown to provide no additional benefit when combined with corticosteroid injection of the first dorsal compartment sheath.[116]

As with trigger digits, corticosteroid injection was initially discouraged as ineffective but later hailed as a successful form of treatment of de Quervain disease. Success with corticosteroid

FIGURE 56.12 Anteroposterior radiographs of the wrist in a patient with de Quervain disease occasionally reveal localized osteopenia or a small spur (*arrow*).

FIGURE 56.13 **A** and **B,** Local complications from the use of corticosteroid injections for the treatment of de Quervain disease. Although successfully relieved of pain, both patients had localized capillary fragility and recurrent transient hemangioma-like lesions at the site of injection.

injection has been reported in 50 to 80% of patients after one to two injections,[116] and it is particularly effective in relatively acute cases. Injection is less effective in patients with diabetes.

In de Quervain disease of pregnancy and lactation, nonoperative treatment is highly effective, and the condition tends to resolve after cessation of lactation.[3] In a comparative study of splinting and corticosteroid injection, Avci and coworkers demonstrated complete resolution of pain and a negative Finkelstein test result after injection of methylprednisolone in nine patients, whereas all patients in the splinted group continued to report pain during the treatment period. Eight of the nine patients in the latter group experienced complete resolution 2 to 6 weeks after cessation of lactation.[3]

Technique of Injection. The radial styloid area is prepared with antiseptic solution. A number of corticosteroid preparations are available and differ predominantly in their solubility and thus their duration of action. Less soluble preparations may contribute to a higher incidence of local complications, including depigmentation,[66] subcutaneous atrophy, and fat necrosis (Figure 56.13). Therefore, in this very superficial location, I prefer a water-soluble preparation of 2 to 4 mg of dexamethasone or 6 mg of betamethasone mixed with 1 mL of 1% lidocaine (no epinephrine). The anesthetic effect of lidocaine allows confirmation of correct needle placement and diagnosis by immediate, temporary relief of discomfort.

The first dorsal compartment tendons can easily be palpated as the patient abducts and extends the thumb. While ethyl chloride is sprayed as a local refrigerant, the examiner's gloved index finger and thumb bracket the tendons at a level 1 cm proximal to the radial styloid, which serves to steady the patient's wrist and localize the injection site. A short 25- or 27-gauge needle is introduced into the tendon sheath, and resistance may be felt as the injection is attempted. The needle is slowly backed out of the tendon while pressure is maintained on the plunger, and a fluid wave should be palpable proximal and distal to the injection site as the APL sheath fills. A portion of the solution should be redirected slightly dorsal (ulnar) to the first site in an attempt to infiltrate a possible separate EPB sheath.[65] In a study in which radiopaque dye was mixed with a corticosteroid and injected into the first dorsal compartment, 13 of 19 wrists failed to demonstrate dye filling the EPB subsheath, thus suggesting that it is technically more difficult to successfully administer the medication to the EPB compartment.[121] The accuracy of EPB injection may be improved by palpating the tendons at the tip of the radial styloid while the patient flexes and extends the thumb MP joint. Should the injection fail to relieve symptoms, a second injection may be performed 4 to 6 weeks after the first; however, repeated ongoing injections are not indicated and may be detrimental to local tissues (see Figure 56.13).

Surgical Treatment

PERTINENT ANATOMY

Although early anatomic textbooks showed one long thumb abductor tendon accompanying one extensor brevis tendon passing through a single first dorsal compartment as the normal

anatomy, modern anatomic and surgical studies have shown that this is not usually the case. In most reports, less than 20% of patients exhibit the so-called normal anatomy.[56]

In fact, the first dorsal compartment of the wrist is probably the site of the most numerous variations in tendon structure in the upper limb. Failure to recognize these variations can cause persistence or recurrence of pain because of incomplete surgical release of the tendon sheath.

The EPB is a phylogenetically young structure found only in humans and gorillas as a separate muscle distinct from the thumb abductor. The muscle is always thinner than and courses dorsal to the abductor and is absent in 5 to 7% of people. The larger APL usually has two and sometimes three or more tendinous slips inserting variously into the base of the first metacarpal, trapezium, volar carpal ligament, opponens pollicis, or abductor pollicis brevis.

In 24 to 37% of specimens in anatomic studies, the first compartment was found to be subdivided by a longitudinal ridge and septum into two distinct fibroosseous tunnels, the ulnar one for the EPB and the radial tunnel containing one or more slips of the APL.[65] A third deep tunnel containing an anomalous tendon has also been reported. The reported incidence of separate compartments at surgery is higher than that seen in anatomic specimens in several series,[98,116] which raises the possibility that septation of the EPB increases the probability that nonsurgical treatment will fail. Harvey and associates reported success with one or two corticosteroid injections in 80% of patients and found separate compartments for the APL and EPB in 10 of 11 wrists that failed injection and required surgical release.[51] As noted in various published reports of operative findings, either one of the subdivisions, or both, of the first dorsal compartment may be stenotic. The *EPB entrapment test* was reported to be 81% sensitive in its ability to identify the presence of a septated EPB compartment in patients who had failed corticosteroid treatment and required surgery. The test is a two-part test in which the patient is asked to forcibly (1) extend the MP joint or (2) abduct the CMC joint against resistance from the examiner.[2] Pain during the MP joint portion of the test is said to be a positive predictor of a separate compartment for the EPB tendon.

The anatomic relationship of the radial artery and nerve to this compartment must be understood to prevent injury to these structures during surgical release of the tendons (Figure 56.14). The radial artery passes diagonally across the anatomic snuffbox from the volar aspect of the wrist to the dorsum of the web space deep to the thumb abductor and both extensors. It is separated from the first compartment sheath by enough areolar tissue that it need not be exposed during the dissection. However, two or three terminal divisions of the radial sensory nerve lie immediately superficial to the first dorsal compartment and must be identified and protected during the surgical procedure.

❖ AUTHOR'S PREFERRED METHOD

The procedure is usually performed with only local infiltration of anesthesia. A pneumatic tourniquet around the forearm is well tolerated for the short duration of the procedure, and a bloodless surgical field is essential for identification of the radial sensory branches, as well as the anatomic variations discussed earlier.

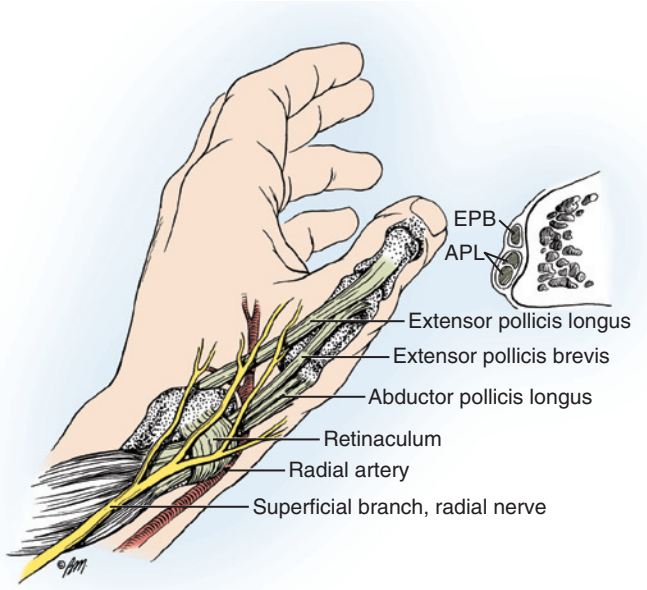

FIGURE 56.14 Anatomic relationships in the first dorsal compartment. *APL,* Abductor pollicis longus; *EPB,* extensor pollicis brevis. (Copyright © Elizabeth Martin.)

A 2-cm transverse skin incision is made over the first dorsal compartment about 1 cm proximal to the tip of the radial styloid process (Figure 56.15). Care is taken to identify and gently retract the one to three radial sensory branches that cross the compartment obliquely by using gentle, blunt longitudinal dissection as soon as the deepest dermal layer of skin has been incised. A common technical error is to transversely incise the subcutaneous fat with the skin knife, which may injure a superficial nerve branch. As an alternative, one can make a longitudinal skin incision, which may pose less risk to the nerve. The exposed annular ligament covering the compartment is sharply incised with a scalpel.

CRITICAL POINTS *De Quervain Release*

- A positive response to a diagnostic injection should precede the decision for surgery.
- Use a transverse incision; protect the numerous superficial sensory nerves.
- Incise the sheath on its dorsal margin to prevent tendon subluxation.
- Identify both tendons; inspect for the EPB subsheath; and excise the septa.
- Ask the patient to voluntarily move the thumb to confirm release.

Complete excision of the entire sheath should be avoided because this has occasionally been associated with painful palmar subluxation of the tendons postoperatively. Burton and Littler recommended incising the sheath on its most dorsal margin and leaving a flap of palmar sheath to prevent subluxation.[14] A thorough exploration for separate compartments must be performed, with complete division of all intervening septa and identification of each tendon slip. Unusually thick septa can be excised entirely. If the tenosynovial tissue is thick and opaque, surgical debulking is performed. The tendons are lifted by hook or blunt retractors out of the tunnel to ensure

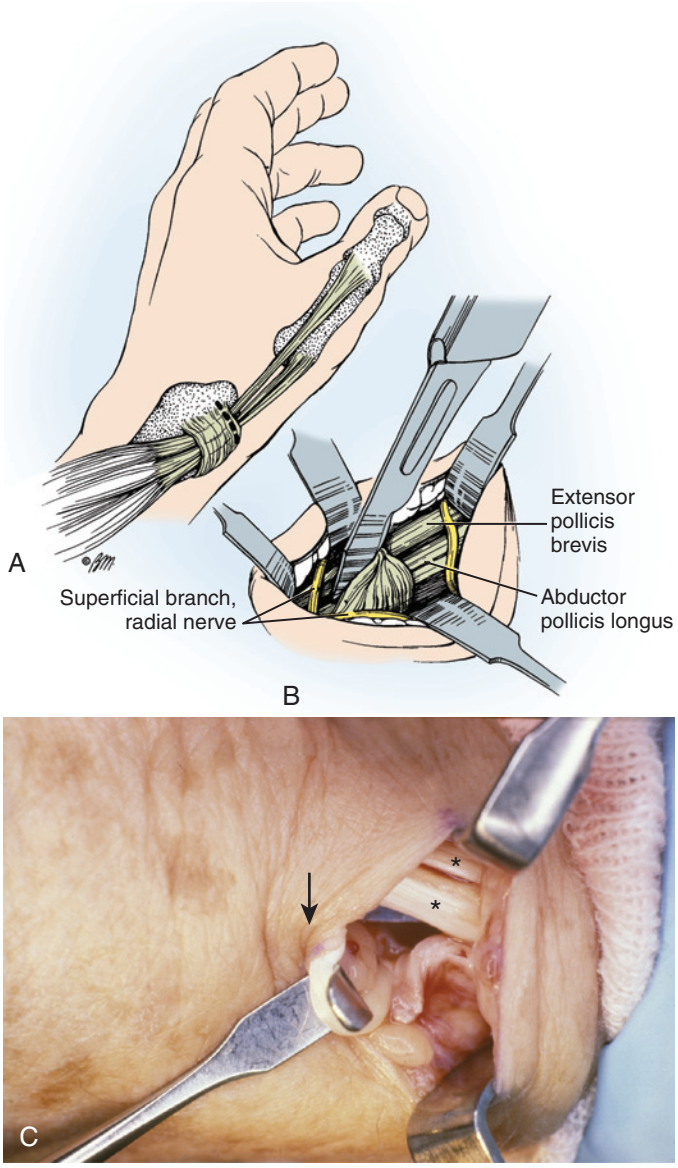

FIGURE 56.15 Release for de Quervain disease. **A,** The first dorsal compartment is approached by a short transverse skin incision. **B,** The annular ligament is incised with a scalpel from the snuffbox to the musculotendinous junctions. **C,** Surgical demonstration of a separate compartment for the extensor pollicis brevis (*arrow*) after release of the abductor pollicis longus (*asterisks*). (**A** and **B,** Copyright © Elizabeth Martin.)

complete decompression from the musculotendinous junction of the EPB to the radial styloid. The tendons are replaced and the patient is asked to move the thumb to demonstrate free and independent movement of the long abductor and short extensor. It is imperative that the separate tendon of the EPB be specifically identified by demonstrating passive extension of the thumb MP joint with gentle retraction on the tendon.

Hemostasis is established with electrocautery after release of the tourniquet, and the skin is closed with an intradermal absorbable monofilament suture and adhesive glue. A soft bulky dressing is applied and thumb motion is encouraged in the immediate postoperative period. If it is thought that the released tendons are unstable after release, a palmar thumb spica splint may be applied with the wrist in 20 degrees of extension for 10 to 14 days, although this is rarely necessary. Thereafter, the patient may begin to resume use of the thumb and wrist as tolerated. Supervised hand therapy is rarely necessary. Localized soreness may persist for 4 to 6 weeks postoperatively and generally responds to wound massage and light use of the hand. It is advised to avoid heavy mechanical activities for the initial 4 to 6 weeks.

Complications

Not infrequently, extravasation of injected corticosteroid into superficial tissues can cause subcutaneous atrophy, fat necrosis, depigmentation, or any combination of these complications (see Figure 56.13).[66,98,99] Darker-skinned individuals are particularly prone to this occurrence, and all patients should be counseled before injection concerning the 5 to 10% risk for this complication. In my experience, these adverse effects have usually resolved within a year, but persistent symptoms can be severe enough to warrant transposition of healthy skin or fat grafts to the area. Though decidedly uncommon, corticosteroid injection can lead to tendon rupture: one case report describes the rupture of both the APL and the EPB following repeated corticosteroid injections for de Quervain disease.[86]

The most serious complication of this operation follows iatrogenic injury to a superficial sensory branch of the radial nerve and the subsequent formation of a painful neuroma. Overly vigorous retraction of a radial nerve branch without apparent injury may cause a painful neuroma-in-continuity. Injuries to this vulnerable nerve can result in excruciating, disabling symptoms that dwarf the initial symptoms in severity. Management of an inadvertently lacerated radial sensory nerve is a controversial subject. Some authors advise resection of the lacerated nerve to put the resultant neuroma well proximal to the operative scar, where it will be less exposed to repeated contusion. However, because I have not been entirely satisfied with the persistent pain of those who have undergone proximal transposition of painful forearm neuromas, I agree with those who advocate immediate nerve reapproximation using microsurgical technique to reduce the likelihood of neuroma formation and minimize hypoesthesia in the thumb and index finger. (For a more detailed discussion of this complication, the reader is referred to Chapter 320.)

Incomplete relief of pain after release of the first dorsal compartment is not uncommon. Associated diagnoses, including painful CMC and IP joint arthritis or instability, are common and may be confirmed with a diagnostic lidocaine injection into the suspected area. If documentation of specific identification and release of both the EPB and APL tendons in the operative report is lacking, some consideration should be given to ultrasound or magnetic resonance imaging to establish adequacy of release. Reexploration for an unreleased septated compartment of the extensor brevis may be required, and a preoperative lidocaine challenge into this compartment can be helpful in predicting the outcome of reexploration. Hypertrophic or painful longitudinal scars may be modified by "Z"-plasty. For the rare patient with painful palmar or dorsal subluxation of the tendons after release, pulley reconstruction with a slip of extensor retinaculum, a distally based slip of the brachioradialis,[73] or a strip of the second dorsal compartment retinaculum has been described.

OTHER STENOTIC CONDITIONS OF TENDONS AT THE WRIST

ANATOMY

The second compartment contains the two radial wrist extensors, the extensor carpi radialis longus and brevis, respectively. The third compartment contains the EPL tendon, which angulates acutely around the Lister tubercle en route to the distal phalanx of the thumb. Four slips of the extensor digitorum communis tendon and the single extensor indicis proprius tendon compose the fourth compartment. The fifth and sixth compartments each contain a single tendon: the extensor digiti minimi and the extensor carpi ulnaris (ECU) tendons. The floor of the ECU tendon sheath is quite thick and forms an important structural component of the TFCC that aids in stabilization of the distal radioulnar joint. Although each of the dorsal extensor compartments may be involved in tendon entrapment, the most commonly involved are the first and sixth compartments.

Intersection Syndrome

Pain and swelling about the muscle bellies of the APL and EPB are characteristic of intersection syndrome. This area, which lies about 4 cm proximal to the wrist joint, may show increased swelling of a normally prominent area (Figure 56.16) and, in severe cases, redness and crepitus. There is controversy as to the precise site of the syndrome: whether it occurs at the intersection between the muscle bellies of the APL and EPB and the radial wrist extensor tendons, or whether it involves only the tendons of the second dorsal compartment. The finding of a positive Finklestein test in patients with this condition and ultrasound reports of peritendinous fluid collection about the first dorsal compartment tendons at their intersection with the wrist extensors support the former. In 13 operative cases, Grundberg and Reagan demonstrated histologic evidence of acute and chronic synovitis about the tendons of the second dorsal compartment.[45]

The syndrome, like other stenotic conditions about the hand and wrist, has been associated with activities requiring frequent or repetitive motions of the wrist. Though rare, it is most often seen in athletes, particularly those involved in sports such as rowing, cycling, and weightlifting. Initial nonoperative treatment consists of eliminating the inciting activity, taking nonsteroidal antiinflammatory agents, and wearing a thermoplastic molded wrist splint in 15 degrees of extension for 2 to 3 weeks. Incorporating the thumb into the splint may provide more rapid relief by immobilizing the first dorsal compartment tendons. In refractory cases, steroid injection into the area of maximal tenderness usually relieves symptoms. The majority of patients remain permanently asymptomatic with nonoperative treatment.

For those with persistent pain, Grundberg and Reagan suggested a longitudinal incision to approach the radial wrist extensors that begins at the wrist and extends proximal to the swollen area.[45] After incising the deep fascia, release of the second dorsal compartment demonstrates the area of pathologic structures (Figure 56.17). The tendons are elevated and inspected, and no attempt is made to close the retinaculum. The wrist is splinted in neutral to slight extension for 10 days postoperatively, and patients are advised to use the hand and wrist as tolerated thereafter. Although bowstringing of the extensor

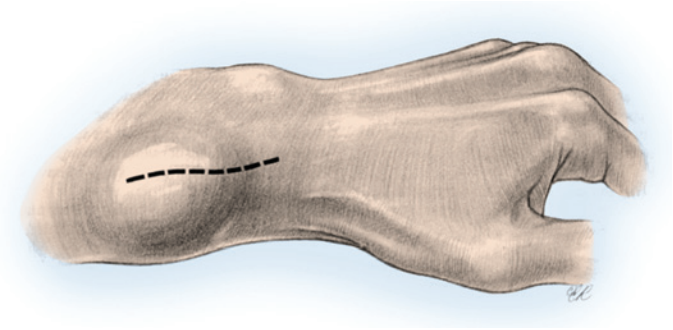

FIGURE 56.16 A patient with intersection syndrome has swelling in the area where the abductor pollicis longus and extensor pollicis brevis cross the common radial wrist extensors. The *dashed line* indicates the location of the surgical incision. (Adapted from Grundberg AB, Reagan DS: Pathologic anatomy of the forearm: intersection syndrome. *J Hand Surg [Am]* 10:299–302, 1985, with permission. Redrawn by Elizabeth Martin.)

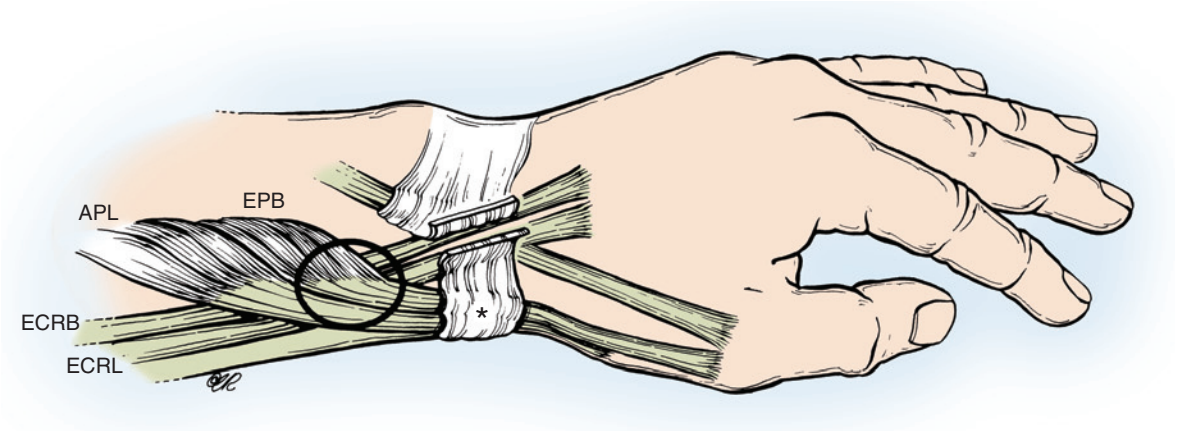

FIGURE 56.17 The *circled area* shows where the extensor pollicis brevis (EPB) and abductor pollicis longus (APL) cross the common radial wrist extensors. The location of the first dorsal compartment where de Quervain disease occurs is indicated with an *asterisk*. The second dorsal compartment has been released in the manner recommended for the treatment of intersection syndrome. *ECRB,* Extensor carpi radialis brevis; *ECRL,* extensor carpi radialis longus. tendons is a theoretical problem after incising the dorsal retinaculum, Grundberg and Reagan did not report any symptomatic bowstringing in their series.

Extensor Pollicis Longus Entrapment

Tendon entrapment of the EPL occurs rarely but requires early diagnosis and urgent operative treatment to prevent tendon rupture, a complication that is seldom seen in de Quervain disease, trigger finger, or trigger thumb. The condition is recognized by pain, swelling, tenderness, and often crepitus on the dorsum of the distal end of the radius at the Lister tubercle, around which the long thumb extensor tendon angulates as it courses to its insertion on the thumb. Passive or active flexion of the thumb IP joint is associated with pain at the level of the Lister tubercle, and triggering has been reported.[63] The tendon has a separate synovial sheath–lined tunnel beneath the extensor retinaculum that may be compromised by blunt trauma or a Colles' fracture. Rupture of the tendon has been reported and occurs most commonly in association with initially undisplaced distal radial fractures. Its tendency to rupture in these circumstances may be secondary to the local ischemia produced by increased pressure or hematoma within a relatively unyielding fibroosseous canal. Microvascular studies have demonstrated a watershed zone in proximity to the Lister tubercle wherein the tendon is entirely dependent on synovial fluid for its nutrition[33] and that may be vulnerable to ischemic rupture after local trauma. A recent report suggests an incidence as high as 5% in patients with nondisplaced distal radius fractures treated with immobilization.[96] The tendon is also exquisitely sensitive in this location to prominent screws and pegs inserted from the palmar approach during fixation of distal radius fractures, and special care should be taken to avoid violation of the dorsal cortex by hardware and consequent tendon rupture (see Chapter 15).

Operative treatment of EPL tendon entrapment is recommended to prevent attritional rupture of the tendon. The tendon is exposed through a 2-cm dorsal incision centered over the Lister tubercle. Care is taken to avoid injury to small branches of the radial sensory nerve. The third dorsal compartment is identified and incised completely, and the tendon is elevated from its bed and transposed radial to the tubercle. Any osteophytes within the tunnel may be débrided and the tunnel closed to prevent the EPL from returning to its groove (Figure 56.18). The skin is closed with a single subcuticular suture, and postoperative splinting is not necessary. Unrestricted use of the hand and wrist is permitted as tolerated.

Stenosis of the Fourth and Fifth Extensor Compartments

Although common in patients with RA, primary symptomatic stenosis of the fourth and fifth extensor compartments is extremely rare. The condition most commonly affects the extensor digitorum communis tendons to the index and small digits because these tendons angulate more acutely at the distal edge of the retinacular sheath. Isolated extensor indicis proprius tenosynovitis has been reported and is attributed to the presence of the distal extensor indicis proprius muscle belly within the retinacular sheath. The process may be initiated after a Colles' fracture and has also been thought to be due to increased demands on the extensor tendons secondary to loss of wrist flexion. Clinical findings demonstrate tenderness and swelling

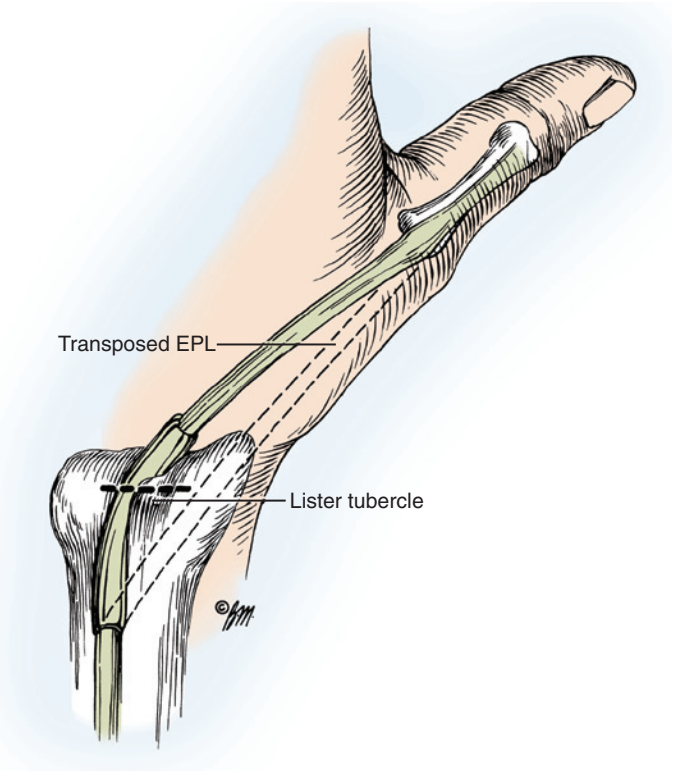

FIGURE 56.18 The extensor pollicis longus (EPL) tendon is rerouted superficially radial to the Lister tubercle (*dashed lines*) to relieve tenosynovitis. (Copyright © Elizabeth Martin.)

over the affected compartment. With the wrist flexed, pain may be elicited at the involved retinacular sheath by attempted MP extension against resistance. Pathologic findings show thickening of the tendon sheath, tight stenosis, and sparse inflammatory tissue. Duplicate tendons or anomalous muscle bellies should be suspected in a patient who does not respond to the usual conservative modalities of rest, ice, antiinflammatory medications, or corticosteroid injection.[54]

Extensor Carpi Ulnaris Tendinitis

Reactive tendinitis of the ECU is the second most common pattern of tendinopathy in the wrist and must be included in the differential diagnosis of ulnar-sided wrist pain. The ECU tendon occupies a narrow subsheath within the sixth dorsal compartment, and its relative position changes with rotation of the forearm. The tendon assumes a linear path in pronation but angulates approximately 30 degrees around the ulnar styloid to reach the fifth metacarpal base in full supination. Tendinitis may be initiated by a twisting injury or overuse, followed within 24 to 48 hours by increasing pain and swelling. Nocturnal pain is frequent and occasionally severe enough to interfere with sleep. Dysesthesias along the course of the overlying dorsal sensory branch of the ulnar nerve are frequent findings. Because the floor of the ECU tendon sheath is an important stabilizer of the TFCC, the process may be difficult to differentiate from traumatic disruption of the TFCC (see Chapter 14).

Pain is generally poorly localized by the patient and frequently felt to be deep within the joint. Pain is increased with all motions of the wrist, and extension/ulnar deviation against applied resistance is a useful provocative diagnostic maneuver.

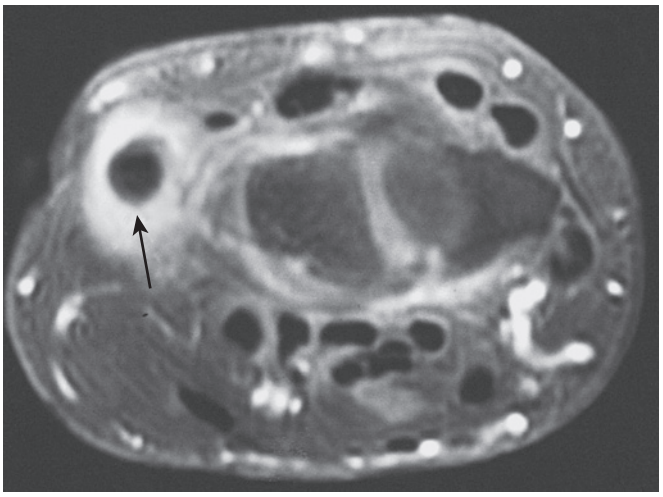

FIGURE 56.19 Magnetic resonance image of the wrist demonstrating abundant tenosynovial thickening and a halo of edema surrounding the extensor carpi ulnaris tendon (*arrow*).

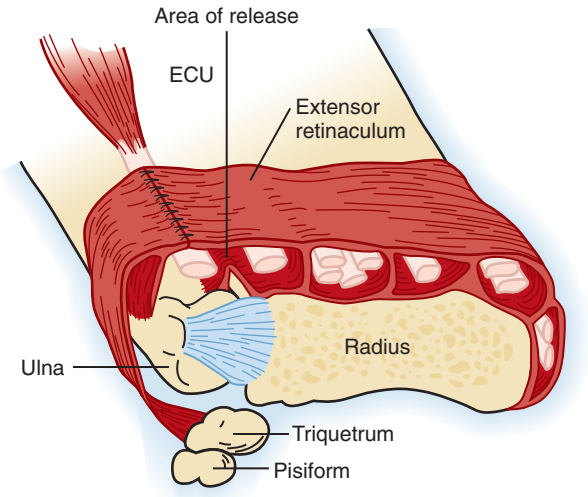

FIGURE 56.20 Technique of release of the intervening septum between the fifth and sixth dorsal compartments combined with retinacular repair for the treatment of tendinopathy of the extensor carpi ulnaris (ECU) tendon. (Redrawn with permission, from Hajj AA, Wood MB: Stenosing tenosynovitis of the extensor carpi ulnaris. *J Hand Surg [Am]* 11:519–520, 1986.)

Crepitus may be palpable within the swollen ECU sheath (Figure 56.19). The condition may coexist with tendon entrapment of other wrist compartments, an anomalous accessory tendon slip of the ECU, TFCC tears, ulnar styloid nonunion, distal radioulnar degenerative disease, and lunotriquetral ligament injury. Rarely, complete rupture of the tendon has been reported, usually following one or more corticosteroid injections[77]; repair with an intercalated tendon graft is recommended in active patients to restore its stabilizing effect on the TFCC and to maintain wrist balance and strength.

Instability of the tendon may coexist with tendon entrapment or may be isolated and symptomatic enough to warrant operative reconstruction. It is important to differentiate acute instability from the more chronic overuse tendinopathy, as treatment options differ. In athletes, ECU instability is usually heralded by an acute episode of moderate to severe pain during a forceful supinated activity; a frequent example is the upper hand of a two-handed backhand tennis swing.[77] ECU instability may be elicited by palpating the tendon while the patient actively rotates the extended wrist from full pronation to full supination. The tendon may subluxate, occasionally with an audible snap, as the supinated wrist is brought from extension into ulnar deviation and flexion. Magnetic resonance imaging (MRI) may be helpful to identify tendon subluxation and to differentiate it from peritendinous synovitis, longitudinal splitting of the tendon substance, a shallow ECU groove on the distal ulna, or anomalous extensor tendon anatomy. Dynamic ultrasonography is a valuable adjunct to clinical examination in patients with suspected ECU subluxation.[77] Both MRI and ultrasound should be performed in full supination and in pronation.

Transient but complete relief of discomfort after filling the ECU sheath with lidocaine confirms the diagnosis of ECU tendinitis and helps differentiate the process from intraarticular pathologic conditions. Conservative treatment with ice, extension splinting or casting, and antiinflammatory agents generally provides relief of symptoms. Corticosteroid injection is helpful when splinting and antiinflammatory medications have failed. On occasion, recalcitrant cases require surgical release or reconstruction of the stenotic retinacular subsheath. Among operative cases, splitting or fraying of the ECU tendon is frequently observed.

Surgical Treatment

Operative treatment of ECU tendinitis without instability involves complete incision of the fibroosseous canal of the sixth dorsal compartment through a 3-cm curvilinear incision over the distal radioulnar joint that parallels the course of the underlying ulnar sensory nerve. Care must be taken to identify and protect subcutaneous nerve branches with vessel loops throughout the procedure. Controversy exists about whether retinacular repair (see Chapter 14) is necessary to prevent postoperative instability, but several authors have reported no postoperative ECU instability after complete release without repair of the retinaculum.[13,60] Hajj and Wood demonstrated success with a technique in which the septum between the fifth and sixth compartments was excised through an open incision of the ECU retinaculum, followed by complete repair of the retinaculum to prevent potential instability (Figure 56.20 and Case Study 56.1).[49] Operative reconstructive options for athletic patients with disabling instability of the ECU are discussed further in Chapter 14.

Flexor Carpi Radialis Tendinitis

The sharp angulation of the FCR tendon across the ridge of the trapezium and the tight fibrous canal through which it runs on its course to the base of the index metacarpal make this tendon prone to stenotic tendinopathy. The multiplicity of other diagnoses in the immediate vicinity of the tendon, including ganglion cysts, basal joint degenerative disease, scaphoid fractures and nonunions, and de Quervain disease, may lead to misdiagnosis and prolong the treatment of this condition.

ANATOMY

On the flexor surface, the radial and ulnar wrist flexors span the carpal tunnel, and each enters a short tenosynovial sheath

CASE STUDY 56.1 Tendinopathy

A 17-year-old female high school hockey star presented with ulnar-sided right wrist pain. She had felt a "snap" during a slap shot 6 months earlier. The patient attempted rest and splinting for several months. After a 3-month course of therapy, she was unable to return to play. She reported minimal discomfort with daily, school, or other recreational activities. There had been no improvement with cortisone injection. The patient was referred for definitive treatment.

Physical examination showed tenderness to ECU without snapping, laxness but no gross instability of the dorsal radioulnar joint; pain with resisted supination and ulnar deviation; and ulnar impaction positive in full supination.

Radiographs (eFigure 56.1)

What is your working diagnosis?

A. Ulnar impaction syndrome
B. Kienbock disease
C. Tear of the triangular fibrocartilage complex
D. Extensor carpi ulnaris instability
E. Radioulnar instability

What additional workup should be completed?

A. Bone scan
B. Computed tomography in three positions of rotation
C. Magnetic resonance imaging
D. Bilateral pronated grip films
E. Dynamic ultrasound

(Video 56.2)

What is the diagnosis?

A. Ulnar impaction syndrome
B. Kienböck disease
C. Tear of the triangular fibrocartilage complex
D. Extensor carpi ulnaris instability
E. Radioulnar instability

What are the treatment recommendations?

A. Ulnar-shortening osteotomy
B. Radial-shortening osteotomy
C. Arthroscopic repair of the triangular fibrocartilage complex
D. Extensor carpi ulnaris stabilization
E. Tendon graft ligament reconstruction of the dorsal radioulnar ligament

Surgical Procedure

Through a 5-cm dorsoulnar incision, the retinaculum is incised and reflected radialward (eFigure 56.2, *arrows*) to expose the extensor carpi ulnaris (ECU) subsheath (*asterisk*) and ulna. A Bennett retractor is placed in the interosseous space. The *arrow* in eFigure 56.3 demonstrates the ECU groove (not deepened). Drill holes are made on the ulnar side, and multiple suture anchors are placed. The ECU subsheath is imbricated and tied down. As shown in eFigure 56.4, the sheath has been successfully imbricated. The retinacular flap is securely repaired. The patient was treated with a long-arm cast for 4 weeks, a short-arm cast for 4 weeks, and a splint and range-of-motion exercises for 4 weeks. The patient successfully returned to playing hockey in her senior year (eFigure 56.5).

MacLennan AJ, Nemechek NM, Waitayawinyu BS, et al: Diagnosis and anatomic reconstruction of extensor carpi ulnaris subluxation. *J Hand Surg [Am]* 33(1):59–64, 2008.

where it crosses the wrist joint. The musculotendinous junction of the FCR tendon is located approximately 8 cm proximal to the wrist crease, and the tendon is surrounded by a thin paratenon. The tendon becomes invested by antebrachial fascia as it approaches the wrist crease and is completely lined by a true synovial sheath from the level of the trapezial crest to the metacarpal insertion distally.[8] Bishop and colleagues demonstrated that the tendon is nearly encircled by the tubercle of the trapezium, which constitutes between 61 and 80% of the wall of the tunnel.[8] Within this tunnel, these authors found the tendon to occupy 90% of the available cross-sectional area. The authors propose that the tendon's narrow fibrous sheath and the rigid anchoring of the tendon to the wall of the trapezium make it vulnerable to both primary tendon entrapment and secondary injury in association with traumatic or degenerative lesions of the trapezium.

The condition typically affects persons in their fifth decade and is more often diagnosed in women. The process does not appear to have a predilection for the dominant hand. Most cases develop insidiously, and a history of repetitive flexion/extension of the wrist or blunt trauma is rarely elicited. Low and Hales reported a 25% incidence of FCR tendinopathy following trapezial excision and APL suspensionplasty, attributed to the passage of the APL slip around the FCR tendon.[68] I have seen a low incidence of FCR tendinitis following the use of half of the FCR tendon for basal joint arthroplasty and now prefer to use the entire tendon.

Pain is most pronounced at the palmar wrist crease over the scaphoid tubercle. Increased pain with resisted wrist flexion and radial deviation is pathognomonic of the process. Localized swelling may be evident, and a ganglion may overlie the tendon. Radiographs may identify trapezial degenerative disease, and the neighboring degenerative process may be responsible for attrition and fraying of the FCR within the adjacent tendon sheath. Successful relief of pain after injection of lidocaine and/or corticosteroid into the offending sheath helps to confirm the diagnosis.

Treatment

Nonoperative Treatment. As for other stenotic conditions of the wrist tendons, nonoperative treatment is attempted initially, with a period of splinting, ice, and antiinflammatory agents. Corticosteroid injection provides relief in cases not associated with neighboring degenerative disease or bone spurs. Chronic cases may lead to tendon fraying and rupture. Paradoxically, however, FCR rupture is characteristically associated with complete cessation of pain, and operative repair is not generally warranted. In my experience, some restitution of FCR continuity secondary to pseudotendon formation occurs over the 6- to 12-month period after FCR rupture. Operative release is occasionally indicated in active patients who are recalcitrant to splinting and corticosteroid injection.

Operative Technique. Exposure of the tendon is performed through a 3- to 4-cm hockey-stick incision centered over the scaphoid tubercle. Care must be taken to avoid injury to the nearby palmar cutaneous branch of the median nerve, as well as the thenar branches of the radial sensory and lateral antebrachial cutaneous nerves. Limited elevation of the thenar muscles can be performed for exposure. The sheath is opened proximal to the fibrous tunnel and dissection is carried distally to a point just beyond the trapezial tubercle. The tendon should be elevated and inspected, with frayed or degenerated fibers excised. If the trapezial groove has rough, sharp edges or osteophytes, limited débridement with a small rongeur should be performed. No attempt is made to approximate the sheath, and the wound is closed with a subcuticular suture. A light, conforming dressing is applied, and gradually increasing activity is encouraged within days of surgery.

On occasion, a chronically scarred or degenerated FCR tendon must be surgically excised to relieve chronic pain. This procedure should be reserved for patients who have failed a comprehensive course of nonoperative treatment. I use an ultrasound-guided corticosteroid injection to ensure precise localization and confirm at least short-term relief prior to consideration of excision. Relief following excision is generally immediate and profound. I have identified no deficits of motion or function following FCR tendon excision.

Burned Hand

Günter Germann and Manuel Hrabowski

Hands are involved in more than 80% of all severe burns.[114] Each hand represents less than 3% of the total body surface area, but nonetheless, the American Burn Association categorizes burns of the hand as major injuries.[88] Even small burns of the hand may result in severely limited function. When burns of the hand occur as part of a major thermal injury, treatment of the hand receives high priority because the patient's ability to perform useful work after recovery is to a great degree determined by residual hand function. The functional importance of the hand cannot be overemphasized inasmuch as severe hand burns may leave individuals unable to work or even care for themselves. The hand plays a crucial role in the evaluation of our environment ("get a grip on a problem"), in communication with others, in sending and receiving emotional signals, and in sexuality and is frequently a mirror image of our mental state.[139,143]

Burns on the hand frequently have devastating consequences in terms of functional outcome and also aesthetic appearance. Although burned areas of the trunk or lower extremity can easily be hidden under clothing, burned hands are readily visible. Social and professional reintegration of the patient may be delayed because of the psychological stigma that is caused by the visible mutilation. For these reasons, burned hands deserve to be treated with excellent conservative and surgical techniques to achieve not only the best function but also the best possible aesthetic result. The statement of Guy Foucher that "hand surgery is also aesthetic surgery" has never been truer than in the treatment of burned hands. The functional importance of the hand gives it top priority in modern treatment concepts. The most important treatment principles include early initiation of physical therapy; the use of splinting,[133] passive motion movements, and topical treatment; and, when indicated, the use of excision and grafting. A multidisciplinary team, including plastic surgeons, physical and occupational therapists, and psychologists, should be involved from the day of admission to ensure the best quality of care.[78,148]

EPIDEMIOLOGIC FINDINGS

It is estimated that about 1% of the population in Western countries will have a burn injury each year, approximately a quarter of which will require medical care.[13,113] This makes thermal injury the most frequently reported accident. The workplace, however, accounts only for less than a third of burn unit admissions and fire-related deaths. The upper extremity is the most common anatomic area burned, involved in up to 89% of burns.[13,50] The two main reasons for this frequent involvement are the protective reflex with which patients try to guard their faces and the fact that the hand in most instances is exposed without any form of protection. The dorsum of the hand is predominantly involved in flame or explosion injuries, whereas injuries to the palm are more frequently found with chemical exposure, friction burns, or high-voltage injuries. Thermal energy may be transmitted directly by contact with a hot object or liquid. More commonly, however, energy is transmitted indirectly, as when escaping gas from an oven ignites.[50]

ANATOMY

The skin and soft tissues of the hand demonstrate some unique properties. The dorsal skin is thin and very flexible and lies on a rather thin subcutaneous layer of fatty tissue. This structure provides little mechanical protection but allows maximum tendon excursion and joint mobility without the necessity for excess skin. The wrinkles over the metacarpophalangeal (MP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints deepen with finger extension and stretch with flexion. Similar movements are facilitated by longitudinal creases in the web space. The dorsal skin contains large superficial veins, hair follicles, and sebaceous glands, but contains no sweat glands. The skin is especially thin over the PIP joints, where the extensor tendons are at risk. Attenuation or rupture of the central slip with PIP joint exposure is one of the most frequently encountered complications after deep dorsal burns. The underlying cause of many functional disturbances following burns is disruption of the coordinated interplay of extrinsic and intrinsic muscles, tendons, and joints.

The palmar skin shows similarities to the plantar skin of the weight-bearing portion of the foot. The thick subcutaneous fatty layer has a honeycomb-like structure that has shock-absorbing properties and provides grip stability by means of numerous fibrous septa that connect the skin with the deep fascia. Thick epidermal layers are found in the areas of greatest mechanical stress. In the finger, the Cleland ligament (dorsal to the neurovascular bundle) and Grayson ligament (palmar to the neurovascular bundle) provide stability.

PATHOPHYSIOLOGY

The anatomic properties described previously can lead to severe direct thermal effects in the hand that are not seen elsewhere in the body.[122] Blood vessels, tendons, and joints are situated just beneath the skin surface over the dorsum of the fingers, making these structures extremely susceptible to the effects of thermal energy. The cylindrical form of the fingers, with their ligaments

limiting swelling and changes in volume of the fingers after thermal injury, can lead to dermal compartment syndromes in the event of deep dermal circumferential burn injury.[122]

The severity of a thermal injury depends on the amount of transferred energy, which is correlated with the duration of exposure and the temperature of the heat source. Longer exposure to lower temperatures has the same pathophysiologic consequences as short exposure to high temperatures. The character of the skin at the site of injury also determines the depth of the injury. The palmar skin, for example, can withstand greater thermal energy than the dorsal skin can. The heat leads to coagulation of blood vessels, denaturation of proteins, and an increase in capillary permeability (*capillary leak*). This phenomenon divides the burn wound into a zone of necrosis, a zone of stasis, and a zone of impaired circulation.[55] Insufficient primary treatment (i.e., no escharotomy if indicated or insufficient fluid replacement) may convert the zone of stasis into a zone of necrosis (*afterburn*) (Figure 57.1).

Intravascular fluid shifts into the interstitial space and causes a protein-rich edema. Burns of more than 20% of the body surface area lead to a generalized edema in which swelling of the skin and subcutaneous tissue is also encountered in nonburned areas. Edema causes several pathologic effects by increasing intercellular pressure and decreasing circulation. In the intrinsic musculature of the hand, this may lead to a compartment syndrome requiring fasciotomy. Intracellular edema results from disruption of the sodium pump and subsequent entry of sodium and water into the cell.[88] In the hand, persistent interstitial edema that has not resolved after 72 hours may lead to subcutaneous fibrosis with subsequent stiffness of the joints.

Blisters are the cutaneous equivalent of the accumulation of intercellular edema. The blister fluid is rich in proteins and inflammatory cytokines, leukotrienes, and prostaglandins, in addition to multiple growth factors such as angiogenic factors[99] and platelet-derived growth factor, interleukin-6 (IL-6) and IL-8, and transforming growth factor-α.[52,88,98,105,107] Fluid losses through blistering may be considerable in major burns because the ability of the epidermis to limit loss of water vapor is unbalanced, but this does not play a role in isolated hand burns.

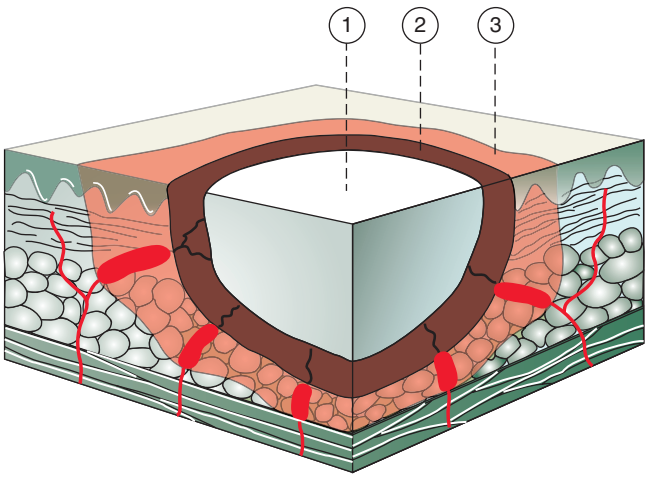

FIGURE 57.1 Model of burn wound pathophysiology. The zone of stasis may convert to a zone of necrosis if insufficient fluid resuscitation is administered.

Blisters are found in partial-thickness (second-degree) burns and superficial dermal (second-degree) burns and less frequently in deep dermal (third-degree) burns.

ACUTE HAND BURNS

Treatment Goals

Any burn injury, even if considered minimal in extent, can still be catastrophic if the hand burns are severe enough to result in deformities that render the individual unable to perform personal daily functions. One of the major basic principles of management of injuries to the skin and subcutaneous tissue of the hand is to achieve wound healing as rapidly as possible. It is equally important to avoid complications that may extend the magnitude of the injury.[50,142] The basic considerations in treating a burned hand can be divided into treatment goals and treatment principles. The most important treatment goals can be defined as follows:

1. Avoid any additional injury or increase in the depth of the burn (do no harm).
2. Achieve early wound closure.
3. Maintain active and passive range of motion.
4. Prevent infection or loss of soft tissue coverage.
5. Initiate early functional rehabilitation.

Treatment should always focus on these goals while taking into consideration the individual circumstances of the patient, which may lead to a shift in priorities.[54,88] To achieve these goals, the following basic treatment principles should be followed (Figure 57.2):

1. Evaluate the size and depth of the burn.
2. Perform escharotomy if indicated.[116]
3. Apply proper wound care and dressings.
4. Make a decision about conservative or operative treatment.
5. Initiate early hand therapy and splinting.
6. Manage the burn surgically (removal of eschar, transplantation of skin grafts, flap coverage if necessary)
7. Begin early postoperative physical therapy.
8. Provide functional rehabilitation.
9. Perform secondary and tertiary corrections if necessary.

Initial Evaluation and Management

A careful and comprehensive history of the injury is of great diagnostic value and prognostic importance and may provide important information for necessary decisions about treatment. After the history, a thorough physical examination should define the extent and probable depth of the burn, the presence and severity of associated injuries, and the general health of the patient. Physical diagnosis of the depth of burn is initially difficult even with years of experience, but knowledge of the mechanism and circumstances can help in indicating the amount of thermal energy conveyed to the tissue.[130]

All injuries should be documented carefully to create a solid foundation for further decisions and a baseline for follow-up and evaluation of outcome during the treatment course. Photographic documentation is highly recommended, especially in view of potential medicolegal issues.[56] The status of perfusion, capillary refill, skin color, and other characteristics has to be documented to facilitate decisions about escharotomy, compartment release, or acute eschar excision.

Dorsal skin deficiency
Digital loss secondary to ischemia
Median and ulnar nerve compression syndrome

Classification of Burns

The cause of the burns can be considered the most useful predictive factor with regard to the prognosis for healing. Scalds usually result in a mixed-depth pattern of injury and frequently involve the palms. Especially in younger patients, scald burns demonstrate a high capacity for spontaneous healing. A more aggressive approach is indicated in elderly individuals with thinner skin. Flame burns are the most serious types of burns, with the notable exception of high-voltage injuries. Flame burns are usually deep partial-thickness or full-thickness burns and often require surgical treatment.[46,130]

Treatment of burns is dictated by the severity of the injury, and severity is determined by the level of thermal energy transmitted to the tissue. Burn wounds have been classified in many ways, although the most common is an anatomic classification based on the depth of the damage (Box 57.1).

Superficial, first-degree burns are characterized by an erythematous epidermis without blistering and are moderately painful. The clinical appearance is similar to sunburn. First-degree burns are those in which cell damage occurs without cell death. These injuries require only symptomatic care, principally directed at relieving pain, which is usually achieved by the application of cooling lotions and pain relievers. They will heal without scarring, usually in 2 to 3 days, and with good return of function.

Superficial partial-thickness second-degree burns destroy the epidermis and some elements of the basal epidermal regenerating layers of the dermis. They are considered to be the most painful type in the immediate posttrauma period because sensitive nerve endings are not damaged. They have the potential to heal by virtue of regeneration from the living epidermal elements remaining in the dermis (sweat or sebaceous glands and hair follicles).[31,98,130] Regeneration, however, may be quite prolonged, depending on the depth of the injury. In second-degree injuries, the resulting scar formation is directly dependent on the depth of injury, and the quality of the regenerated skin is inversely proportional: the deeper the burn, the poorer the quality of the regenerated skin (Figure 57.3).

Deep partial-thickness second-degree burns appear as a moist mottled surface that may be pale or erythematous, depending on the depth of the burn. These wounds typically blanch with pressure and refill on release. Nerve endings are still present in the vital layers, and thus these burns can be quite painful. The skin still bleeds after a needle prick (Figure 57.4).

Full-thickness third-degree burns are characterized by the death of all germinal epidermal elements. The wound extends below the level of the dermis. The skin has a leathery unyielding appearance and is pale to brown in color. The nerve endings are destroyed, so the pain may not be significant. Because all the dermal appendages, as well as the overlying epidermis, are

FIGURE 57.3 Superficial-thickness second-degree burn with blister formation.

FIGURE 57.4 Deep partial-thickness second-degree burn of the palm. The burn will heal spontaneously because of the healing capacity of the palmar skin.

destroyed, these wounds cannot heal by epithelial regeneration and thus are not self-healing.

A *fourth-degree injury* involves necrosis of deeper structures such as tendons and bone[50,130] and is usually found only after contact burns or high-voltage injuries (Figure 57.5).

Determination of Burn Depth

Clinical assessment has not been usurped by modern technology in the evaluation of burn depth. Evaluation is based on the clinical appearance, testing of residual sensibility, pinprick testing for bleeding, and evaluation of capillary refill.[60] These findings are correlated with classification of the burn. Modern devices such as laser Doppler imaging, high-resolution ultrasound studies, and spectrometric analysis are interesting adjunctive techniques but have not improved clinical assessment in hand burns.[155]

FIGURE 57.5 Deep partial-thickness and full-thickness third-degree burns of the forearm. These burns will require excision and grafting.

Control of Edema

Initial delivery of first aid to an individual with a hand burn includes immediate cooling of the wound by rinsing with cold tap water within the first 30 minutes of injury.[116] Cold packs or crushed ice may cause additional harm by decreasing the tissue temperature too much. There is good evidence that the immediate application of cooling to a burn wound will reduce subsequent edema formation and may decrease the actual depth of injury by reducing the zone of stasis.[122,125] A positive side effect is reduction of pain by cooling the burn wound. Another major defense against edema in the early management of acute hand burns is proper positioning of the hand. Strict elevation of the burned hand above the level of the heart of the patient is recommended. This elevation must be maintained continuously during the early postburn period.[130]

Escharotomy

The most important principle in the initial management of a burned upper extremity is maintenance of perfusion, which is ensured by adequate fluid resuscitation to maintain circulating volume and removal of any mechanical obstruction to the flow of fluid in the extremity. The tourniquet effect of an unyielding circumferential burn eschar may worsen the situation of edema following a burn, and the potential for circulation insufficiency is great, especially with deep partial-thickness or full-thickness circumferential burns. The initial therapy for these burn injuries of the upper extremity should therefore be directed toward releasing subdermal tissue pressure and maintenance of the circulation.[112,116,120,142]

Escharotomy for tight constricting burns was first described by Fabry of Hilden in 1607. The need for escharotomy is relatively common in the treatment of circumferential full-thickness burn injuries and has been recommended frequently for some years, especially over the last 3 decades.[116,120,142,158]

Indications for escharotomy include pain, resistance to passive extension of the fingers, and disappearance of capillary refill in the nail beds. The forearm and hand feel tense to palpation. Doppler measurement of digital or superficial palmar arch pulses may also help, but by the time that the radial or

ulnar pulses disappear, tissue ischemia is well advanced.[133] Measurement of subcutaneous pressure with Wick catheters has been recommended by several authors.[1] Escharotomy is indicated when intracompartmental tissue pressure is greater than 30 mm Hg on two separate readings. However, the clinical experience of the surgeon is the most important factor in making the decision to perform an escharotomy.

The surgeon should carefully plan surgical escharotomy incisions with the aim of releasing areas of circulatory restriction and restoring adequate flow while avoiding injuries to underlying structures such as nerves or vessels. Escharotomies can be carried out either with the use of electrocautery or by scalpel. A radial full-thickness incision to decompress the hand and arm should be performed as the first step because there is no risk of any injury to one of the peripheral sensory nerves except the superficial branch of the radial nerve. The length of the incision depends on the size of the constricting eschar. The maximum length of the incision should extend on an axis from the tip of the acromion to the lateral edge of the antecubital flexion crease up to the radial aspect of the distal flexion crease of the wrist.[120,116] If necessary, medial ulnar escharotomy can be added. The incision line should be drawn from the axilla, to the medial aspect of the antecubital flexion crease, to the ulnar aspect of the distal flexion crease of the wrist.

In patients with tight circumferential burn eschar of the fingers, digital escharotomies should be performed. The ulnar incision can be continued along the hypothenar eminence to the midlateral line of the ulnar border of the little finger. The radial escharotomy incision line can be extended along the radial aspect of the thenar eminence and the midlateral aspect of the thumb. The index, long, and ring fingers can be decompressed with similar midlateral incisions on the ulnar aspect of each finger. If the blood supply is not restored adequately with these incisions, the opposite side of each digit can be released in similar fashion by performing bilateral digital escharotomies. Decompression (fasciotomy) of the dorsal interossei should be performed in hands with significant edema and diminished flexion. Small vertical escharotomy incisions are made on the dorsum of the hand between the metacarpals.[112,116] Salisbury and coworkers were able to show in a randomized trial that there was an almost threefold increase in the number of fingers that could be salvaged by extended digital escharotomy (Figure 57.6, *A* to *C*).[128]

Wang and associates have pointed out the importance of intrinsic muscle decompression to overcome ischemic contracture of the hands. It is therefore vitally important with deep burns in the upper extremity to detect possible muscle ischemia to prevent the loss of fingers or the thumb because of secondary vascular compromise. If there is significant subfascial edema, escharotomy can be combined with fasciotomy.[106,112,158,166] The early signs of ischemic necrosis of the intrinsic muscles are hyperextension of the fingers at the MP joint with flexion of the interphalangeal joints.

Splinting

Without appropriate early splinting and positioning, a typical intrinsic-minus posture develops in a severely burned hand that is initially in large part due to swelling of the hand. The injured hand takes the characteristic position of wrist flexion, hyperextension of the MP joints, and flexion of the interphalangeal joints. The thumb usually adducts toward the palm with the interphalangeal joint hyperextended.[13,32,50,64,71,78,135,148] In a short period, edema, inflammation, and immobility are being replaced by scarring and fibrosis, which result in deformities not correctable without surgical intervention. Scar contractures across the dorsum of the hand further accentuate extension of the MP joints and lead to the so-called *claw deformity* that is typical of neglected burns of the hand.

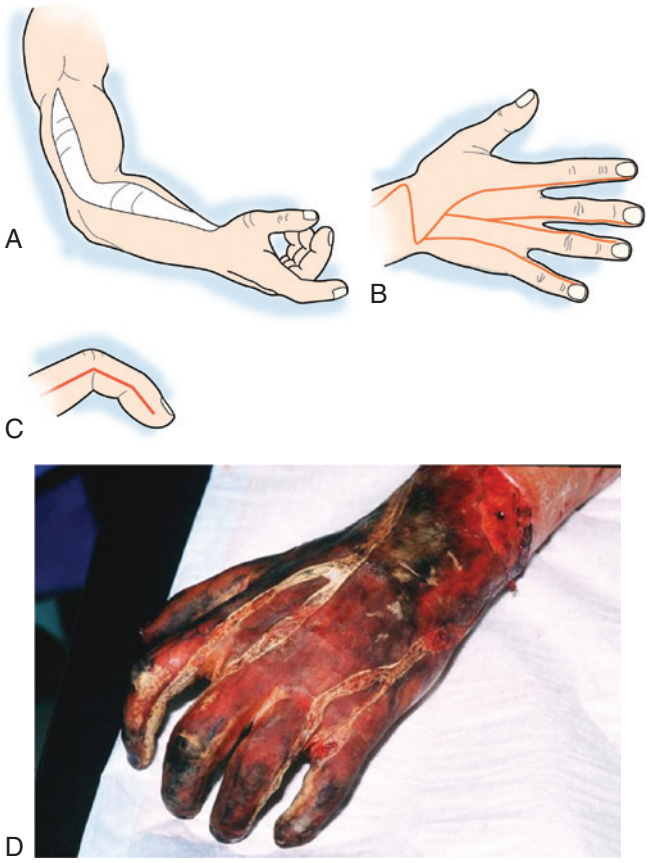

FIGURE 57.6 **A,** Schematic illustration of escharotomy incisions in the upper extremity. **B,** Escharotomy incisions in the dorsum of the hand. **C,** Clinical situation after escharotomy of the dorsum of the hand. **D,** Escharotomy incisions in the digits, midlateral view.

The anticlaw position is essential to prevent permanent contracture deformities. To maintain this position, the hand should be splinted immediately in the so-called *position of safety* (intrinsic-plus position; Figure 57.7). In this position, the MP joints are fully flexed and the interphalangeal joints are essentially fully extended. The first web space is maximally abducted. This position keeps the ligaments of the digital joints in the best tension to prevent shrinking of these ligaments. With the burned hand in this position, the dorsal skin is stretched somewhat tightly across the metacarpals and there is little room for excessive edema formation. The so-called *position of function* with all digital joints slightly flexed should be avoided at all times because this position will inevitably lead to contractures. The elbow should be kept in an extended position because flexion contractures are the most frequent deformities. Care must be taken, however, to keep the elbow moving, for a permanent contracture in the fully extended position is much more

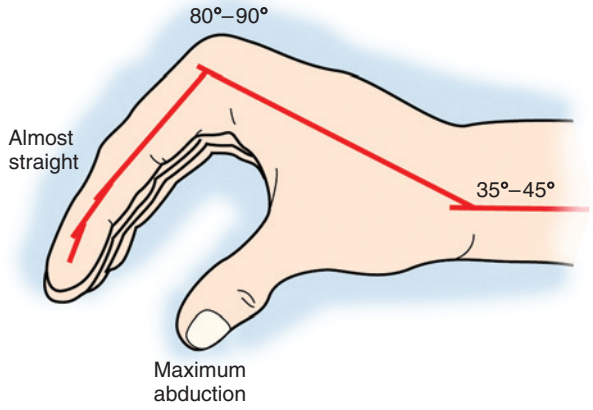

FIGURE 57.7 Ideal splinting position for the hand.

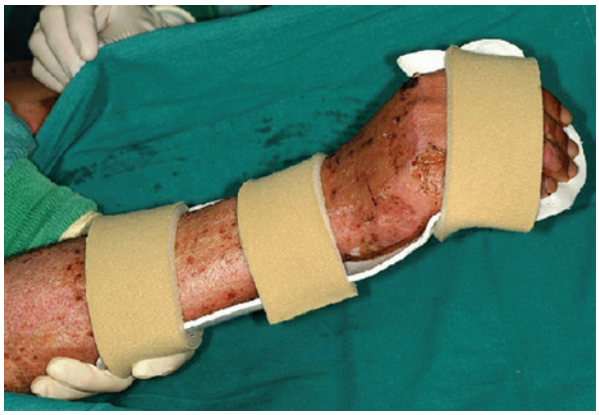

FIGURE 57.8 Custom-made thermoplastic splint in the intrinsic-plus position.

of a functional problem than is a contracture in a flexed position. The shoulder is best positioned in abduction to prevent axillary contractures.

Hand splints should be applied on the day of injury. Customized splints made of thermoplastic material are most effective and can be adjusted to every clinical situation. Whether one chooses to initiate early motion or maintain the hand relatively immobilized for a longer period depends principally on the condition of the skin over the PIP joints. Here the skin is very thin, and deep burns over this area frequently lead to disruption of the central extensor mechanism over the PIP joint and development of the so-called *boutonnière deformity*. If the burn over the PIP joint is fairly superficial, early active flexion and extension exercises of these joints can be initiated. However, if the skin over the PIP joint appears to be more deeply burned, it is best to maintain the joints splinted in nearly full extension. The use of Kirschner wires has been advocated to maintain the PIP joints in extension with deep dorsal burns, but we have seen more problems (such as pin tract infections and joint stiffness) than detectable benefits, so this technique is used only on rare occasions (Figure 57.8).

Local Wound Care

Local care of the burn wound depends on the depth of the injury, the injury pattern, and the general condition of the patient. The decision-making process is illustrated in Figure 57.2. Basic wound care includes débridement, daily cleaning, prevention of infection with topical agents, and wound dressings.[82,130,133,135]

In a partial-thickness second-degree burn, spontaneous healing can be expected within 7 to 14 days, depending on the size of deeper areas. The burn wound should be débrided of all contamination.[133] Areas of peeled skin also need to be removed. Treatment of blisters remains controversial. Small intact blisters less than 1 cm in diameter can be left intact and the wound allowed to heal spontaneously. It has previously been proposed that larger blisters should be left intact as a biologic dressing because they may protect against infection.[54] However, the fluid of burn blisters was found to be rich in prostaglandins and other proinflammatory cytokines, such as IL-6 and IL-8,[52,105,107] that may propagate the burn wound injury and increase the zone of necrosis.[107] The current recommendation for larger blisters is aspiration of the fluid, removal by incision, or débridement of the blisters.[129] Dressings can then be applied directly to the burn wound.

The principle of moist wound healing is applied for spontaneously healing burns. The burn wound should be cleaned daily either in a hydrotherapy tank or under filtered tap water. This is followed by the application of an antibacterial cream. The cutaneous immune response of the individual against bacteria is compromised during the edema phase of the burn wound. Administration of antibacterial creams during this period can prevent sequelae such as streptococcal cellulitis or erysipelas of the burned hand.[54]

With superficial thermal injury, agents such as water-soluble bacitracin can alternatively be used. A deeper partial-thickness burn wound should be dressed with a topical antibacterial agent that has more penetrating capability, such as silver sulfadiazine. Unless the thermal injuries to the hand are associated with large surface areas, systemic antibiotics are not indicated. Vaseline gauze strips and elastic netting are generally used to hold the dressing in place and to provide a custom fit with the opportunity for maximum movement of the extremity. The fingertips should remain visible in the dressings to allow observation of their color and vascularity. Siliconized gauze can alternatively be applied.[82,109]

As the superficially burned areas begin to epithelialize, care must be taken to avoid shearing of the new epithelium with dressing changes or exercise. Bland ointments or creams such as vitamin A and D ointment are helpful to prevent dehydration of the new epithelium. These new epithelial surfaces will require some maturation before sebaceous and sweat gland function recovers.

In recent years, some simpler techniques of burn care have been introduced that involve less work and are less time consuming. The simplest treatment of these types of burns is a large surgical glove filled with silver sulfadiazine cream. The patient slips his hand into the glove, which is then fixed with a bandage at the wrist level. Some patients feel uncomfortable in the rather tight-fitting glove, but for many patients this technique provides a simple, inexpensive solution that is also applicable in developing countries. Harrison and Parkhouse described the use of silicone oil in a glove for the same purpose.[50] In patients who cannot tolerate the tight-fitting glove, the extremely large Gore-Tex glove provides a useful alternative (Figure 57.9). The glove can be left on for several days; however, daily dressing changes are easy and almost painless with both techniques.[70]

The Biobrane glove provides an excellent alternative to the techniques just described. The biohybrid membrane of knitted nylon, silicone mesh, and peptides from porcine proteins is perfectly fitted to the hand and then sealed. It is semipermeable, and small amounts of wound fluid can evaporate through the membrane. Larger fluid collections have to be evacuated through little puncture holes in the material. The glove remains on the wound until the surface is epithelialized and then automatically peels off. Because the glove is transparent, changes in the wound can be observed through the membrane. Dressing changes are not necessary, so the primary high cost of the glove is equalized over time, especially since only limited nursing care is required. The major disadvantage of this method is that the initial wound assessment has to be correct because only wounds of superficial thickness will heal spontaneously under the glove. However, our experience has shown that in cases in which patches of deeper burns are detected, the glove can be removed and treatment in these areas can be directed toward surgical intervention (Figure 57.10, *A* to *C*). Similar techniques can be applied with polyurethane films such as OpSite or Omniderm or with polyacrylic mesh (SurfaSoft).[70,82] Many authors claim that film dressings lead to superior results in superficial burns; however, gauze dressings can provide the same effect, provided that the moist environment of the wound is maintained. Most recently, the new epithelial substitute Suprathel, a cellulose material, has been used for second-degree burns with excellent results.[151]

FIGURE 57.9 Gore-Tex glove filled with silver sulfadiazine for conservative treatment of a superficial partial-thickness second-degree burn.

Excision and Grafting

Deep dermal and full-thickness burns of the hand are best treated by early excision and grafting. It is usually accepted that the burn wound is uninfected and suitable for primary surgical treatment within the first 5 days. If this initial ideal period is missed, a delay of 3 weeks before surgery is thought to be best because of the increased risk for graft loss secondary to infection and excessive bleeding from the inflamed bed of the eschar.[7,13,31,112,133]

Tangential excision is the preferred surgical procedure for hand burns. It involves shaving of the burned skin in thin layers until brisk capillary bleeding is encountered. A typical instrument used for the hand is the Goulian/Weck knife, which

FIGURE 57.10 **A,** Biobrane glove fitted to a superficially burned hand. **B** to **D,** Excellent cosmetic and functional result after spontaneous healing.

consists of a single-edged razor blade with a guard. Layers of devitalized tissue can be removed until healthy tissue is encountered. It is very important to not leave residual devitalized tissue because this might prevent adequate take of skin grafts, promote wound infection, and delay the process of recovery. Reddish areas of fat are considered to represent the zone of stasis and should be excised. No matter how deep the burn is, salvage of the paratenon of the extensor tendons and the fine layer of areolar tissue above the joint capsules is essential to facilitate skin graft take. After excision of the eschar, sponges soaked with epinephrine are applied to reduce bleeding. The most crucial area is the dorsal skin over the PIP and MP joints. Failure of skin graft take in these areas almost inevitably leads to exposure of the joint, with the consequence of joint infection and cartilage erosion and resulting joint stiffness.

Débridement can also be performed under tourniquet control, especially if the hands are involved in a major burn. This makes assessment of the wound a little more difficult and requires more surgical experience, but it may reduce blood loss. Our procedure includes wrapping the hand with epinephrine-soaked sponges and tight elastic bandaging before releasing the tourniquet and leaving the bandages in place for approximately 20 minutes. Most capillary bleeding has usually stopped by this time; however, meticulous further hemostasis is still necessary.

After bleeding is controlled, skin grafts are transplanted. Resurfacing the wound with split-thickness grafts is considered the "gold standard" in most cases.[7,79,89,100] There is still ongoing debate about whether the grafts should be meshed or unmeshed. Many authors claim that sheet grafts provide a superior aesthetic appearance when compared with mesh grafts. It is said that they produce less scar tissue than mesh grafts do and usually provide a more functional result (Figure 57.11, *A* to *C*). Meshed grafts have the advantage of facilitating drainage of wound fluid, blood, and bacteria through the holes in the mesh. They generally have a higher overall "take" rate in critical wound beds when there is some remaining bleeding or patches of questionable viability.[84] The main disadvantage is the high rate of scar contracture that frequently leads to major functional disturbances. The mesh-graft expansion ratio used in burned hands should not exceed 1.5 : 1 (Figure 57.12). There are studies showing no significant difference in aesthetic appearance and function between sheet or meshed split-thickness skin grafts after 12 months, however. In patients with major burns involving the rest of the body, skin grafts may be in short supply and meshed grafts have to be selected for coverage.[89,100,128,133] Our recommendation for the choice of graft depends on the availability of skin graft donor sites and the general condition of the patient. If sufficient donor sites are present, split-thickness sheet grafts are the first choice. In patients with limited graft availability, meshed grafts have to be used. In rare cases with isolated hand burns, split-thickness skin grafts may be harvested a little thicker. This will result in more supple skin with fewer contractures and better functional results.

Full-thickness skin grafts have no indication in acute burns, except in children.[93,114,115] Their take rate depends too much on a perfect wound bed, perfect hemostasis, and the ability to provide a perfect tie-over dressing. With the significant risk for graft loss, full-thickness grafts are generally reserved for secondary corrections.

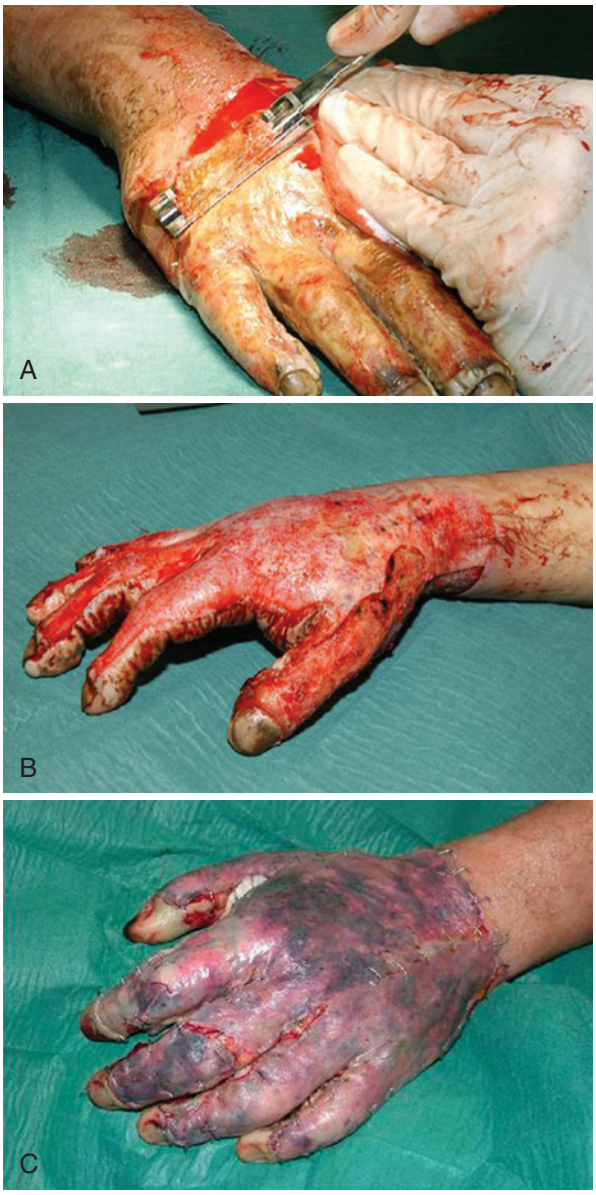

FIGURE 57.11 **A,** Tangential excision of a deep partial-thickness burn on the dorsum of the hand. **B,** Sheet graft transplantation to the excised areas. **C,** Short-term postoperative result after sheet graft transplantation.

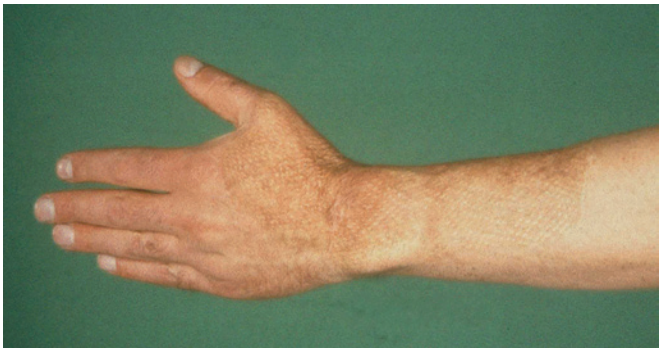

FIGURE 57.12 Cosmetic result of a meshed skin graft transplant on the hand.

The graft is held in place with either single interrupted stitches or a running stitch (4-0 or 5-0), and metal skin staples are a good choice on larger grafts. Care should be taken to create smooth transitions between the grafts and the edges of the remaining skin. The wound is dressed with Vaseline gauze or siliconized gauze. Cotton balls are placed over the gauze for a bolster tie-over dressing. Experimental data suggest that skin graft take is best when pressure of 30 mm Hg is exerted evenly over the wound. Clinical experience has shown that a conventional bolster tie-over dressing reaches this goal. A rather new technique to enhance skin graft take is the application of vacuum pressure to the wound. This has been shown to yield very good results in skin grafting of chronic wounds, but it is technically very difficult to apply this technique to a burned hand. The first results with vacuum gloves have been reported, but larger series are still lacking.[65,101]

In full-thickness burns of the upper extremity and involvement of a large surface area of the entire body, epifascial excision may be indicated. The skin envelope may be reconstructed with meshed skin grafts in these cases, but this will most likely result in severe postburn contractures. Artificial dermal equivalents such as Integra, AlloDerm, Dermacell, or Matriderm[28,29,51,85] can be used in these circumstances. Use of one of these materials may result in a more pliable skin envelope with less need for corrective surgeries later (Figure 57.13, *A* to *C*).

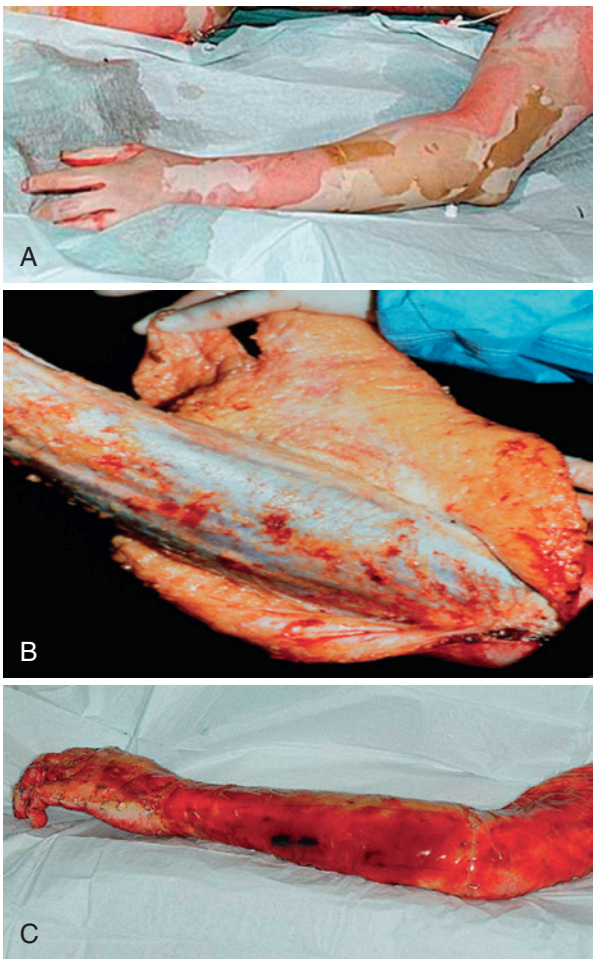

FIGURE 57.13 **A,** Deep full-thickness burn on the left upper extremity. **B,** Epifascial excision of a severe full-thickness burn on the left upper extremity. **C,** Application of Integra to the extremity.

Dressings are left in place for 5 days. Skin graft take can be assessed by then, and decisions for further wound care can be made. If the wound becomes odiferous, the dressing can be changed earlier to avoid graft loss through infection. If the wound is found to be clean with satisfying graft take, no particular treatment is indicated. Only Vaseline or any similar basic cream is administered to keep the graft moist and supple. If traces of infection such as suppuration or colored crusts are found, all debris has to be removed carefully, and the wound rinsed with an antiseptic solution such as chlorhexidine (Hibiclens) or polyhexanide (Lavasept). All skin graft areas that seem to be nonviable have to be removed. The wound is redressed with gauze and an antiseptic cream such as mafenide acetate (Sulfamylon) or silver sulfadiazine (Silvadene).[50,55,82] Dressing changes are performed daily until the wound does not show any signs of infection. With this technique, many "endangered" grafts may be salvaged.

Special emphasis has to be given to postoperative splinting and physical therapy. Splints are an integral part of the postoperative treatment plan. After grafting, the hands are immobilized for 5 days until graft take is secured. Passive physical therapy is then initiated to prevent and reduce stiffening of the joints. Minor graft loss has to be accepted if joint mobility can be maintained. Even in situations in which graft take over the PIP joints is not guaranteed, mobility of the remaining joints has priority. Active range of motion is initiated as soon as the patient is awake and conscious.

In rare cases, tangential excision does not suffice. With full-thickness injuries the skin damage may reach down to the paratenon and tendons, and the metacarpal bones or joints may be exposed. In these cases primary flap coverage is indicated. The choice of flaps depends on donor site availability and the ideal tissue for the particular situation. In younger females and children, a conventional groin flap still may be the prime choice. This donor site can easily be hidden, the skin is supple, and immobilization of the shoulder is usually well tolerated. A drawback of this flap is that four to five procedures are required to achieve a definitive result. However, in patients with thick subcutaneous fatty layers, the flap may be too thick and yield aesthetically unsatisfying results.

In most situations when the general condition of the patient allows more sophisticated procedures, the flap can be tailored to the individual need of the patient (i.e., free flaps, pedicled forearm flaps, or intrinsic hand flaps).[11,22,128] Fascial flaps have proved to be very helpful for coverage of dorsal hand defects when cutaneous flaps would yield flaps that are too thick.[31,35,118] They provide stable but supple tissue; secondary reconstructive procedures can be performed under these flaps; and the aesthetic results after grafting the fascia with split-thickness skin grafts are pleasing. Temporoparietal fascia, serratus fascia, or anterolateral thigh fascia flaps are the most frequently used. They seldom require secondary debulking (Figure 57.14, *A* and *B*).[35,36,66,131]

In situations in which large flaps are required, the latissimus dorsi flap, the anterolateral thigh flap, or a cutaneous flap from the subscapular system would be the primary choice.[92,94] These flaps are rarely indicated for flame burns but are more frequently used for chemical burns, contact burns, or high-voltage injuries (see later). Secondary revisions of these flaps are frequently required.

FIGURE 57.14 **A,** Deep contact burn on both hands with exposed proximal interphalangeal joints after failed skin grafts. **B,** Result after the application of free serratus fascia flaps to both hands with skin grafts.

The principles of physical therapy are the same for a flap-covered hand as for a grafted hand. After 5 days, flap healing is usually secured, and passive exercises can be initiated.

Skin grafting is rarely necessary with palmar burns because of the enormous capacity for spontaneous healing from the many glabrous skin appendages. This is the reason why thick split-thickness skin grafts are seldom required. Flap coverage may be needed more frequently with deep palmar burns. In our practice, fascial flaps offer the best solution for this problem. The stability of the tissue is sufficient, and there is almost no shearing within the flap to diminish the quality of grip. Deep sensation is reported to return within 12 to 15 months.

In children, Pensler and colleagues found no significant difference in the number of operative procedures with either full-thickness or split-thickness grafts. They claim that split-thickness skin grafts have less tendency toward hyperpigmentation, thereby leading to superior cosmetic results, are more expeditious to harvest, and preserve donor sites for future reconstruction.[114] In contrast, Pham and coauthors consider full-thickness skin grafts as a first choice for deep palm burn injuries in children.[115]

Complications

Complications after isolated hand burns are rare and can usually be avoided by proper treatment. They are more frequent with major burns in which the immune response of the patient is severely suppressed and the patient remains in a catabolic state for a considerable period. Three types of complications can jeopardize the treatment result: secondary infection, graft loss, and early hypergranulation.

Secondary Infection

Secondary infection can be a major problem in hand burn injuries. Two areas of the hand are extremely susceptible to secondary infection.[130,133] The thin skin overlying the dorsum of the PIP joints makes the tendons likely to be injured or can result in an open joint. A decreased blood supply may also increase susceptibility to infection with secondary joint involvement (Figure 57.15, *A* to *D*). The nail bed is the other area that is particularly susceptible to injuries. Despite its high vascularity, the nail bed is readily exposed to thermal injury and to secondary trauma and infection.

Infected areas are treated with the local application of antibacterial creams or ointments (see above). Systemic antibiotic therapy is rarely indicated and should be used only when clinical signs of cellulitis or ascending lymphangitis are seen. The hand is cleaned and rinsed daily and then antibacterial agents are applied.

Graft Loss

The loss of skin grafts can have several underlying causes:

- Insufficient débridement with residual layers of nonvital tissue
- Bleeding of the wound bed with hematoma under the graft
- Imperfectly fitting tie-over dressing
- Secondary infection of the wound bed

In the event of graft loss or nonviable grafts, the wound has to be débrided surgically. All nonviable skin must be removed, and the wound bed has to be débrided until healthy bleeding is encountered; meticulous hemostasis is mandatory to prevent further graft loss. Regrafting can be performed in the same session if there is minimal drainage and hemostasis is adequate. If the wound is seriously infected, the viability of the deeper layers is questionable, or if the wound is bleeding too much because of inflammation, it is best to treat the wound for several days with local care and delay secondary regrafting to avoid additional graft loss.

Early Hypergranulation

Early hypergranulation occurs between nonepithelialized areas of mesh grafts or the borders of sheet grafts. It is rarely encountered in large surface area burns because the immune response of patients with these injuries is usually severely impaired. Surgical removal of these hypergranulated areas is not recommended, because it will cause profuse bleeding. Dressing the wound with steroid-containing gauze (Corticotulle) has proved to be extremely useful. Several days of treatment generally suffice until the wound has reepithelialized. Early treatment with pressure gloves and silicone sheets is mandatory in these patients.

POSTBURN DEFORMITIES

Even if in the initial phase of acute hand burn injury all treatment measures have been executed properly, postburn deformities still occur and are the most common causes of skin contracture in the hand.[12,16,33,47,71,73,90,119] Postburn scarring and

FIGURE 57.15 **A,** Typical exposure of the proximal interphalangeal joint after a deep partial-thickness second-degree burn and graft loss. **B,** Design of a reversed dorsal metacarpal artery (DMCA) flap based on the second DMCA. **C,** Flap raised on its pedicle. contractures affect the function as well as the aesthetic appearance of the hand and remain the most frustrating late complication of a hand burn. If contractures or scarring affect the dominant hand, as they do on most occasions, the vocation and thereby the economic status of the patient suffer. Proper management of these deformities is thus highly desirable. A classification of postburn deformities has been proposed by Achauer.[1]

A. Claw deformity
   1. Complete
   2. Incomplete
B. Palmar contracture
C. Web space deformity
   1. Web space contracture
   2. Adduction contracture
   3. Syndactylism
D. Hypertrophic scar and contracture bands
E. Amputation deformity
F. Nail bed deformity
G. Elbow
   1. Flexion contracture
   2. Deep burn with extensive tissue loss
   3. Heterotopic ossification
H. Axilla

Scars can also be assessed with scoring systems such as the Vancouver Scar Score,[8] which allows classification of the scar based on the variable clinical picture.

Prevention

It is well accepted that the best therapy for burn wound contractures is prevention. Prasad and colleagues suggest that comprehensive treatment efforts have led to a significant reduction in the development of burn scar contractures.[119] It appears that factors such as improved burn wound management, liberal use of positioning, improved splinting, early maintenance of range of motion, and exercise programs have contributed to this success.[119] A decrease in the need for late reconstructive surgical procedures is reflected in the literature over the last 35 years. Dobbs and Curreri reported a serious contracture rate of 27% in 681 adult burn patients.[25] Pegg and coauthors reported on 411 patients with a 7.8% incidence of burn scar contractures,[113] and Kraemer and associates noted only a 3.7% rate of reconstructive procedures 9 years after burn scar release in a population of 839 adults and children with burn injury.[71] These data suggest that improved treatment protocols and splinting for prolonged periods are reducing the need for readmission for reconstructive procedures.

Treatment

Postburn deformities are usually related to the initial soft tissue deficit. Contractures can be caused by spontaneous healing of deeper burns (i.e., the burn wound itself) or more frequently by the inevitable contracture of transplanted split-thickness skin grafts. This phenomenon occurs more extensively in the acute burn situation and is less pronounced in elective situations. The clinical impression that secondary split-thickness grafts contract more in burn wound releases than in other posttrauma situations is shared by many authors; however, scientific evidence of this tendency is rare. Release of contractures may be accomplished by various patterns of "Z"-plasties,[40,47,73,128,144] but skin grafting or flap coverage is frequently required.

Full-thickness skin grafts play an important role in these secondary corrections because they are more similar to normal skin than split-thickness grafts in texture, color, and resilience. However, full-thickness grafts take less readily than do split-thickness grafts and may suffer the setback of limited availability in patients with larger burns.[59,89,90,93,171] The latter problem, in some situations, may be solved by preexpansion of the donor sites.[10] Full-thickness grafts have less tendency for contraction because there is an inverse relationship between thickness of the dermis and graft contraction.[59,63]

Before surgically addressing the problem, a thorough analysis is mandatory. Several questions have to be answered:

1. What is the nature of the contracture or the limiting scarring?
2. Are there any underlying joint problems (e.g., shrinking of the ligaments or capsules, cartilage destruction)?
3. Are soft tissue procedures sufficient?
4. Which type of coverage is adequate after contracture release?
5. Where should the skin grafts or flaps be harvested?

Only after these questions have been answered can a surgical plan be designed. The most disturbing functional problems are usually addressed first; however, the patient may perceive aesthetic deformities as the more urgent problem. Decision-making algorithms are presented in Figures 57.16 and 57.17.

Nail Bed Deformities

Dorsal scarring over the DIP joint leads to distortion of the eponychial fold, retraction of the eponychium, and proximal nail exposure. In cases involving only skin tightness without severe retraction of the nail fold, skin release and skin grafting may be sufficient.

When reconstruction of the nail fold is required or skin grafts are not appropriate, proximally based lateral skin flaps are recommended. The donor site of these narrow flaps can generally be closed primarily, and the resulting tip deformity evens out over time (Figure 57.18).[1,2]

Claw Deformities

Claw deformities may be difficult to correct (Figure 57.19). They usually consist of hyperextended MP joints with flexion contracture of the PIP joints. In contrast to Achauer's classification, we prefer to divide claw deformities into (1) long-standing fixed deformities with ligament shrinkage and (2) cutaneous deformities in which simple release of the skin contracture solves the joint position problem.

The first group requires arthrolysis, either from the dorsum or in rare cases from the palmar aspect of the joint. Both approaches to the joint can usually be performed from the dorsal skin incision. These situations generally require some sort of flap coverage because the extensive dissection has eliminated all tissue layers where skin graft take is likely. The same holds true for situations in which the extensor tendon apparatus is exposed and stable soft tissue coverage is required. As mentioned previously, the choice of flaps depends on the individual profile of the patient and ranges from regional flaps such as the radial forearm flap to distant flaps (groin flap) and microvascular flaps.[3,5,11,23,26,33,38,44,49,66,73,91,96,118,132,138,152]

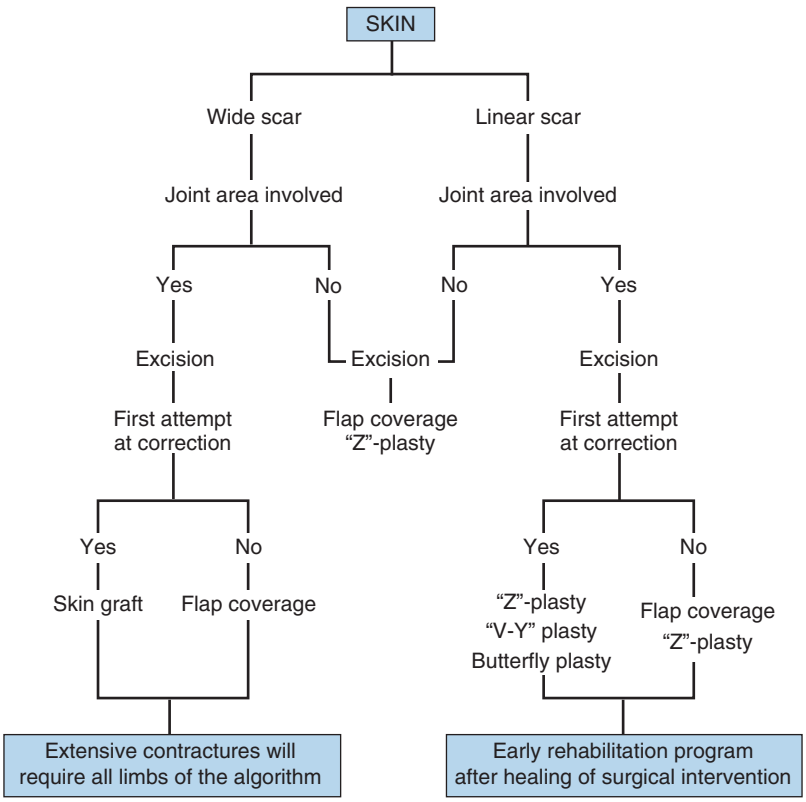

FIGURE 57.16 Decision-making algorithm for skin contractures. (With permission from Germann G, Sherman R, Levin SL: *Decision making in reconstructive surgery on the upper extremity*, New York, 1999, Springer-Verlag.)

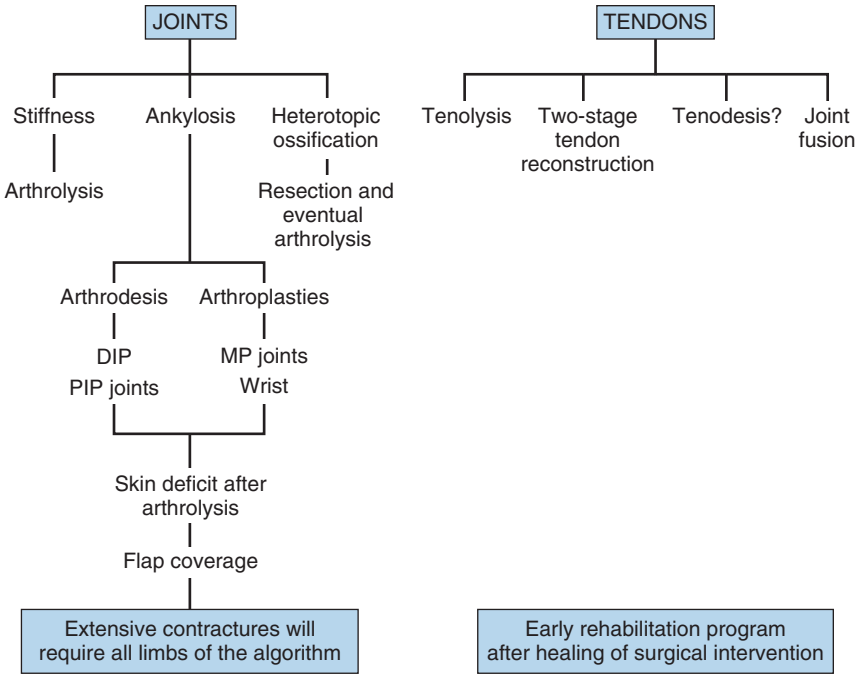

FIGURE 57.17 Decision-making algorithm for joint contractures. *DIP,* Dorsal interphalangeal; *MP,* metacarpophalangeal; *PIP,* proximal interphalangeal. (With permission from Germann G, Sherman R, Levin SL: *Decision making in reconstructive surgery on the upper extremity,* New York, 1999, Springer-Verlag.)

Full-thickness skin grafts are preferred when skin grafts will suffice for skin reconstruction. Only in cases of limited availability, as when other important areas require full-thickness skin grafts (e.g., eyelids, lips), are split-thickness grafts used.

Temporary fixation with Kirschner wires is indicated only in joints in which "elastic" resistance remains after release of the skin and ligaments and the patient will probably not be able to mobilize sufficient strength to overcome this resistance.[137,141]

The same holds true for the PIP joint in claw deformities. In most cases there will remain palmar tissue deficit that requires either full-thickness skin grafting or flap coverage after release. Local intrinsic hand flaps are generally limited in these hands, so distant flaps or free tissue transfers are frequently indicated because the problem is usually encountered in more than one digit.

Web Space Syndactyly and Interdigital Contractures

There are two mechanisms in burn injuries of the hand that cause interdigital fusion (i.e., syndactyly). Adjacent burned digits may be allowed to fuse together during the healing process, and granulation or contractures of the digital skin could allow distal migration of the web. Contracture of the second, third, and fourth web spaces usually occurs along the dorsal margin of the web. Numerous methods that generally involve local flaps and grafts have been developed to improve this surgically. They usually consist of variations of "Z"-plasty, such as three-, four-, or five-flap ("V-M") "Z"-plasty.[144,145] The most important step in correcting these deformities is to reconstruct the natural slope of the web space, from proximally dorsal to distally palmar. This re-creates the natural appearance of the web and the natural motion pattern of the dorsal skin creases (Figure 57.20).

In cases in which any type of "Z"-plasty cannot provide sufficient skin, patches of full-thickness skin grafts are used. To achieve a satisfying take rate, the wound bed must be dry, all cavities of the wound surface have to be filled with Vaseline gauze, and the tie-over bolsters are meticulously applied. Mancoll and associates reported the long-term follow-up of various techniques used to surgically correct interdigital contractures. Although all techniques using skin grafts or local flaps showed a high recurrence rate, "Z"-plasties alone had the lowest recurrence rate.[90] With all techniques, care should be taken during these procedures to avoid damage to the neurovascular bundles in the web space.[4,9,16]

Contractures of the Thumb

Contractures of the first web space are usually the result not only of hypertrophic scarring or skin shortage in the web but also shrinking of the adductor muscle, fascia, and possibly the basal joint capsule. First web space contractures limit movement of the thumb at the trapeziometacarpal joint, affecting both grasp and pinch.[16] They can be treated by release of all structures involved and soft tissue reconstruction with skin grafts or any type of suitable flap (Figure 57.21, *A* to *C*). Our experience has shown that in most cases at least the adductor muscle is involved, so division of the muscle is an integral part of the contracture release.

Contractures of the first web space can be released with a variety of techniques, including "Z"-plasties, four-flap "Z"-plasties, local rotation flaps, and full-thickness or split-thickness skin grafts. Distant or free microvascular flaps will be required infrequently.[5,58,91,111,152] The technique of simple 60-degree "Z"-plasty gives the greatest increase in length and depth of the web space. A four-flap "Z"-plasty with a 90-degree flap on each end

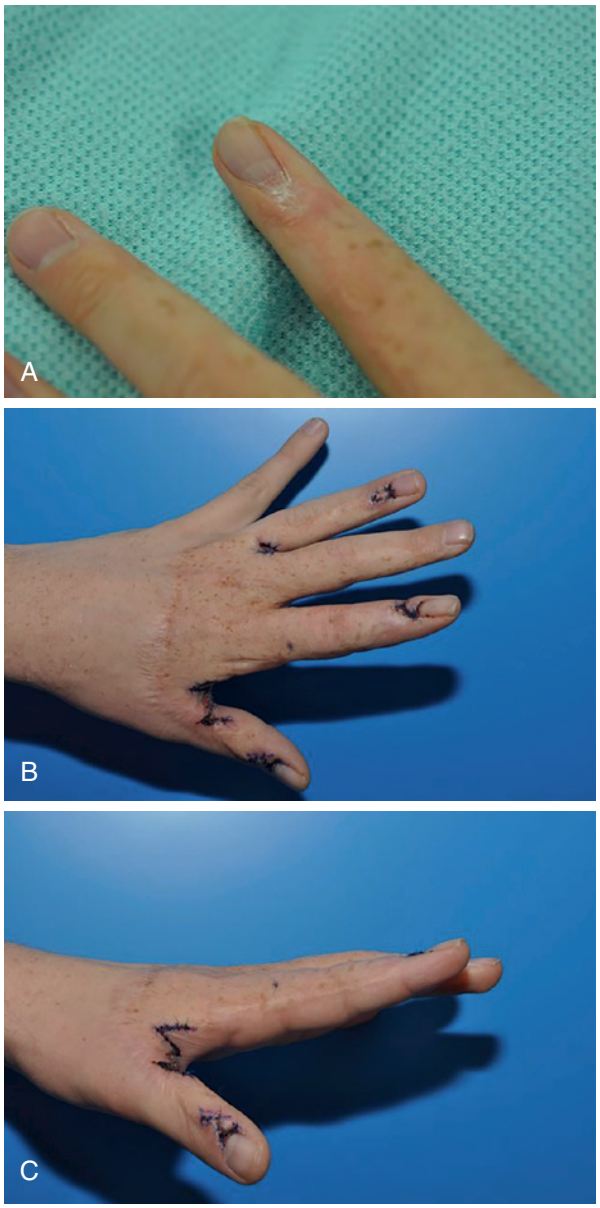

FIGURE 57.18 **A,** Typical nail bed deformity with tissue deficit over the proximal matrix. **B,** Correction of the tissue deficit with local pedicled flaps. Creation of a new nail fold is not possible. **C,** Simultaneous correction of the first web space with "Z"-plasties.

FIGURE 57.19 Bilateral claw deformity.

of the central incision and each of these flaps divided into two 45-degree flaps will provide a smoother contour than the standard "Z"-plasty does. In addition, other types of rotation flaps have been described by many authors.[33,39,112]

Although the most common contracture of the thumb is an adduction deformity, other anatomic deformities are also seen. Less frequently, the thumb metacarpal may be contracted in opposition and extension as a result of bands of dorsal hypertrophic scars between the distal radius and first metacarpal, or in flexion as a result of palmar scarring producing flexion of the interphalangeal or MP joint.[137] Correction of these contractures requires surgical release, sometimes combined with wider burn scar excision, followed by appropriate soft tissue coverage (Figure 57.22, *A* to *C*).[1,93,128,135,137,145] Fusion may be necessary in selected cases.

Digital Flexion Contracture

Release of flexion contracture of the digits and palm is one of the most commonly performed procedures in patients with burn injuries.[47] The skin of the palmar surface of the hand is specialized because of its unique functional requirements. It is hairless, thick, and sturdy and has relatively nonelastic skin designed to withstand the heavy demands of daily work. It is the best tactile organ with optimal sensitivity and is rich in sweat glands to provide the moisture essential for sure grasp and touch. The fundamental principle of reconstruction is to replace the lost tissue with similar tissue. Because of the unique similarities in characteristics, plantar skin is an excellent donor area for skin grafting of the palmar aspect of the digits and hand. The similarities between palmar and plantar skin have been described by many authors.[10,18,47,59,79,100,103,146,164,171] Histologically, both types of skin have a thick epidermal layer with a well-defined stratum lucidum and solid stratum corneum. The connective tissue of the dermis in both is less elastic and more compact than dermis elsewhere to provide stability against pressure and shearing forces. Both are hairless and lack sebaceous glands and melanocytes. They have numerous pacinian corpuscles for optimal sensibility and abundant sweat glands to provide moisture. The sweat glands produce multicentric epithelial budding, and this leads to rapid and good-quality healing of the plantar area.

Le Worthy first reported split-thickness plantar skin grafting.[79] Webster and Zoltie and colleagues used full-thickness plantar skin grafts from the plantar instep area,[164,171] and more recently Tanabe and coworkers described the use of plantar dermal grafts for reconstruction of palmar skin defects of the digits and hand.[146] Hyperpigmentation, scarring, and recurrence of contracture are the common problems encountered with traditional skin grafts on the palm. Skin grafts from the plantar area of the foot are probably better because they have few pigment cells and tend to contract less because of less elasticity and more compact connective tissue in the dermis. Good cosmetic and functional results were obtained at both the donor and recipient sites.[100,103,146]

Postburn flexion contractures of the fingers functionally impair the digits and restrict the functional capability of the entire hand. They have been classified by Kurtzman and Stern[73,74]:

Type I: Skin only, MP joint in passive flexion, PIP joint able to be fully extended

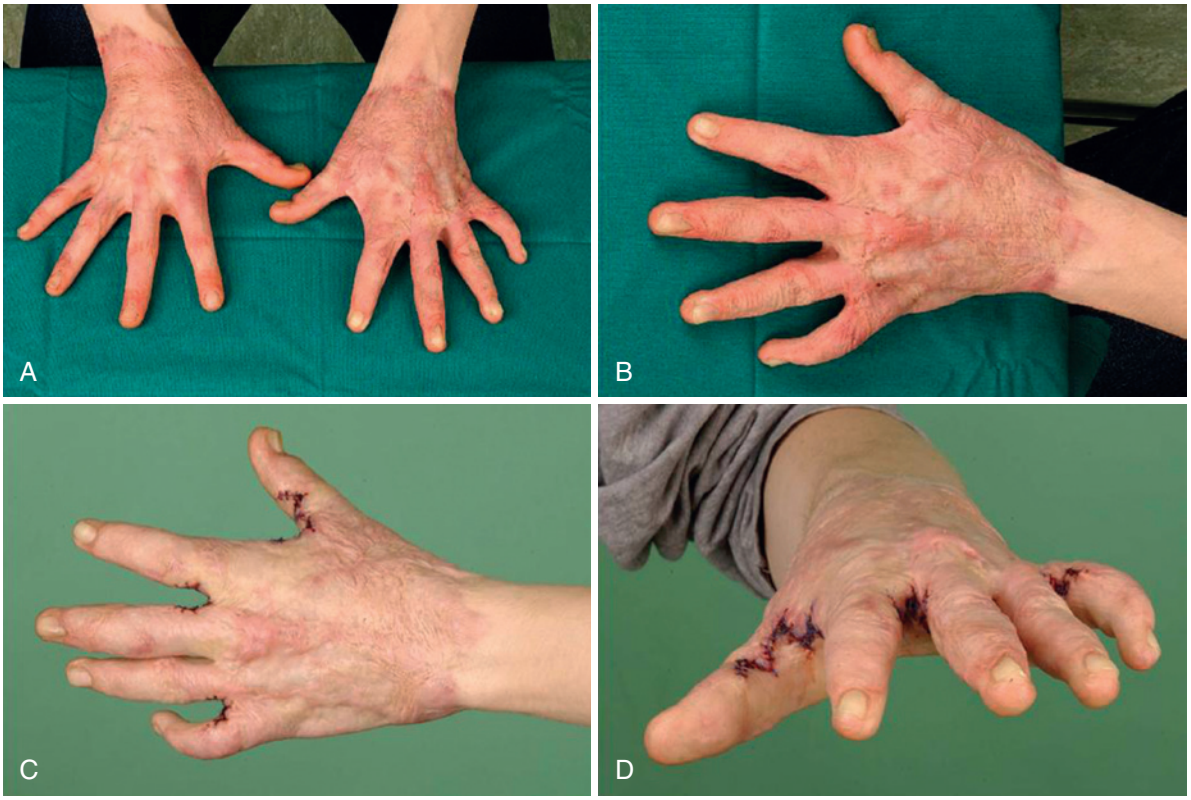

FIGURE 57.20 **A** to **D,** Web space contracture.

Type II: Palmar capsular structures—MP joint in passive flexion, no passive extension of the PIP joint possible

Type III: Soft tissue, joint structures—fixed PIP joint regardless of MP position

The skin shortage between the palmar digital and DIP skin creases limits extension of the PIP joint. This deformity can be corrected by releasing the contracted structures and replacing the palmar skin deficiency.[1] Whenever possible, we attempt to achieve the treatment goal with modified "Z"-plasties and prefer full-thickness skin grafts if the "Z"-plasty is not sufficient.

Type II deformities frequently require release of the volar plate and division of the checkreins to free the joint. Flap coverage can be indicated in these cases when the joint capsule or flexor tendons are exposed.

Type III deformities are fixed with joint irregularities and frequent cartilage destruction. These patients are often best served by joint fusion despite available complex soft tissue reconstructive procedures.

Boutonnière Deformity

A postburn boutonnière deformity is a multifaceted disorder, and the damaged central slip of the extensor apparatus is only one facet of the problem. Deep dermal and full-thickness burns of the dorsum of the PIP joint are a potential cause of the development of a boutonnière deformity. These burns damage the central slip of the extensor apparatus over the PIP joint initially or during the healing phase. When this occurs, the lateral bands slide below the axis of rotation of the PIP joint. As a result, the lateral bands become PIP joint flexors rather than extensors, and thus the PIP joint is flexed up to 90 degrees and unable to actively extend. Absence of the central slip creates a loss of restraint of the extensor mechanism that allows this system to move proximally. This results in excessive pull on the DIP joint through the lateral bands and subsequent hyperextension at the DIP joint.

Such postburn boutonnière deformities are a challenge to surgeons and call for a comprehensive approach. Surgical management is extremely difficult, and the results of the various operations are unpredictable. First of all, it is necessary to eliminate the related contractures of all hand joints and restore the passive movements of the PIP joint by preparatory operations, and distraction devices set the stage for successful tenoplasty.[45] A variety of tenoplasty techniques are described in the literature. It has been proposed that the lateral bands be shifted to the dorsum of the finger and be sutured together or that a figure-of-eight tenoplasty be created.[75,129,136] Other authors perform a tenoplasty with transected lateral bands.[11] More widespread is a technique in which the tendon transplant is pulled through a hole in the base of the middle phalanx to connect it with the lateral bands or with the central slip over the proximal phalanx.[75] Although methods vary, the results are frequently unsatisfactory. Consequently, PIP joint fusion or finger amputation is common, and many authors believe that arthrodesis is more effective than tenoplasty.[43,129,136] By shortening the finger with an arthrodesis, no additional coverage is usually necessary and healing time is often shorter than with tendon reconstruction.

Contractures of the Dorsum of the Hand

The initial thermal injury to the hand is almost always limited to the skin alone, and the underlying tendons and joints are usually spared. Therefore, dorsal contracture is the most

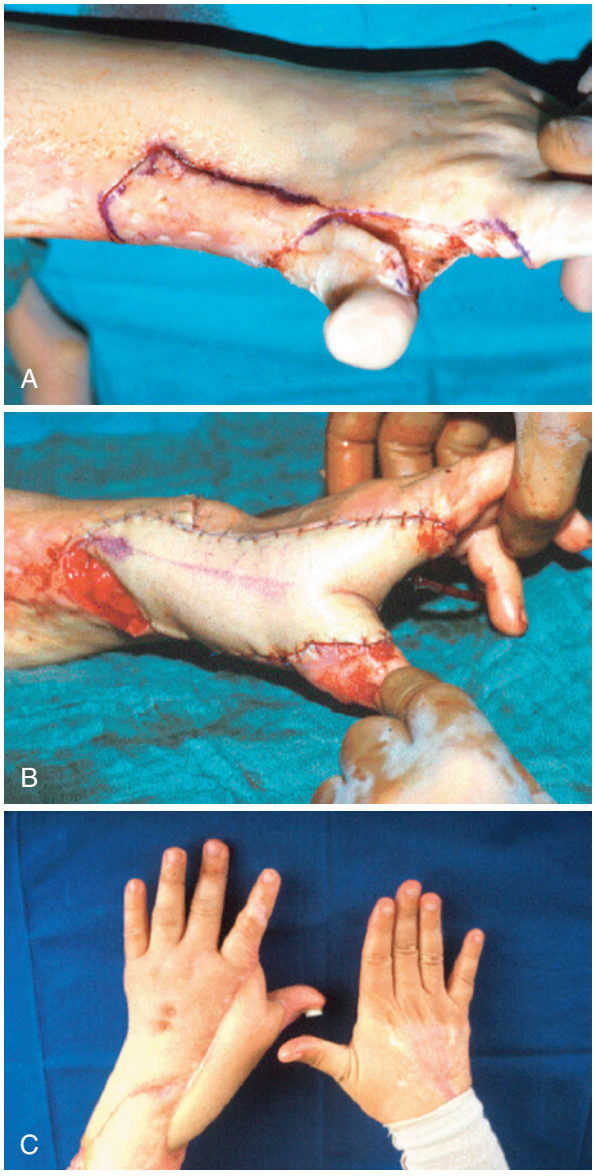

FIGURE 57.21 **A,** Severe contracture of the first web space. **B,** After release of the contracture, a posterior interosseous flap is rotated into the resulting defect. **C,** Long-term result.

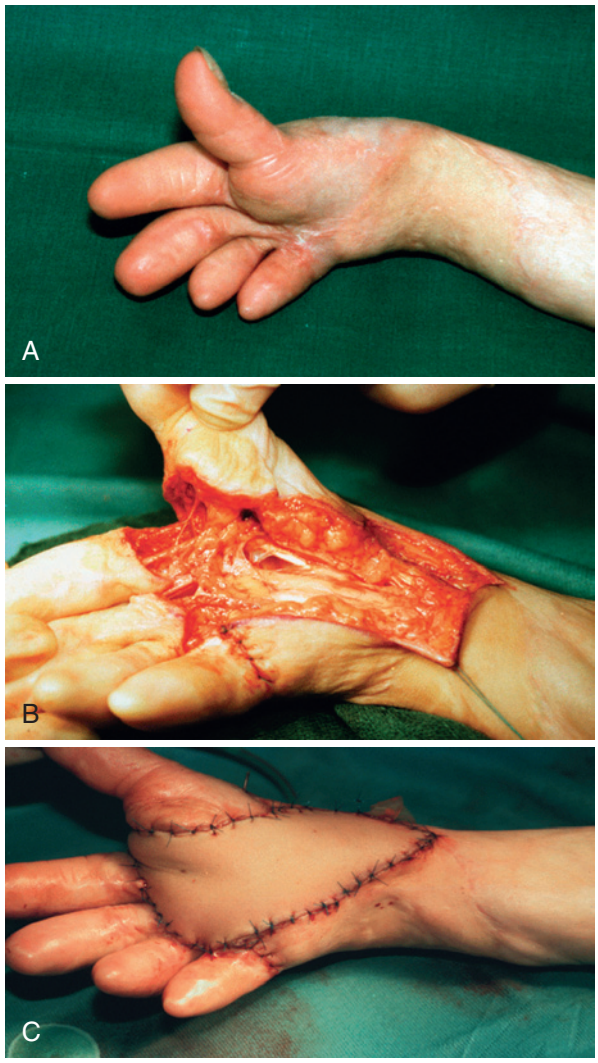

FIGURE 57.22 **A,** Severe adduction contracture of the palm of a 10-year-old child. **B,** Resulting defect after release of the contracture. **C,** Reconstruction with a free parascapular free flap.

common problem encountered after hand burns. This deformity, which generally occurs after skin grafting, may be due to unsatisfactory skin coverage, partial graft loss as a result of wound infection, or inadequate exercise and splinting in the antideformity position.[13,19] This results in a feeling of tightness, MP joint hyperextension, and limitation of finger flexion.[13,19]

Correction consists of complete excision of the contracted tissues and mobilization of all adjacent joints. Full-thickness skin grafts are the primary choice for reconstruction. Resurfacing the dorsum of a hand with full-thickness skin grafts requires a considerable amount of skin, however, which frequently may not be available. Thick split-thickness skin grafts may be a reasonable alternative. A simple solution is to use the crane principle. Subcutaneous tissue can be carried on a skin flap placed temporarily over a wound defect. The skin flap, along with a thin layer of subcutaneous tissue, is later returned to the donor site *while* leaving a layer of subcutaneous tissue, suitable for skin grafting, over the original defect.[98]

Whenever there is doubt about the wound bed and the graft take rate, flaps should be considered.[5,22,23,110,149] In addition to all types of skin flaps, fascial flaps have proved to be excellently suited because they provide thin, stable, and supple coverage that requires only split-thickness skin grafting.[118] To avoid any graft loss, hemostasis should be meticulous. If oozing persists at the time of scar excision and fascial flap placement, secondary grafting should be considered. This can be done as a secondary bedside procedure 2 to 3 days postoperatively, with the skin graft harvested at the time of flap transfer (Figure 57.23, *A* and *B*).[35,66]

Volume Deficiencies and Contour Irregularities

Major volume deficiencies and contour irregularities require complex reconstructive procedures. In many cases, however, dorsal contractures and atrophy of the subcutaneous tissues lead to minor volume deficiencies and contour deformities. These minimal deformities are difficult to correct. An excellent

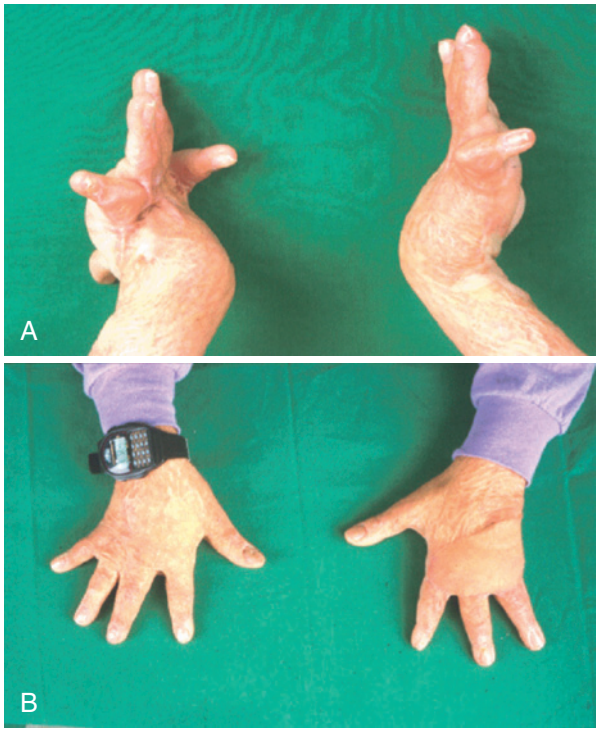

FIGURE 57.23 **A,** Severe bilateral contractions of the dorsum of the hand. **B,** Long-term result after release and reconstruction of the right hand with full-thickness skin grafts and use of a conventional groin flap on the left hand.

alternative for these types of deformities is the lipofilling technique.

The technique is usually used in aesthetic and reconstructive procedures to treat volume deficiencies after deep inferior epigastric perforator flap reconstruction or to fill wrinkles in facial rejuvenation. The fat is applied in a "microdrop technique" to achieve a maximal take rate of the transplanted fat. The transplanted fat creates a new tissue layer between contracted scars and the suprafascial plane. This makes the scars softer and more pliable. The method is increasingly used in our department with excellent results.

With this technique, a permanent take rate of up to 70% can be achieved. Multiple procedures may be required (Figure 57.24, *A* and *B*).

Amputation Deformity

Patients with significant burns of the hand and digital involvement are always at risk for vascular compromise of the digits. Early escharotomy to preserve the intrinsic muscles of the hand and improve the circulation in digits is crucial. Despite these procedures, some patients face partial or total amputation of the digits. Such losses both distort the aesthetic appearance of the hand and severely affect its function.

Salisbury pointed out that it might be inappropriate to concentrate multiple surgical efforts on one finger if a patient has other extensive problems. Amputation might rapidly relieve the problems of "hooking" or chronic pain in these cases. The overall goal is to do only the operations necessary to rehabilitate the patient.[128]

Reconstruction of the digits usually concentrates on restoration of a three-point grip involving the thumb and predominantly the index finger. The thumb accounts for approximately 40% of hand function, which is why its reconstruction is a primary concern in rehabilitation of a burned hand with multiple digital loss. Any reconstructive procedure in a burned hand is surgically more difficult than in other posttraumatic situations.

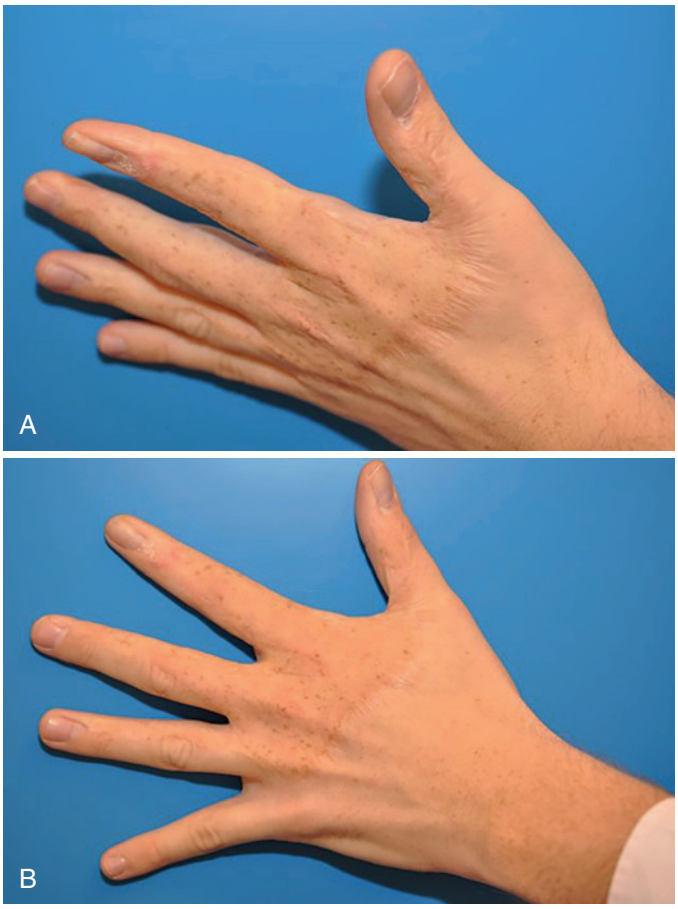

FIGURE 57.24 **A,** Significant volume deficiency in the intertendinous spaces. **B,** Marked improvement after one session of lipofilling.

Thumb Reconstruction. In thumb reconstruction, the adequacy of soft tissue coverage must first be assessed. If soft tissue coverage is not adequate, flap coverage of the area of the first metacarpal and web space should be undertaken as an initial stage. Adequate length, mobility, stability, and sensation, as well as aesthetics, are the goals of functional thumb reconstruction.[83,84,153]

With thumb loss distal to the interphalangeal joint, function remains good. Frequently, simple deepening of the web space by "Z"-plasties yields sufficient additional length for the thumb. When the proximal phalanx becomes foreshortened, function progressively diminishes. In such deformities, pollicization or transfer of partial digits is very useful and should be considered when the thumb does not have sufficient length to oppose the remaining digits. Littler addressed the issue of thumb reconstruction in patients with multiple digital amputations by performing first-to-second metacarpal transfer via a vascularized osteocutaneous transfer.[84,159] In these patients, two functionless digits are combined to make a functional thumb. This procedure both lengthens the thumb and creates a newly developed first web space, which allows pinch.[84] Although Littler's patients

were not burn victims, other surgeons have applied this approach to thumb reconstruction in cases of burn injuries to the hand with digital amputations.[159]

Toe-to-thumb transfer is an alternative for thumb reconstruction,[53,58,153] especially in cases in which no digits are available for pollicization. In a severely burned patient with large total body area burns, most toes and fingers will be damaged, so pollicization may be a more viable solution.

In some cases, such as electrical injuries with complete loss of the thumb, toe-to-thumb transfer is a better choice. Frequently, soft tissue shortage is encountered, so procedures such as groin flaps or free tissue transfers are necessary as a first stage to provide a sufficient soft tissue envelope for the transplanted toe. Technical difficulties of toe transfer in burn patients are many and include dissection in heavily scarred tissue, shortage of large-caliber cutaneous veins, and tight surrounding tissues with a risk for compression of the vascular pedicle after toe transfer.

Modified toe transfers such as en bloc transfer of the second and third toes to facilitate a three-point grip or additional transfers to the fourth or fifth rays may be indicated in severe cases to provide grip in the dominant hand. Whenever possible, local finger transpositions or partial finger transpositions should be performed to use any available intrinsic "spare parts."

FIGURE 57.25 **A** and **B,** Elbow release.

Elbow Contractures

Elbow contractures are divided according to the structures involved into intraarticular and extraarticular types involving skin, musculotendinous units, and the joint capsule. Most contractures are extraarticular flexion contractures. Correction can usually be achieved with all of the measures described earlier (see Figure 57.16). Contraction bands can be released with any type of suitable "Z"-plasty. Thick split-thickness skin grafts can be used to resurface the volar aspect of the elbow if no vital structures are exposed. The combination of artificial dermis equivalents such as Integra, AlloDerm, or Dermacell with split-thickness skin grafts has also yielded favorable results.[21,28,29,51] With deeper defects after release, flap coverage may be indicated. The spectrum of flaps ranges from local and regional flaps to more sophisticated free flaps, depending on the availability of surrounding tissue. Most commonly used are[11,68,131]:

- Antegrade forearm flaps
- Posterior interosseous transposition flaps[3]
- Recurrent radial collateral artery flaps
- Inner upper arm fasciocutaneous flaps
- Scapular free flaps
- Parascapular free flaps
- Anterolateral thigh free flaps
- Fascial free flaps (temporoparietal, serratus)

Physical therapy is initiated as soon as graft take is guaranteed or secure healing of the flap is confirmed (Figure 57.25).

Heterotopic Ossification. In severely burned patients, the incidence of heterotopic bone formation is estimated to be 2%.[31] The incidence is higher with massive full-thickness burns and in elbows that have to be immobilized for a prolonged period. Radiographs are recommended before any contracture release of the elbow to rule out heterotopic ossification. Bone formation is usually found posteriorly and medially and occasionally leads to ulnar nerve entrapment. There are several reports about reduction of bone formation after hip surgery with the use of nonsteroidal antiinflammatory drugs; however, data are sparse in the burn literature, and prophylactic use of such drugs is not applicable. The same holds true for protocols using bisphosphonates.[34,124]

Early excision is indicated only when severe impairment of active motion is caused by the newly formed bone. Otherwise, it is recommended that one wait until the bone has matured, usually after 12 to 18 months. Maturity can be confirmed by serial x-rays. The surgical approach is through a posteromedial incision. Care has to be taken to not injure the ulnar nerve (which is generally released as part of the procedure) and to avoid resection of the stabilizing medial collateral ligament complex. An arthrotomy should be part of the procedure to release any intraarticular adhesions. Physical therapy is of utmost importance and should be initiated after 2 days if the wound is stable. Continuous passive motion in the postoperative period has proved to be useful in our practice in these cases.

Axillary Contractures

Axillary contractures are divided into three groups[73,147]:

- Type I patterns involve either the posterior (IA) or, in the majority of cases, the anterior axillary fold (IB).
- Type II contractures involve both axillary folds, with an island of intact skin in the axillary dome.
- Type III contractures involve all structures in the axilla, including the skin of the dome.

Contraction bands in both axillary folds are usually addressed by variations of the "Z"-plasty if sufficient local tissue is available. In type II patterns, sequential operations are recommended because vascularization of the flaps may be jeopardized by a bilateral approach. Release has to be performed to the underlying fascia of the latissimus or the pectoralis muscle to prevent early recurrence.

In type III patterns, skin grafting is correlated with an extremely high incidence of recurrence. In this frequently

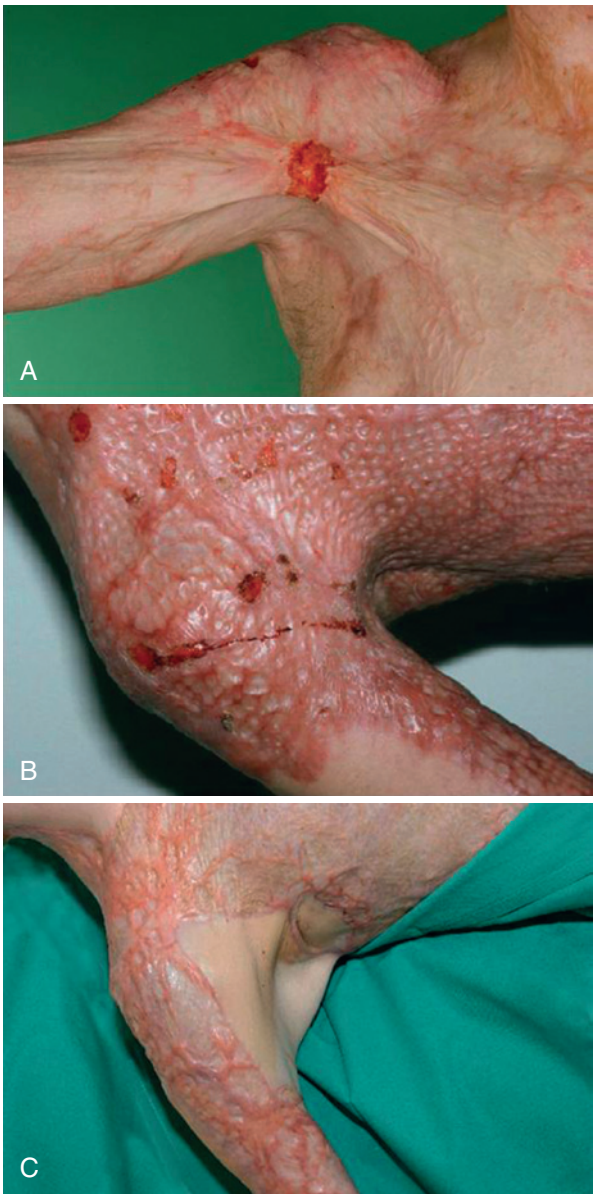

FIGURE 57.26 **A** and **B,** Type II axillary contracture, anteroposterior view. **C,** Contracture release with an anterolateral thigh free flap. A perfect contour with almost free range of motion was achieved.

uneven area, skin graft take can be poor, and secondary healing promotes further recontraction. The same holds true for transplantation of dermis equivalents. Flap reconstruction has proved to be very helpful in these cases. Regional flaps such as the pedicled scapular, parascapular, latissimus dorsi, or regional perforator flaps are preferred when available. In severe cases in which no regional options exist, one should not hesitate to choose the option of a microsurgical free flap. The spectrum of flaps is identical to those listed earlier for elbow release with the exception of fascial flaps, which require skin graft coverage and thus are not desirable in axillary release (Figure 57.26).

RECONSTRUCTIVE TOOLS

Most "Z"-plasties and their modifications, as well as most regional or microvascular flaps, are described elsewhere. However, some flaps have proved to be very useful and are discussed in this chapter.[95,156]

A number of distant pedicle flaps are available for hand coverage. The choice of flap depends on the type of soft tissue coverage required, as well as the experience of the surgeon involved. The entire armamentarium of flaps can be used in burn reconstruction. The spectrum ranges from simple distant flaps such as the random abdominal wall flap to regional pedicled flaps such as the groin flap or the tensor fasciae latae flap. The cross-arm flap has also been used for acute coverage of burned hands[13] but has generally been abandoned because of its unsightly donor site and the necessary immobilization of both extremities. Some of the more commonly used flaps are described in the following sections.

Random Abdominal Wall Flap

The random abdominal wall flap has the advantage of simplicity in that no knowledge of specific vascular anatomy is necessary to perform the procedure. The flap is suitable for coverage of the entire hand and fingers. A disadvantage is that the covered hand is inaccessible for inspection. In the event that the patient becomes febrile, operative exploration may be necessary to rule out infection. A second disadvantage is that the transplanted skin retains the fat cell characteristics of abdominal skin; an increase in body weight will result in thickening of the transposed abdominal skin, as well as increased abdominal girth. Finally, the immobility of the hand while in the abdominal tissue pocket results in joint stiffness at the hand, elbow, and shoulder, and the donor site is highly unaesthetic.[117]

Groin Flap

One of the most important distant flaps is the groin flap.[40,41] Since the pedicled groin flap was first described by McGregor and Jackson in 1972[96] and the free groin flap was first applied clinically by Daniel and Taylor in 1973,[26] the free groin flap has become a well-accepted and widely used method for the reconstruction of many types of defects.[22,24,80,96] The groin flap is a particularly useful flap in burn reconstruction because the groin is usually spared even in large body surface area burns. Use of the groin flap for acute coverage of burned hands has been described earlier in detail.[5,22,41,46,132,170]

The specific advantages of a free groin flap are as follows: large size of the flap, direct closure of the donor defect in most cases, scar situated in an area that is usually hidden, and reliability of the blood supply.[41] The blood supply to the flap consists of the superficial epigastric artery or the superficial circumflex iliac artery (or both) and their branches. These two arteries constitute a subcutaneous vascular network to give the flap adequate blood supply. This method, when compared with the pedicled groin flap, is more convenient for the patient, hospitalization time is shorter, and cost is lower. The free groin flap has been used less frequently as other donor sites have emerged because of problems with frequent anatomic variations in the pedicle, limited length and inconsistent caliber of the vascular pedicle, and excessive bulk in obese patients.[41,48,49,132,170]

Tensor Fasciae Latae Flap

The tensor fasciae latae flap is based on the tensor fasciae latae muscle and can be considered a second line of defense in reconstruction of a burned hand. A fasciocutaneous territory three

to four times larger than the muscle can reliably be elevated for a total flap size of up to 15 by 14 cm. The anterior aspect of the flap is defined as a line running from the anterior superior iliac spine to the lateral tibial condyle. The distal margin is a point approximately 8 cm superior to the knee. The posterior border runs along a line drawn from the greater trochanter to the head of the fibula.[92,138] The vascular pedicle, located 6 to 10 cm below the anterior superior iliac spine, is the axis of rotation and allows coverage of defects of the groin, sacrum, lower part of the abdomen, or hand.[66,92,94] Use of the tensor fasciae latae flap as a pedicled flap for hand coverage allows some shoulder and elbow motion before division of the pedicle. A disadvantage of this flap in burn patients is the need to place operative incisions on the lateral aspect of the thigh, normally a prime donor site for split-thickness autografts.

Forearm Flaps

Forearm flaps are distally based on either the ulnar or the radial artery or their perforating vessels; they provide thin, tailored flap coverage and allow the upper extremity to be appropriately elevated during the initial phase of healing. Forearm flaps may be raised either as a fascial flap alone on the ulnar or radial artery or as a fasciocutaneous flap.[44,119] The fascia alone provides a supple layer of subcutaneous tissue that is readily grafted with split skin. The forearm skin is relatively thin and provides acceptable coverage for the dorsum of the hand, although it leaves a more obvious donor defect. Nevertheless, with reversed-flow forearm flaps, the donor defects are placed proximally over muscle bellies rather than over tendons close to the wrist, and donor morbidity in general is low. Very large flaps can be raised if necessary. It is essential to ensure the presence and viability of the palmar arch before embarking on one of these flaps. Generally, the venae comitantes provide adequate venous drainage, and it has not been found necessary to anastomose additional superficial veins.[38,40,61]

Anterolateral Thigh Flaps

Anterolateral thigh fasciocutaneous flaps can be used for defects involving an extremely large skin territory on the dorsum of the hand when extensor tendons are exposed. The vascular supply is based on the lateral circumflex femoral artery. The donor site can be closed directly, with a low morbidity rate. Some patients suffer from temporary numbness at the donor site, but this generally disappears after 6 months. Satisfactory functional and cosmetic results are usually obtained at 1 year postoperatively. Free anterolateral thigh flaps can be thinned as necessary to achieve optimal contouring. In experienced hands, the mean operative time required for anterolateral thigh flap transfers is less than that required for other free flaps.[110]

Lateral Arm Flap

The lateral arm fasciocutaneous flap is raised on the lateral aspect of the upper part of the arm, just above the lateral epicondyle of the humerus, and its vascular basis is the posterior branch of the radial collateral artery and its venae comitantes. The advantage of this flap is that it provides a good tissue match and contour in the forearm and hand. Another advantage of this flap is that it can be taken from the injured arm in some cases via a single operative field. The donor site can generally be closed primarily. When placed on a flap surface, the flap may be bulky and secondary contouring by liposuction or excision may be necessary. Its short pedicle length may require an interposition vein graft for tension-free anastomosis.[110]

Free Serratus Fascial Flap

With this flap, coverage of exposed functional structures such as tendons, bones, vessels, or nerves at the dorsal and palmar sides of the hand can be achieved. This flap is thin and provides supple tissue to allow adequate range of motion and satisfying aesthetic results.[35,36,131]

ELECTRICAL INJURY

Epidemiologic Findings

Injuries caused by electric current are seen infrequently and account for less than 3% of all admissions to specialized burn units in industrialized countries. Two thirds of all injuries are low-voltage injuries. The victims of major electrical trauma are characteristically young, previously healthy men and adolescents. The upper extremity is involved in 75% to 88% of all electrical injuries.[14] Patient profiles reflect the risk for occupational exposure, with a third of all accidents occurring through contact with power lines and another third sustained in construction work.[62] Amputation rates range between 40% and 70%,[52] and the mortality rate ranges from 8% to 14%. The hospital stay is usually prolonged.[62] Five years after trauma, more than 50% of patients still suffer from neurologic problems. In cases of occupational accidents, permanent disability has been noted in 85% of all patients sustaining a high-voltage injury.[154]

Properties of Electricity and Pathophysiologic Conditions

The history of electrical injuries starts with the invention of the electric incandescent lamp by Thomas Alva Edison in 1879 and the death of a theater carpenter in Lyon, France, in the same year, who was killed by an alternating current of 250 V.[62] To understand the pattern of injuries it is helpful to consider the physical properties of electric current.

The quantity of charge in a wire is expressed in amperes (André M. Ampère, French physicist, 1775-1836); one unit is defined as a flow of 6.2×10^{18} electrons per second. The potential difference between two points in a conductor characterizes the electromotive force and is defined in volts (Alessandro Volta, Italian physicist, 1745-1827). Resistance describes the opposition to electron flow and is caused by collisions of current-carrying charged particles. Resistance is directly proportional to the length of the conductor and inversely proportional to its cross-sectional area and depends on the material of the conductor. Resistance is measured in ohms (Georg S. Ohm, German physicist, 1789-1854).

Today, distribution of electrical energy is mainly through alternating current. The motion of the electric charge is periodically reversed. The frequency of this change per cycle is defined as frequency in hertz (Heinrich Rudolph Hertz, German physicist, 1857-1894). The voltage used in households and most industrial fields ranges from 110 to 380 V, depending on the country. Cross-country power lines carry 38,000 V, and most train power lines carry 15,000 V with 16 Hz. Direct current is used only for specialized applications, such as subway train networks.

The three units of current are related by *Ohm's law*. It states that resistance equals the ratio of electromotive force and current in amperes:

$$R = \frac{V}{I}$$

Another important equation is *Joule's law*, which describes the heat production in an electric circuit. The heat in centigrade can be calculated as

$$H = 0.24\, I^2 \times R \times t \text{ (duration in seconds)}$$

The extent of tissue damage is determined by the current, voltage, duration of contact, tissue resistance, and pathway of flow through the body. Alternating current is more dangerous than direct current with respect to cardiac function. One milliampere to 2 mA causes a tingling sensation, and muscular contraction is seen at between 8 and 12 mA. A current of more than 20 mA may exceed the "let-go threshold" because of tetanic contractions caused by the alternating current, which can be strong enough to cause joint dislocations and even fractures. One hundred milliamperes can lead to ventricular fibrillation when flowing from the hand to the foot, with the same current passing through the brain, immediately rendering the victim unconscious.[150]

Tissue resistance is a decisive factor for the extent of damage. The skin demonstrates values between 5000 and 50,000 Ω/cm^2. The glabrous skin of the palm and feet may have a resistance of 2 million Ω, which can be reduced 1000-fold in the presence of moisture. When skin resistance is low, the direct cutaneous effect is also low, but a high-energy current flows through the deeper tissues. When skin resistance is high, low energy flows through deeper tissues, but the skin manifestation of the burn is significant. The amount of heat generated by the flow of the current is also proportional to the resistance of the tissue, which is also determined by the conducting properties and the cross-sectional area.

There are three current theories about the mechanism through which tissue damage is inflicted.

The first theory is that largest current densities (A/cm^2) are passed through nerves and arteries, followed by muscle, skin, and bone. Muscle with the largest cross-sectional area passes the largest portion, although the resistance is relatively low. Regions with a small cross-sectional area such as the elbow or wrist demonstrate high resistance, which leads, according to Joule's law, to extraproportional generation of heat. These areas are called "choke points."[144] This hypothesis is supported by experimental data from Hunt and colleagues, who showed in rats that the individual conducting properties of tissues are less significant than the resistance related to the cross-sectional area.[62,77]

The second theory is that current causes formation of pores or defects in the cell membrane that lead to severe cell damage and death (*electroporation*). Lee and Kolodney demonstrated that nonthermal electrical forces cause defects in the cell membrane, preferably in the largest cell populations such as neurons or myocytes.[77] The lesions can be found scattered throughout the muscle (*skipping lesions*). This would explain a portion of the myolysis and persistent neurologic deficits.[27,168,169]

The third theory is based on progressive constant release of arachidonic acid metabolites such as thromboxane from disrupted cells. Robson and associates postulated that this will disturb the balance in prostaglandin E_2 and $E_{2\alpha}$.[126]

An ongoing discussion circles around the question of whether there is progressive tissue damage or whether the extent of damage is determined primarily at the moment of trauma. Experimental data by Zelt and colleagues support the occurrence of a definitive extent of damage at the time of the injury,[169] thus suggesting that in the clinical situation the surgeon may be able to determine the true extent of the damage.

Many surgeons strongly oppose these data based on their clinical experience. They frequently encounter progressive damage (i.e., necrotic muscle in serial débridements) in places where healthy muscle has been seen 2 days before. Damage to the vascular intima and media may lead to delayed occlusion with progressive damage, a theory supported by local ischemia induced by the release of thromboxane metabolites.[126] The truth most likely lies somewhere in between, but burn surgeons agree that assessment of tissue damage after high-voltage injuries always poses a challenge, even for experienced surgeons.

Mechanism and Classification

Although as described earlier many factors determine the extent of tissue damage in electrical injuries, they have been divided for clinical purposes into low-voltage injuries (<1000 V) and high-voltage injuries (>1000 V).

- Low-voltage injuries
  - Flash burns
  - Direct contact burns
    - Cutaneous burns
    - Muscle contractures
    - Cardiac involvement
      - Arrhythmias, ventricular and atrial fibrillation
      - ST-T changes
- High-voltage injuries
  - Flash burns
  - Arcing burns
  - Direct contact burns
    - Cutaneous burns
    - Muscle contractures, fractures, dislocations
    - Tissue destruction
      - Muscle, nerve, vessel, bone, or tendon destruction
    - Cardiac involvement
      - Arrhythmias, ventricular and atrial fibrillation
      - Elevated isoenzymes
      - Electrocardiographic changes

Arcing occurs between objects of opposite charge and does not require direct contact. It is estimated that approximately 10,000 V can bridge a distance of 1 cm. Although voltage drops immediately after skin contact, temperatures from 3000°C to 5000°C develop for milliseconds, which is enough to inflict severe cutaneous destruction. Direct contact with high-tension lines frequently exceeds the "let-go" threshold, and the victim suffers continuous flow of current through the body. Flash burns are principally flame burns with ignition of the clothing and follow the same pathophysiologic principles as thermal burns.

Clinical Manifestations

High-voltage injuries are often life-threatening because of the combination of deep tissue destruction and large surface

cutaneous burns. The clinical manifestations are related to exposure to the current, the pathway through the body, and the patient's premorbid medical status. The majority of injuries involve the hands. Contact burns are localized, deep, depressed, sometimes blistered, and frequently charred, with surrounding redness and swelling.

Arcing occurs across flexor surfaces and typically involves the distal part of the forearm, the antecubital fossa, and the axilla.[14] High-tension injuries are devastating injuries that are usually associated with an entrance wound and one or more exit wounds at the points where the current enters and exits the body.[54,57] High-tension injuries have a high incidence of compartment syndrome. The main source of damage in tissues by the electric current is conversion of the electrical energy into heat.[37] The heat generated by the electrical injury causes coagulation necrosis of the tissues involved. As explained earlier, the muscles with the largest cross-sectional areas suffer the greatest energy load. The rich vascular network also conveys thermal energy. It is therefore assumed today that bony necrosis is not caused by the poor conducting properties of bone with high resistance but by the extremely heated muscle environment.[37] Similarly, intravascular thrombosis can be quite extensive[57,77] and lead to occlusion of major vessels. The extent of cutaneous damage is correlated with the resistance of the skin (see earlier). The upper extremity is frequently initially seen in a fixed flexion contracture position, indicative of severe muscle contraction and necrosis, and often with a compartment syndrome. The loss of intracellular proteins (such as myoglobin) into the circulation because of rhabdomyolysis is responsible for myoglobinuria, which may obstruct the renal collecting system and potentially lead to renal failure (Figure 57.27).

FIGURE 57.27 Clinical situation after a high-voltage injury with flow of current through the upper extremity.

Because peripheral nerves are very sensitive to electrical forces, even minor electrical trauma may cause temporary nerve dysfunction. Symptoms of anesthesia, paresthesia, or dysesthesia may occur.

Other clinically significant features of electrical injury include refractory cardiac arrhythmias, spinal fractures as a result of tetanic muscular contraction, other fractures and dislocations, derangements in serum electrolytes, and blast trauma.[57] Any coexisting injuries must be diagnosed, assessed, and managed.

Treatment

General Management

Patient evaluation and resuscitation should proceed simultaneously. Stabilization of vital signs is necessary, and monitoring should include a urinary catheter, central venous access, and invasive hemodynamic monitoring if indicated. Fluid requirements are significantly higher than with pure cutaneous burns, and care must be taken not to underestimate the amount of fluid necessary to maintain a urinary output that should be at least 2 mL/kg/hr. With severe muscle destruction, the clinical picture of a "crush syndrome" is seen. Our experience has shown that with high-voltage injuries, the amount of crystalloid required is 2.5 to 3 times more than that required with similar surface flame burns.[4,27] Some authors have recommended alkalinization of the urine to improve clearance of hemoglobin and myoglobin from the renal tubuli,[4,86] whereas others have used resuscitation with high-volume lactated Ringer solution alone.[86,87] Levels of creatine kinase are indicative of the extent of muscle destruction but are not clearly correlated. Low or normal levels, however, indicate only that there is little or no dead muscle tissue.

Once the patient is stabilized, a detailed history is essential, followed by a thorough physical examination for skeletal, neurologic, and intraabdominal injuries. If there is concern about cardiac injury as indicated by electrocardiographic abnormalities on admission, continuous cardiac monitoring, daily 12-lead electrocardiograms, and cardiac isoenzyme analyses are performed to assess direct myocardial damage. Tetanus prophylaxis and antibiotics protecting against clostridial infection should be given.

Surgical Management

Once the patient is stabilized, treatment is directed toward preservation of function, prevention of infection, débridement of clearly necrotic parts, and resurfacing of defects. Wounds over vital structures such as arteries, nerves, tendons, and bone take first priority.[14,22]

Tissue decompression techniques are central to the successful initial treatment of electrical injuries to the upper extremity.[27] Standard escharotomies as described earlier should be combined with fasciotomies. Both escharotomies and fasciotomies should decompress the digits, carpal tunnel, and Guyon canal.[116] All compartments should be addressed both dorsally and palmarly, and the muscle compartments in the hand should be adequately decompressed within 6 to 8 hours of injury.[27] It has to be emphasized that division of the epimysium is also sometimes necessary. The need for this is based on clinical assessment. Measurements of intracompartmental pressure may be a useful adjunct, but symptoms such as swelling, pain

on passive motion, and firmness are usually sufficient for diagnosis. Skin burns should be incorporated into incision lines. Although escharotomies can be performed at the bedside, fasciotomies should be performed in the operating room and have to be considered emergency measures that can make the difference between amputation or limb salvage. Temporary coverage is recommended until conditions for definitive coverage are reached.

Radical débridement of nonviable tissue should be performed as soon as the patient is stabilized. Regardless of the initial technique, a second-look operation to reinspect tissues and to débride additional necrotic tissue should be undertaken every 48 hours until only viable tissue remains.[27] After each débridement, allografts or topical antimicrobial agents are applied to the wounds. Splints are essential between surgeries to reduce pain, maintain the position of function, prevent tendon rupture, and protect vascular perfusion.

Assessment of tissue viability can be performed by

- Clinical evaluation (muscle color, contractile response)
- Scintigraphy with technetium 99m pyrophosphate
- Magnetic resonance imaging (MRI) with contrast enhancement
- Sequential histologic sections
- Perfusion with nitroblue tetrazolium

Most surgeons rely on their clinical experience, which can be misleading. To date, however, good clinical judgment of tissue viability has not been surpassed by imaging techniques, of which scintigraphy is probably the most useful. Although muscle is generously débrided, tendons and nerves are resected only if they are clearly necrotic. If viability is questionable, early flap coverage may salvage the structures. If essential vessels are occluded, vein graft reconstruction can be performed if placed under well-vascularized tissue coverage.[167] Excision plus grafting of damaged arteries, especially at the wrist level, has been described for the salvage of extremities.[167] Whether more aggressive surgical reconstruction may prove to be beneficial in long-term patient outcomes remains controversial.[27]

Once viability of the remaining tissue is established, skin grafts, local skin or fasciocutaneous flaps, or microvascular free flaps may be used to close the wound and salvage the injured extremity. The method of resurfacing is dependent on the tissue exposed, with split-skin grafts suitable for muscle and local, pedicled, and free flaps suitable for the coverage of nerves, patent arteries, tendons, and bone. Chick and coauthors reported promising results with radical débridement and free flap coverage within 3 days based on their experience with other extremity trauma.[22] Many authors have also applied microvascular techniques to the salvage of limb and function in severe electrical injuries (Figure 57.28).[38,61,131,134]

On occasion, the tissue destruction in a limb is so extensive that limb salvage would jeopardize the patient's life. In these cases, patient survival and functional outcome are best optimized by proximal limb amputation early in the course of treatment (life over limb). The threshold for this decision has moved more toward amputation in recent years. Today, use of microvascular free tissue transfer techniques has added much to limb salvage,[38,131,164] although somewhat higher complication rates have been reported in this group of patients.[11,165] All reconstructive techniques described earlier and in other sections of this volume can be applied to patients with electrical burns. Selection of the technique depends on the size of the defect, the availability of flaps, and the condition of the patient.

Complications

Early complications include vascular occlusion, wound infection caused by residual nonvital tissue, systemic sepsis, multiorgan failure, and failure of reconstructive procedures with subsequent limb amputation.

Late sequelae include cataract formation, peripheral neuropathies, pulmonary dysfunction, cerebral hemorrhage, and muscle fibrosis.[27]

Rehabilitation

In view of the devastating nature of these injuries, rehabilitation is an essential part of the treatment regimen. Despite all efforts, many patients are left with permanent disabilities and are not able to return to their original occupations. Besides all conservative measures such as splinting, continuous passive motion, lymph drainage, compression therapy, prosthetic fitting, and intensive physical therapy, operative procedures such as tendon transfers to restore muscle function, transfer of innervated muscles, and toe transfer for missing thumbs are also an integral part of the rehabilitation program.

CHEMICAL BURNS

Chemical burns are unique injuries that need specialized knowledge and management principles to obtain a satisfactory outcome. The literature about therapy for chemical burns is relatively sparse; however, chemical burns are common problems, especially for hand surgeons. Many chemicals are widespread in common household and industrial use. Products containing chemicals capable of causing a cutaneous injury number more than 25,000.[25] More than 60% of admissions to the hospital because of chemical injury are due to work-related injuries.[102,123] The upper extremity is one of the most commonly injured parts of the body, specifically the digits. Chemical burns involve an average total body surface area of 19.5%. Prolonged hospitalization with poor wound healing is the rule.[15]

As with thermal burns, the damage caused by chemical burns of the hand is usually limited to the skin. The major difference, however, is that some chemical agents may continue to be active at the site and continue to destroy tissues.[30] Ongoing tissue destruction will occur for as long as the chemical remains active and in contact with the skin. The level of injury depends on the area exposed to the chemicals, the nature and concentration of the noxious agent, the volume of substance contacting the skin, the local characteristics of the skin, and the duration of contact with the chemical.[15,123] The duration of contact of the noxious agent with the skin is the major determinant of the severity of chemical injury.[117] Most chemical injuries are the result of contact of the individual with either acidic or alkaline agents.[15,72]

Acid burns are classically described as hydroscopic in nature and gain access through the protective stratum corneum. Cellular dehydration occurs, as well as destruction of cell membranes and liquefaction necrosis. The reactions are progressive unless lavage or neutralization therapy is used to chemically bind, inactivate, or remove the offending agent. The depth of tissue damage is limited by the buffering capacity for acids

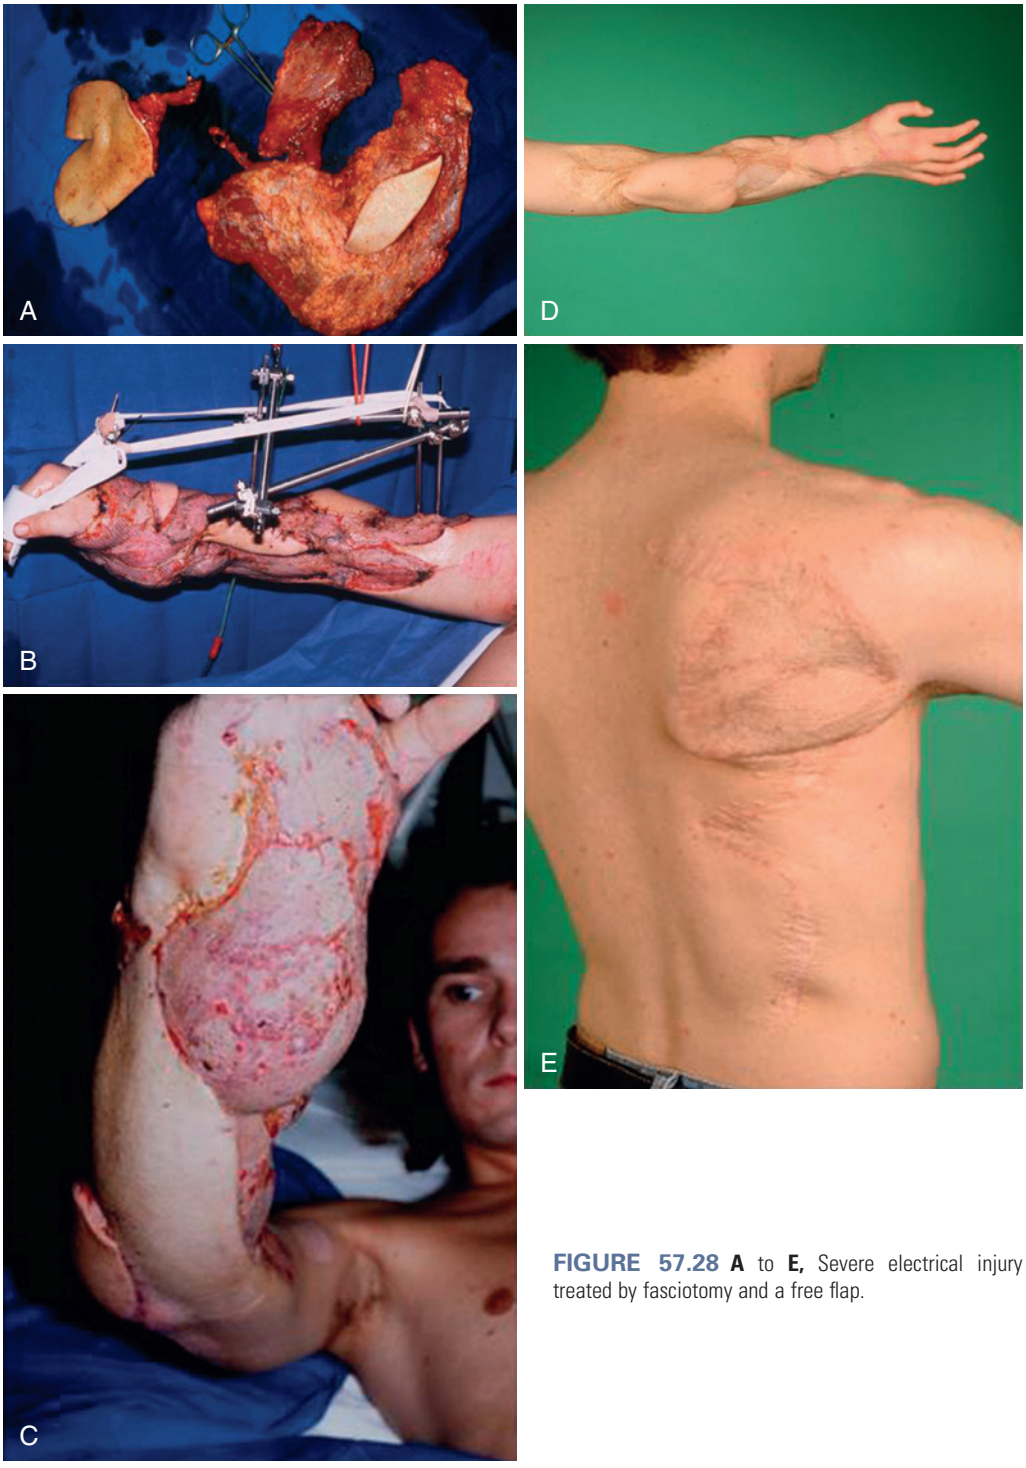

FIGURE 57.28 A to **E,** Severe electrical injury treated by fasciotomy and a free flap.

contained in the injured tissue. Alkali burns are clinically more latent than acid burns. Alkaline albuminates combine with tissue elements to form fatty soaps. These hydroscopic reactions may continue for days with extensive destruction of tissue.[15] This tissue injury is commonly known as *liquefaction necrosis*. It allows a deeper injury than occurs with acid burns as a result of a continued basic wound milieu produced by the alkaline injury. Because damaged tissue has a limited capacity to buffer alkalis, there is further penetration of the lipophilic alkali, which results in deeper injury.

Management

Chemical burns of the upper extremity do not present any special management problems that have not already been discussed under thermal or electrical injuries. The same careful attention must be given to elevation, immobilization, tetanus immunization, and monitoring of pulses (Figure 57.29).

There is no question about the first step of treatment. The essential activity in the initial care is to stop the burning process. Immediately after contact with either acid or alkali, removal of the patient from the offending chemical agent should be

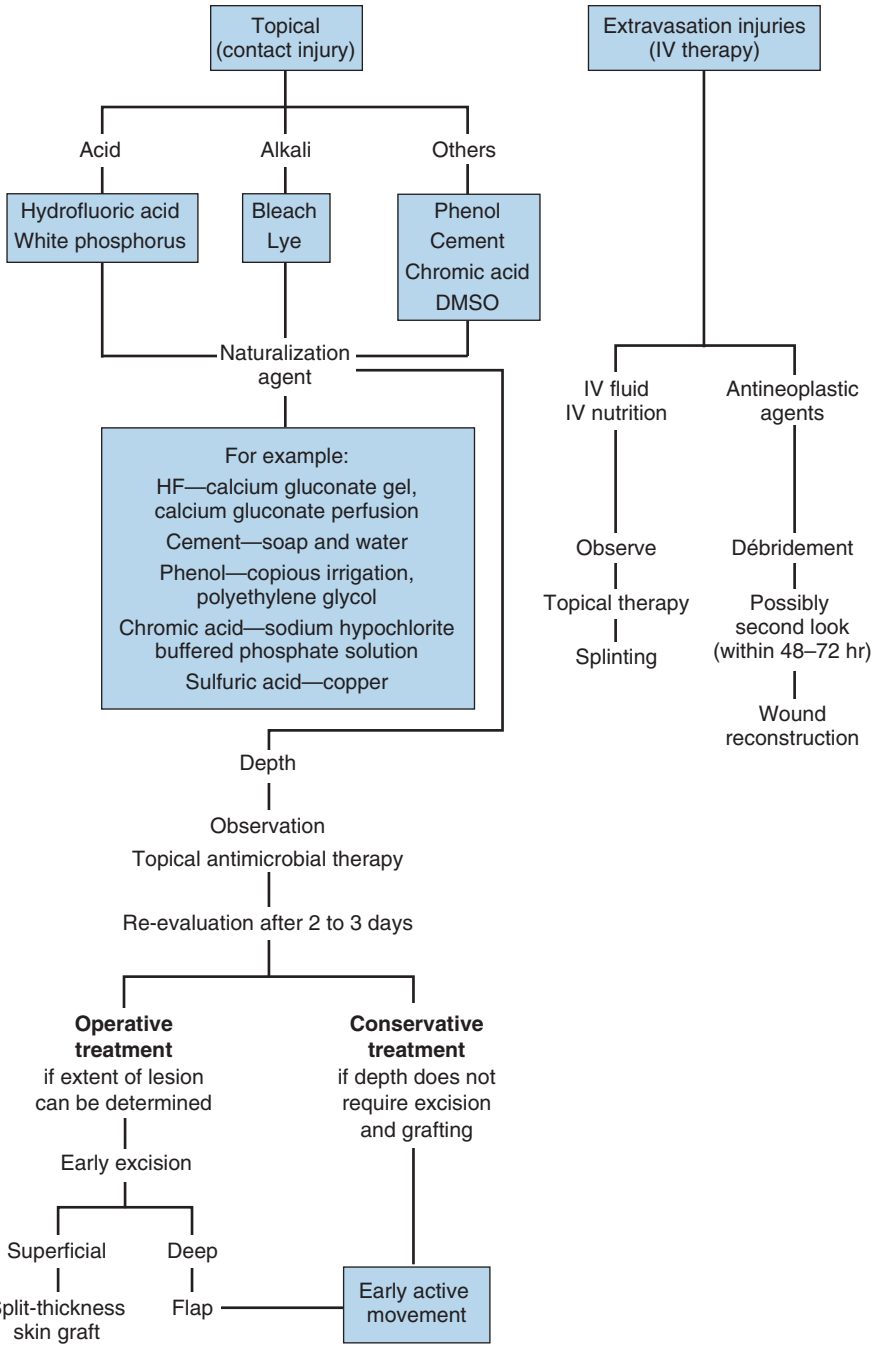

FIGURE 57.29 Decision-making algorithm for chemical burns. *DMSO*, Dimethyl sulfoxide; *HF*, hydrofluoric acid; *IV*, intravenous.

performed and all affected clothing should be removed. The initial goal in the treatment of chemical injuries is immediate dilution or, better, neutralization of the chemical agent. Lavage that is not thorough enough enhances absorption of the agent. Water is the appropriate emergency treatment of most chemical contact spills. Water lavage lasting 1 to 2 hours is recommended for acid burns and longer for alkali burns.[27] Water lavage facilitates dilution of the chemical agent away from the victim, thereby decreasing the chemical load to the skin. In addition, water lavage decreases the rate of the chemical reaction and tissue metabolism and contributes to restoration of normal skin pH.[123] Both animal studies and human experience confirm the essential fact that copious and continuous water irrigation immediately after chemical exposure is critical to limiting the injury process.[117] A delay of just 15 minutes after contact with a chemical agent may allow the epidermis to be destroyed.

Once the agent has been clearly established, neutralizing substances can be added.[54] Skin pH measurements with litmus paper give a rough guide to neutralization of the surface skin but do not provide an accurate estimate of the pH of deeper tissues, where the damage may be ongoing. Pain may also be a useful guide but is not completely reliable because some chemicals, such as phenols, demyelinate nerves and make the wound anesthetic.[123]

After adequate removal of the chemical from the injured part, the damaged skin must be protected from infection. Nonviable tissue, blisters, and bullae should be débrided because they may contain residual concentrations of the chemical agent. Topical antibacterial agents should be applied. Partial-thickness chemical burns are generally managed conservatively with dressing changes. Patients with deep partial-thickness burns of the hands should be hospitalized and the injured skin excised and grafted early in a fashion similar to that outlined for thermal injuries.[15] Deeper injuries may require local or even microvascular flap coverage (Figure 57.30).

Persistent chemical contact beneath the nail bed can be difficult to treat as a result of the lack of access to water because of the overlying nail. Partial or even complete removal of the nail may be necessary for adequate water irrigation.

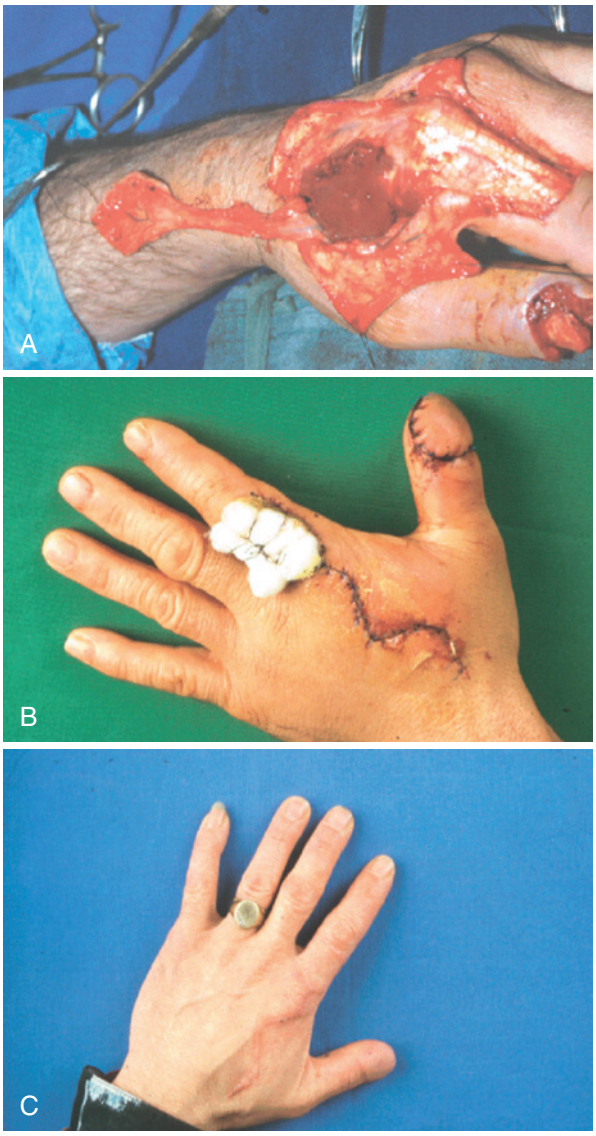

FIGURE 57.30 **A,** Hydrofluoric acid burn of the tip of the thumb with loss of the nail. The area is débrided, and a "kite flap" (first dorsal metacarpal artery flap) has been raised. The artery is clearly visible in the pedicle, which includes the fascia of the interosseous muscle. **B,** The flap has securely healed in place. A full-thickness skin graft was applied to the donor site. **C,** Very appealing aesthetic result.

As in thermal injuries, the fascial compartments of the upper extremity are at risk for the development of edema. Because the magnitude of a chemical injury can often be underdiagnosed in the early hours, compartment syndromes may be missed in their initial stages unless careful surveillance of the patient's neurovascular status is carried out. Consequently, surgical release of the fascial compartments is performed in standard fashion and treated as for open burn areas.[123]

There are several specific exceptions, however, to the rule of copious water dilution for chemical injuries that deserve mention.

Phenol

Phenol was historically used as an antiseptic. Its use was limited by the occurrence of cutaneous irritation and systemic symptoms (phenol marasmus). Today, phenol has wide application in industrial substances, such as cleaning agents, cosmetics, plastics, and explosives.

Phenol is not water soluble, and specific therapy is required. Phenol should be removed from the skin with glycerol or polyethylene glycol.

Hydrofluoric Acid

Hydrofluoric acid is a common industrial chemical. It penetrates the skin, especially areas not protected by the stratum corneum such as the nail bed, and causes severe pain. Treatment consists of immediate water lavage followed by specific fluoride-binding therapies. Traditionally, magnesium sulfate solutions have been used with limited success. More recent therapies include subdermal injections around the lesions of 10% calcium gluconate.

Cement Burns

Cement burns are traditionally considered alkali burns because the lime (calcium oxide) component of cement has a pH as high as 12.9. There is usually no initial pain, so the injury remains unrecognized and untreated for hours. The final result is generally manifested as a full-thickness injury that is very slow to heal.

White Phosphorus

Phosphorus is highly fat soluble. Absorption of this chemical is enhanced by oils used topically and should be avoided. Therapy consists of water lavage followed by identification and excision of any remaining particles. A dilute solution of copper sulfate (0.05% to 1%) is helpful in identifying phosphorus particles (Table 57.1).

FROSTBITE INJURIES

Frostbite is an injury that results from exposure to temperatures that are low enough to cause crystal formation in the exposed tissue. There is risk for tissue exposed to temperatures below 2° C.[17,127] Frostbite can develop after exposure to these low temperatures for more than 1 hour.[64] This usually happens when protection from the environment is insufficient.[155] The severity of a frostbite depends on numerous factors besides the ambient temperature, such as wind velocity (wind chill factor), altitude, duration of exposure, wetness of the tissue, the patient's vascular status, and previous exposure to cold injury.[17]

TABLE 57.1 Common Chemical Agents and Their Characteristics in Causing Tissue Damage

Agent	Commercial Use	Characteristics of Damage	Treatment
Phenol	Cleaning agents, cosmetics, plastics	Protein denaturation, rapid absorption	Water irrigation, cover with oil, no alcohol
Phosphorus (white)	—	Highly fat soluble	Water irrigation, excision
Lyes	Cement, oven cleaners	Liquefaction necrosis, fulminant initial response, saponification of fats, dehydration of other cells	Water irrigation
Hydrofluoric acid	Rust removers	Painful, deep ulcerations below a tough coagulum	Local infiltration of calcium gluconates
Hydrochloric acid	Pool cleaners	Shallow ulcers form with a coagulated eschar and base	Water irrigation, magnesium oxide, soaps
Muriatic acid	Toilet bowl cleaners	Hard eschar with an indolent ulcer	Water irrigation
Sodium hypochloride	Bleach	Coagulation of proteins	Water irrigation

Adapted from Bentivegna PE, Deane LM: Chemical burns of the upper extremity. *Hand Clin* 6:253–259, 1990; and Reilly DA, Garner WL: Management of chemical injuries to the upper extremity. *Hand Clin* 16:215–224, 2000.

A variety of classification systems have been developed to describe frostbite injuries. Traditionally, cold injuries have been classified into four degrees[17,67,69,133]:

First degree (superficial skin): Erythema, edema, and hyperemia develop in the injured areas; blisters and tissue loss do not occur.

Second degree (full-thickness skin): Erythema, vesicle formation, and superficial skin sloughing occur; no deeper necrosis develops.

Third degree (full-thickness and subcutaneous tissue): Local edema and grayish blue discoloration occur and are followed by skin loss down to the subcutaneous level.

Fourth degree: Deep cyanosis without the development of vesiculation or local edema is observed. There is necrosis of the subcutis or deeper tissues down to muscle, tendon, and bone.

Currently, a more clinically useful classification system considers frostbite injuries as superficial or deep.[155] This classification system is useful because it has prognostic implications and defines frostbite through its fluctuating clinical course. Superficial frostbite results in minimal, if any, tissue loss. In contrast, deep frostbite injuries result in significant tissue loss.[133]

Outdoor winter activities such as downhill skiing, cross-country skiing, or other sporting activities[98] and mountaineering make cold injury a common clinical problem. Inadequate clothing or prolonged exposure because of alcohol abuse,[17] psychiatric disorders, or accidents[67] might lead to these injuries. The fingers, toes, nose, and ears are most commonly involved.

Pathophysiologic Findings

In cold-exposed areas, the blood becomes viscous and the circulation in the capillaries slows. Vessel damage leads to fluid extravasation and blistering. Thrombosis may occur in the terminal arterioles. Although cellular dehydration and enzymatic damage undoubtedly contribute to the necrosis of frozen tissue, peripheral circulatory failure may play the major role in determining the extent of the eventual tissue loss.[139,140] Venules clot with thrombi within the first 10 minutes after warming. Within 1 hour, most of the capillaries are thrombosed and blood flow is short-circuited from the arterial to the venous circulation via arteriovenous communications. Thus, while blood may continue to flow through the larger arterioles and venules, the tissues are not nourished.[139] Two different theories on the pathogenesis of frostbite are discussed:

1. Cold injury directly damages the tissue cells.[99]
2. Cold produces injury to the endothelial lining of small blood vessels with a consequent increase in capillary permeability, loss of fluid from the circulation, and intravascular cellular aggregation in the injured area. The clumping of red blood cells causes occlusion of small blood vessels with resulting tissue ischemia and necrosis.[163]

Diagnosis

Both the history and physical examination are important in assessing the depth and degree of frostbite injury. The severity is proportional to both the temperature and the duration of exposure and depends on the amount of heat lost from tissues.[133]

Various imaging techniques have been used in an attempt to more accurately predict the extent and severity of frostbite injury. Plain radiographs are of no value in determining the ultimate level of demarcation.[133] Technetium 99m bone scanning has become the standard imaging study used within the first several days to assess tissue perfusion and viability.[42] Such scans allow evaluation of the microcirculation of both soft tissue and bone.[133] Cauchy and colleagues found a strong correlation between positive uptake and eventual healing. They showed that technetium 99m bone scanning in the first few days after frostbite injury indicates the level of amputation in severe frostbite in more than 84% of cases.[20]

Barker and coworkers compared MRI and magnetic resonance angiography (MRA) with bone scanning for the evaluation of frostbite injuries.[6] MRI and MRA directly image occluded vessels and surrounding tissues. Both define the extent of tissue ischemia well before clinical signs of necrosis. T2-weighted images show increased signal intensity in muscles after the disruption of cell membranes, as well as an increased content of extracellular water, an indicator of cell death. The major disadvantage of MRI and MRA is their high cost in comparison with bone scans.[6]

Treatment

Management of acute frostbite is carried out in accordance with the guidelines popularized by Mills (Box 57.2).[99]

Early treatment includes a thorough assessment of the patient's general condition and stabilization of other disorders in a routine system of priorities. Normal body temperature is restored by provision of a warm environment and oral or intravenous administration of warm liquids.

Immediate local treatment consists of rewarming the frozen extremity in warm water (40°C to 44°C).[53,99] This emergency treatment is widely accepted as the single most important step in the salvage of tissue and limb function, followed by elevation and splinting of the extremity.[121] Tetanus prophylaxis and appropriate analgesia are given, and some consider antibiotic prophylaxis for the first several days.[17,133] Local treatment concepts of the affected areas vary. Some reports consider early débridement of all blisters to be adequate,[17] whereas other authors favor débridement of only ruptured blisters.[97]

No adjuvant intervention but hydrotherapy (daily for 30 to 45 minutes at 40°C) reliably improves revascularization of the affected tissues after cold injury.[53] Heparinization has been used to prevent intravascular thrombosis, but the results have been inconclusive.[97] Hyperbaric oxygen was successfully used in exemplary cases.[76,160] Pentoxifylline shows some beneficial effects in animal models[121] but has not become a generally accepted therapeutic agent. Inhibitors of prostaglandin synthesis and inhibitors of free radicals such as superoxide dismutase may be promising agents in the future.[17,67]

Surgical management leans toward the conservative. The principle of early excision and grafting is not applied to frostbite injuries because determination of tissue damage is extremely difficult and a high capacity for spontaneous healing under the eschar is frequently observed. During the first 9 to 15 days, seriously frostbitten skin forms a black, hard, leathery eschar.[133] Over time the eschar separates, with relatively healthy underlying skin frequently being revealed. Some patients will not heal and instead proceed to complete mummification within 3 to 6 weeks.[104,108] Once mummification of the involved extremity has taken place, reconstructive or ablative options are to be considered. Primary amputation of an affected digital part is often the most expeditious and least morbid method of restoring function to the remaining digit or hand.[155]

When more extensive upper extremity frostbite injuries are encountered, skin grafts, local rotation flaps, and staged pedicled grafts have been the mainstay of reconstructive techniques. With the advent of microsurgical tissue transfer, surgical options for reconstruction of the extremity, including restoration of grip function, have been significantly broadened. Although the functional results have improved by virtue of thin tissue transfer, aesthetic restoration still remains a challenge.[155]

BOX 57.2 Management of Acute Frostbite

- Restoration of core body heat
- Rapid rewarming of the frozen extremity in a water bath at 40°C to 44°C
- Sedation or analgesia, or both
- Triple-phase technetium 99m bone scan
- Tetanus prophylaxis
- Open dressing
- Oral ibuprofen
- Antibiotics for confirmed infections
- Physical therapy
- Amputation or surgical débridement only after clear demarcation

REHABILITATION

As in all hand surgery cases, planned rehabilitation with intensive physical and occupational therapy is an essential prerequisite for the best possible results. In general terms, active movement is encouraged from the earliest time after thermal injury. Immediately after contracture release, splinting is of the utmost importance. The joints can be immobilized in ideal positions (Figure 57.31), or a dynamic splint can be applied to encourage active motion after surgical corrections[78] (Figure 57.32). Psychological support is mandatory.[157]

The first few months after a burn are characterized by a period of scar hypertrophy.[111] Scars become thick, red, and tight, and they limit range of motion. The patient needs to overcome this tightness with active range-of-motion exercises of all joints every day. An important adjunct to scar management is custom-fitted elastic pressure garments. Linares and coworkers provided interesting details about the history of pressure treatment.[81,162] The first reference was written by Johnson in 1678, who himself referred to the work of Ambroise Paré from the 16th century. The first full description dates back to Petz in 1790. Nason observed in 1942 that the ischemia produced by pressure stops the formation of hypertrophic scarring. The ideal pressure for these garments ranges from 15 to 40 mm Hg.

Pressure therapy should be initiated as early as 2 weeks after grafting. The pressure garments should be worn 23 hours a day for the initial period of approximately 6 months for burns with a prolonged healing time or burns that have required skin grafting.[133,135] Subsequent pressure garment use is individualized depending on scar quality and response. The exact mechanism by which pressure garments alter scar formation is not yet clear[106,161]; however, they improve the quality of scars in terms of both texture and color in the long term (Figure 57.33). Special spacers may be placed in the web spaces to minimize the problem of compromised web spaces by burn scar contractures.[1]

FIGURE 57.31 Adjustable splint after release of an axillary contracture.

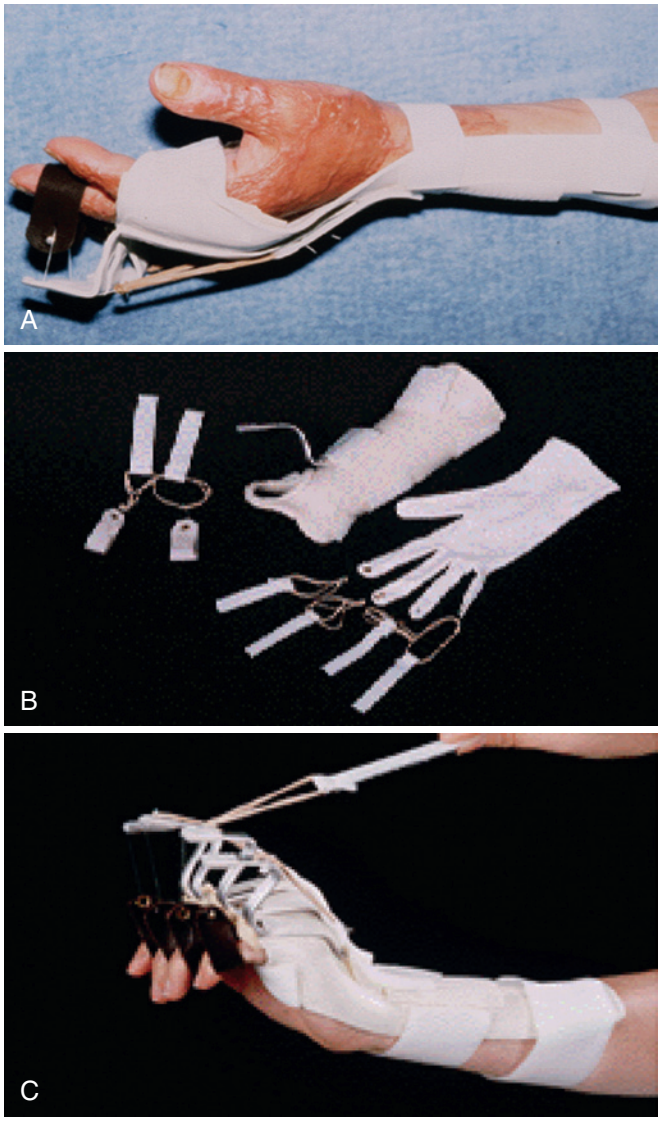

FIGURE 57.32 **A** to **C,** Active dynamic extension splint after release of the extensor tendons.

FIGURE 57.33 Custom-fitted pressure gloves after a skin graft.

Silicone sheets have proved to be useful on the dorsum of fingers and web spaces if placed under the pressure garment gloves. Coban wrapping is useful in controlling edema.[154] Hand therapy continues until function returns to normal or treatment is no longer demonstrating improvement. A maintenance hand therapy program should then be continued.[133,135]

CRITICAL POINTS *Hand Burns*

Management of Hand Burns
- Avoid any additional injury or an increase in the depth of burn (do no harm)
- Achieve early wound closure
- Maintain active and passive range of motion
- Prevent infection or loss of soft tissue coverage
- Start early functional rehabilitation

Basic Treatment Principles of Hand Burns
- Evaluation of size and depth
- Escharotomy if indicated
- Application of proper wound care and dressings
- Decision about operative or conservative treatment
- Initiation of early hand therapy, including splinting

Surgical Management
- Removal of eschar
- Meticulous hemostasis
- Transplantation of skin grafts
- Sheet grafts preferable
- Flap coverage if necessary
- Early postoperative physical therapy
- Functional rehabilitation

Causes of Skin Graft Loss
- Insufficient débridement with remaining nonviable layers of burned tissue
- Hematoma formation under the graft
- Imperfectly fitting tie-over dressing
- Secondary infection of the burn wound

Commonly Used Flaps
- Random abdominal wall flap
- Groin flap
- Anterior lateral thigh flap
- Free fascia flaps (serratus, temporoparietal fascia)
- Lateral arm flap
- Scapula flap

Expected Functional Outcome
- Satisfying aesthetic result
- Function that allows return to work or activities of daily living
- Stable coverage of joint surfaces
- Minimal development of residual contractures
- Low incidence of secondary corrections

Skin Tumors of the Hand and Upper Extremity

David T. Netscher

ANATOMY AND CLINICAL EXAMINATION

Skin is made up of the epidermis, dermis, and subcutaneous layers (Figure 58.1). The epidermis possesses the following appendages:[7,8]

- Eccrine glands
- Apocrine glands
- Sebaceous glands
- Hair follicles
- Nails***

Glands and hair follicles arise as "down growths" from the epidermis and project into the dermis. The two types of sweat glands are the eccrine and apocrine. Eccrine glands exist all over the skin. They start as a coil in the dermis and open onto the skin's surface and secrete clear, watery fluid. The apocrine glands are large sweat glands that open into hair follicles, to which they are attached, but rarely directly, to the skin's surface. They are also coiled tubular glands found mainly in the axilla that do not develop fully until puberty. Secretion is evoked in response to stress, pain, and fright. Sebaceous glands are found all over the body, except the palms and soles of the feet. They have no lumen, are multilobulated, appearing as a pouch hanging on the side of the hair follicle, and secrete a fatty sebum.

The dermis is divided into two parts: (1) papillary and (2) reticular. The papillary dermis lies up against the epidermis, and papillae project up into it so that the alternating areas of epidermis, which drop down into it, are called "rete pegs." It is these pegs that help resist shear disruption between the dermal and epidermal layers. The reticular dermis is deeper, made of coarser bundles of connective tissue fibers, and extends to the subcutaneous layer; it contains:

- Connective tissue fibers—collagen, elastin, and reticulin
- Cellular elements—migratory cells (leukocytes, histiocytes) and fixed cells (fibroblasts, mast)
- Blood vessels
- Nerves and specialized nerve endings
- Smooth muscle
- Lymphatics
- Ground substance

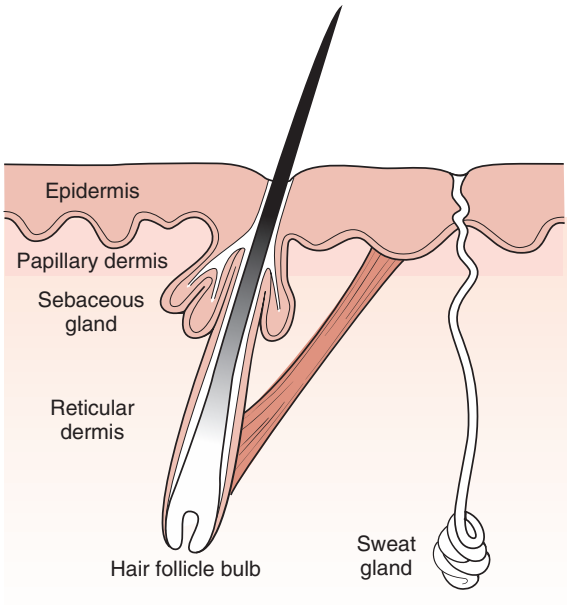
The epidermis is superficial to the basal lamina and is comprised histologically of four cell layers (five layers in the palm) (Figure 58.2), as follows:

1. The basal layer (stratum basale) consists of a single layer of columnar cells that stain deeply basophilic. At haphazard intervals between these basal cells are melanocytes—clear cells with small nuclei. Melanin is produced through the conversion of tyrosine to dopa, facilitated by the enzyme tyrosinase. Melanocytes can multiply and form nests in the deep epidermis and even spread into the subadjacent dermis, where they lose the ability to synthesize melanin but retain the melanin-storing property and remain pigmented. These intradermal clusters are called "nevus cells" and give the appearance of nevi. Melanocytes are actually dendritic cells that connect to each other over distances. They are derived from the neural crest. Merkel cells, like melanocytes, are nonkeratinocyte intraepidermal cells. They also occur in the basal cell layer and are associated with sensory axons for slow-adapting mechanoreceptors and pressure sensors. They are found in hair follicles as well.
2. The malpighian (or prickle cell) layer (i.e., stratum spinosum) is made up of cells connected to each other by intracellular bridges, so artifactually (during tissue processing) give the spiny, or prickle, appearance of this layer.
3. The granular layer (stratum granulosum) is made up of a few layers of diamond-shaped cells filled with basophilic granules (keratohyalin).
4. The horny layer (stratum corneum) has cells with no nuclei, and they are continuously shed from the surface.
5. In the palm only, the clear layer (stratum lucidum) gives a translucent appearance to the skin. It is composed of up to five layers of "dead" keratinocytes; this layer is situated between the stratum granulosum and the stratum corneum. Cells are filled with eleidin, an intermediate form of keratin.

There is a normal progression of maturation from deep to superficial layers of the epidermis.

In epidermal cancers, this natural progressive maturation is lost and becomes disorderly and finally totally anaplastic.[27,54] The relative invasiveness of such cancers is also seen first by invasion deep into the basement membrane, then by depth of invasion, next entering the papillary dermis, and on into the deeper reticular dermis. Thus, carcinoma in situ is a true cancer that is disorganized in its progressive epidermal cell maturation but nonetheless has not invaded through the basement membrane of the dermis.

Originally, Clark's levels were applied descriptively to the depth of melanoma invasion into the papillary dermis, reticular dermis, and on into subcutaneous sites. However, Breslow's levels of actual millimeter thickness of invasion have been found to be more accurate prognostically.[54] In the subungual regions, rete pegs and papillary dermis are less well defined, and



BENIGN	MALIGNANT	
Verrucae	Bowen squamous cell carcinoma	Epidermal
Seborrheic keratosis	Basal cell carcinoma Merkel	Epidermal
Actinic keratosis		Epidermal
Lentigines	Melanoma	Epidermal
Nevus		Epidermal
Inclusion and keratinous cysts		Dermal
Dermatofibroma		Dermal
Eccrine poroma	Sweat gland cancers	Dermal
	Sarcoma	Dermal

FIGURE 58.1 Layers of skin that include adnexal structures and the origin of benign and malignant tumors.

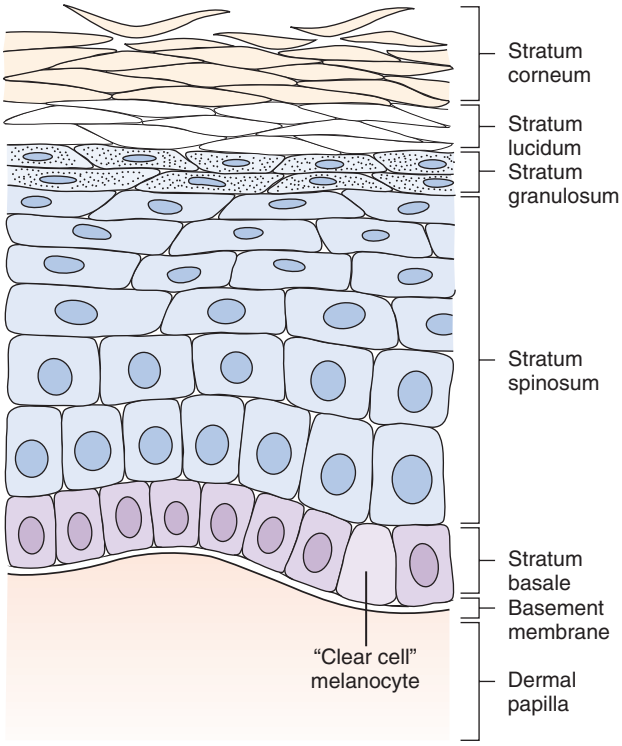


FIGURE 58.2 Cellular layers of the epidermis.

there is also no subcutaneous fat, which means that the distance of tumor penetration between epidermis and periosteum is very small. In this region especially, the Clark and Breslow measurements cannot be used as an effective treatment guide.[54]

Benign and malignant skin tumors thus may arise from epithelial elements (in which case malignancies are termed *carcinoma*) of the epidermis, as well as from the adnexae in the dermis (i.e., hair follicles and sweat glands) (see Figure 58.1). Basal cell carcinoma (BCC) is derived from the basal cell layer of the epidermis and squamous cell carcinoma (SCC) comes from the more superficial keratinocytes.

Epithelial cysts within the dermis may be a result of implantation into the dermis (epidermal inclusion cyst), from blocked gland ducts (pilosebaceous cysts), and/or from hair follicles (trichilemmal cysts). Connective tissue tumors (malignant forms are termed *sarcomas*) may arise from the fibrous tissue of the dermis, such as dermatofibromas and the rarer dermatofibrosarcoma protuberans. Nerve-ending tumors and those relative to blood vessels also occur in the dermis (e.g., neurofibroma, glomus, Merkel cell). Hemangiomas and capillary stains and vascular malformations are discussed elsewhere in this book.

Having an understanding of skin anatomy and tumor location is helpful in arriving at a clinical diagnosis.[46] Intraepidermal lesions may be plaquelike but are not elevated into papules or nodules (the hallmark of intradermal lesions). Junctional (between dermis and epidermis) lesions are also not elevated, as is the case with a junctional nevus—a flat pigmented lesion. Dermatofibromas and the more vertically invasive nodular melanomas, in contrast, are elevated into a nodule. Melanomas are pigmented (though not always) because their cell of origin is the melanocyte, which produces melanin. However, melanocytes also do pass melanin into adjacent basal and spongy cells, so both BCCs and SCCs may be pigmented.

Epidermal lesions often have an "irritated" surface that may be ulcerative or thickened. Hyperkeratosis is a thickening of the stratum corneum, leading to an exuberant, flaking, and cracked appearance of the skin as in actinic keratosis and verrucae (or warts).[46] In acanthosis, there is a thickening of the stratum spinosum; it gives the skin a leathery, folded appearance and, if it is pigmented, is called *acanthosis nigricans*. This may occur in simple obesity but can be a marker for internal malignancy. Hyperkeratosis may be so pronounced as to become heaped up to form a cutaneous horn. It is most commonly associated with

actinic keratosis but may have an underlying SCC or keratoacanthoma. Similarly, greasy scaling lesions, which have a "pasted on" appearance, are typical of seborrheic keratosis.

In contradistinction, dermal lesions form a papule or nodule. A dermal inclusion cyst retains its attachment to the overlying epidermis (i.e., a punctum) and a dermatofibroma arises in the superficial dermal layers, so the overlying epidermis adheres to the deeper lesion.[46] In fact, there may be an overlying pressure necrosis from a dermatofibroma, leading to an almost pathognomonic feature of central umbilication. The nodule in dermatofibroma is hard, but a nodular nevus is soft and indents with the back end of a cotton-tipped applicator.[46]

The lesions of the deeper dermis will not have an overlying epidermal adherence. Lesions that are deeply attached will be nonmobile. Physicians should always clinically assess skin cancers for deep fixation and lack of deep mobility because these imply a deep invasion.

Regional clinical evaluation of lymph node drainage basins for malignant lesions is also important, and one must have an understanding of this anatomy,[63] including the superficial and deep lymphatics. Superficial lymphatics from the ulnar side of the hand may drain first into the supratrochlear nodes just proximal to the medial epicondyle, but most pass directly up to the axilla. Superficial radial lymphatics ascend to the deltopectoral glands and then on to the subclavicular axillary nodes.

Deep lymphatic vessels accompany the deep blood vessels (e.g., radial, ulnar, anterior and posterior interosseous), along which there may be lymph glands. Most pass up to the lateral axillary nodes. Thus, it is necessary to examine the forearm, epitrochlear, supratrochlear, and deltopectoral regions, as well as the axilla (i.e., medial, lateral, and apex) and supraclavicular lymph node drainage basins. When planning so-called "prophylactic" lymph node biopsy in the absence of palpable glands, physicians cannot rely on a seemingly logical ascent of lymph drainage up the extremity to the axilla, but must assess for the "sentinel" node that can be at any one of these potential sites.

DIAGNOSTIC PROCEDURES AND NONSURGICAL TREATMENT

Most cutaneous lesions do not require special imaging unless, for example, there is a large, deeply invasive skin cancer; in that case, magnetic resonance imaging (MRI) may be helpful in planning resection.

For small lesions, one may proceed directly to an excisional biopsy. However, many small lesions are noncancerous or only minimally invasive, so various diagnostic and/or treatment options are available. Once again, understanding the depth of cutaneous involvement is an important guide. Many epidermal lesions can be treated by shaving or curettage. Where indicated, one of these methods has an advantage over elliptical excision because the deeper dermal layers are not violated, and there is less likelihood of adverse scarring. This is, perhaps, not as critical in the hand as on more cosmetically important areas such as the face. Appropriate nonsurgical treatments may be as follows:

- *Patient surveillance*—Total lesion ablation may not be feasible. Periodic clinical examination and follow-up photographs may detect malignant transformation. This course can be chosen when total excision of a large congenital nevus is impractical, when a patient has multiple dysplastic nevi, or for diffuse syndromal conditions with a high risk of development of cutaneous malignancy (e.g., xeroderma pigmentosum, basal cell nevus syndrome).
- *Topical medications*—Diffusely spread conditions with malignant potential can be treated with topically applied 5-fluorouracil (5-FU) (Figure 58.3). However, Bowen lesions and superficial BCCs or SCCs cannot be treated with 5-FU. Verrucae can be treated by topical application of podophyllin or keratolytic agents (e.g., salicylic acid). A 5% imiquimod cream (Aldera, Graceway Pharmaceuticals, Bristol, TN) is approved for treatment of superficial BCCs; it should be applied 5 to 7 times per week for up to 12 weeks. Incomplete data are available for its use for Bowen disease, SCC, or lentigo maligna melanoma.
- *Curettage*—A 5-mm curet is most commonly used, and curettage is performed after adequate local anesthesia. It yields material for histologic examination but does not allow assessment of tumor margins. Curettage permits safe removal of superficial lesions with minimal scarring and is amenable for actinic, seborrheic keratoses, and verruca vulgaris. It is an excellent treatment for subungual verrucae, leaving almost no residual nail deformity. Remove the nail plate in order to identify a deep curettage cleavage plane using loupe magnification (Figure 58.4).
- *Cryosurgery*—Intense cold is applied and all cells within the freezing wave are killed. Liquid nitrogen can remove warts, superficial keratoses, and actinic lentigines. It must be used with caution where there are adjacent peripheral nerves, such as on the volar finger and olecranon, as permanent freeze damage to the nerve can occur. Also, destruction to critical paronychial and nail bed structures can occur at the fingertip. Aesthetic results are otherwise usually excellent, but cryosurgery must be used with caution in dark-skinned patients because hypopigmentation may result. It causes little pain and rarely requires anesthesia. For the procedure, a cotton-tipped applicator is used, with cotton teased out and tapered. As liquid nitrogen runs down the applicator,

FIGURE 58.3 Topical application of 5-FU can be used to treat a variety of superficial epidermal lesions.

FIGURE 58.4 **A,** Periungual verruca vulgaris on two fingers. **B,** The lesions here have been curettaged after nail plate removal. Reepitheliazation and normal nail growth will follow because the full-thickness epidermis has not been breached.

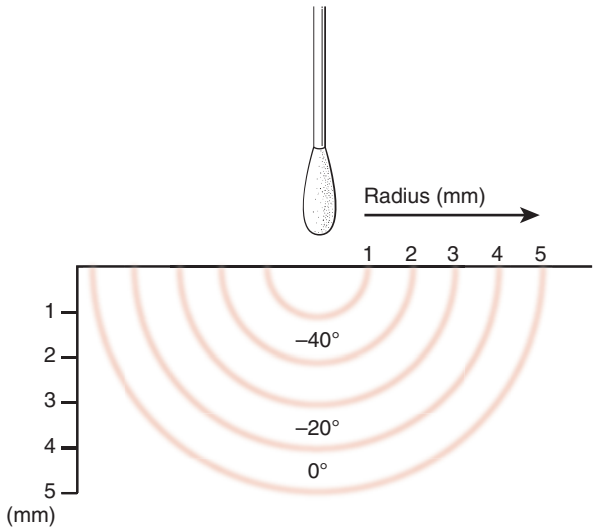

FIGURE 58.5 Diagrammatic representation of cryotherapy with cotton-tipped applicator dipped in liquid nitrogen.

skin at its tip turns white and the ice front spreads outward (Figure 58.5). Application should cease when visible freezing extends just beyond the lesion.

- *Electrosurgery*—Electrical energy is converted to heat by tissue resistance. An office hyfrecator is a good electrosurgical instrument and can be used to destroy seborrheic keratoses, skin tags, lentigines, and spider nevi.
- *Electrodesiccation and curettage*—A curet is used to scrape the lesion down to dermis. Scraping is then paused to use a hyfrecator. This causes electrocoagulation (electrodesiccation) of the raw surgical surface. The process is usually repeated three times or until the surgeon is comfortable with the margins. The technique's effective use depends on clinical experience but has advantages: (1) good cosmetic results, (2) rapid recognition of a recurrence because the lesion is not obscured by a wound closure or flap, and (3) a straightforward office procedure. It can be used for multiple superficial lesions that would otherwise be difficult or tedious to treat with multiple excisions. It is useful for seborrheic keratoses and viral warts but also has been used for multiple superficial BCCs, keratoacanthoma, and Bowen disease. For larger lesions, sometimes scarring can be obvious.

Before ablative surgery, a histologic diagnosis should always be obtained using the following as needed. In some cases, the biopsy process actually may be the curative treatment for smaller lesions.

- *Shave biopsy*—This may totally excise the lesion and be curative or just serve as a diagnostic biopsy. Lesion elevation by the mechanical effects of a wheal of local anesthetic and pinching between thumb and index finger above the plain of the surrounding tissue enables a full-thickness shave biopsy down to dermis. This can be done with a scalpel or a razor blade (Figure 58.6). Shave biopsies are not suitable for neoplasms that clinically appear to infiltrate dermis and generally not for pigmented lesions with a suspicion for melanoma.
- *Punch biopsy*—This may be incisional or excisional, if the lesion is small enough for the punch to fit around. Variable-sized cutting punches are available from 1.5 to 6 mm (4 mm is the most frequently used). Local anesthetic is first injected. When the circular punch incision reaches subcutaneous fat, the punch is removed. The small cylinder of tissue is then lifted and its base transected at the level of the subcutaneous tissue with small iris scissors (Figure 58.7). Sutures are generally not used. Sampling error is minimized by careful choice of the site to be biopsied.
- *Elliptical incisional or excisional biopsy*—If the lesion is too large to make an excisional biopsy impractical, incisional biopsy with a margin of adjacent normal skin is performed. Provided that subsequent excision is performed in a timely manner for histologically proven malignant conditions, prior incisional biopsy does not alter the natural history of melanoma and other cutaneous malignancies. Incisional biopsies should be done longitudinally so that the resulting scar, which may need to be excised later, does not compromise subsequent excision of a potential malignancy.
- *Elliptical excision*—This is usually designed in the line of least skin tension to facilitate linear closure. If the line of least skin tension is difficult to assess, simply excise around the lesion perimeter with appropriate margins and the wound will gape into an ellipse, indicating skin tension; then simply excise the "dog ears" (Figure 58.8).
- *Subungual lesions and longitudinal melanonychia*—Remove the nail plate and perform either incisional or excisional longitudinal removal depending on the ability to finely repair the nail bed in a tension-free manner after lateral undermining.

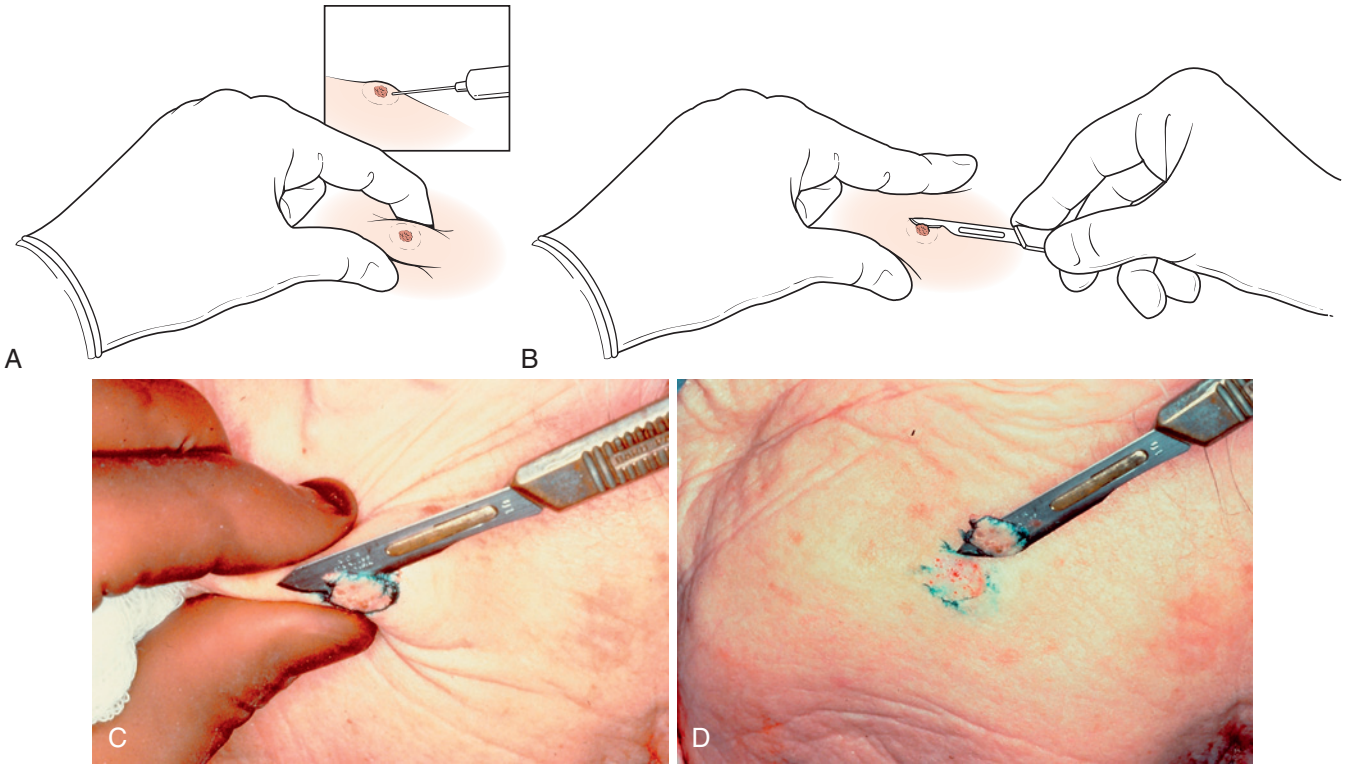

FIGURE 58.6 **A, B,** Diagrammatic illustration of shave biopsy. The lesion is plumped up first by local anesthetic infiltration and then by pinching the skin between the index finger and thumb. Tangential excision of the lesion is thus facilitated. **C, D,** Clinical demonstration of shave biopsy.

SURGICAL LESION EXCISION

Such excisions range from simple elliptical ones and tumor closure, through excision with frozen section assessment of margins, to Mohs micrographic surgery. If the lesion is small and there is abundant surrounding tissue laxity, then excision and linear closure may be permissible. If permanent sections reveal a persistent tumor, then reexcision of the scar is a simple matter. However, if a surgeon is planning a complex wound closure by tissue rearrangement or flap coverage, or if the lesion has complex invasion or is difficult to evaluate clinically by inspection and palpation (e.g., recurrence or certain infiltrative lesions), then intraoperative frozen section analysis of tumor margins is wise or resort to Mohs micrographic surgery.

When performing a simple tumor excision under local anesthesia, first determine tumor extent by loupe magnification inspection and palpation; mark the tumor margin together with the anticipated excision margin. Do this before local anesthetic infiltration because the presence of anesthesia distorts the tissues (Figure 58.9).

Mohs micrographic surgery[27,46,47,52,54,63] is generally reserved for certain widespread lesions with margins that are difficult to interpret clinically and where optimum conservation of uninvolved tissue is necessary such as with diffuse Bowen lesions (Figure 58.10). In contrast to the conventional bread-loafed sectioning of the excised specimen, Mohs surgery involves tangential layered excisions and creating maps of the residual tumor for further excision until the whole lesion is excised. It is applicable to recurrent carcinomas, high-risk squamous carcinomas, tumors with ill-defined clinical margins (e.g., dermatofibrosarcoma protuberans), and in areas where maximal conservation of tissue is required to preserve function.

EPIDERMAL LESIONS

Warts

Verruca vulgaris (wart) is caused by the human papilloma virus (HPV) and is transmissible by direct contact or autoinoculation.[1,25,46] Histologically, physicians see hyperkeratosis (i.e., thickening of the stratum corneum), acanthosis (i.e., thickening of the epidermis), and parakeratosis. The characteristic lesion is a well-demarcated, raised, and rough cauliflower-like lesion. The less frequent plane wart (verruca plana) is flat. Verrucae are common on the hand and fingers and may occur in periungual and subungual locations. Warts may be isolated lesions or groups of them that combine to form plaques.

Most warts spontaneously regress in two years. However, in immunocompromised patients they can reach especially large sizes and take longer to resolve. A variety of treatment options are available, all of which result in about a 70 to 85% cure rate. Most commonly the wart is first pared down and then a topical keratolytic agent is applied. Salicylic acid solution in collodium is the most frequently used topical agent. Treatment with an emery board has been recommended and various other topical applications, which may need to be repeated, have been used, including imiquimod, 5-FU, and cryotherapy. Silver duct tape (not clear tape) has an unknown mechanism of action. It is applied for 7 days, then the lesion is debrided with a pumice stone. This kind of treatment generally is repeated.[19]

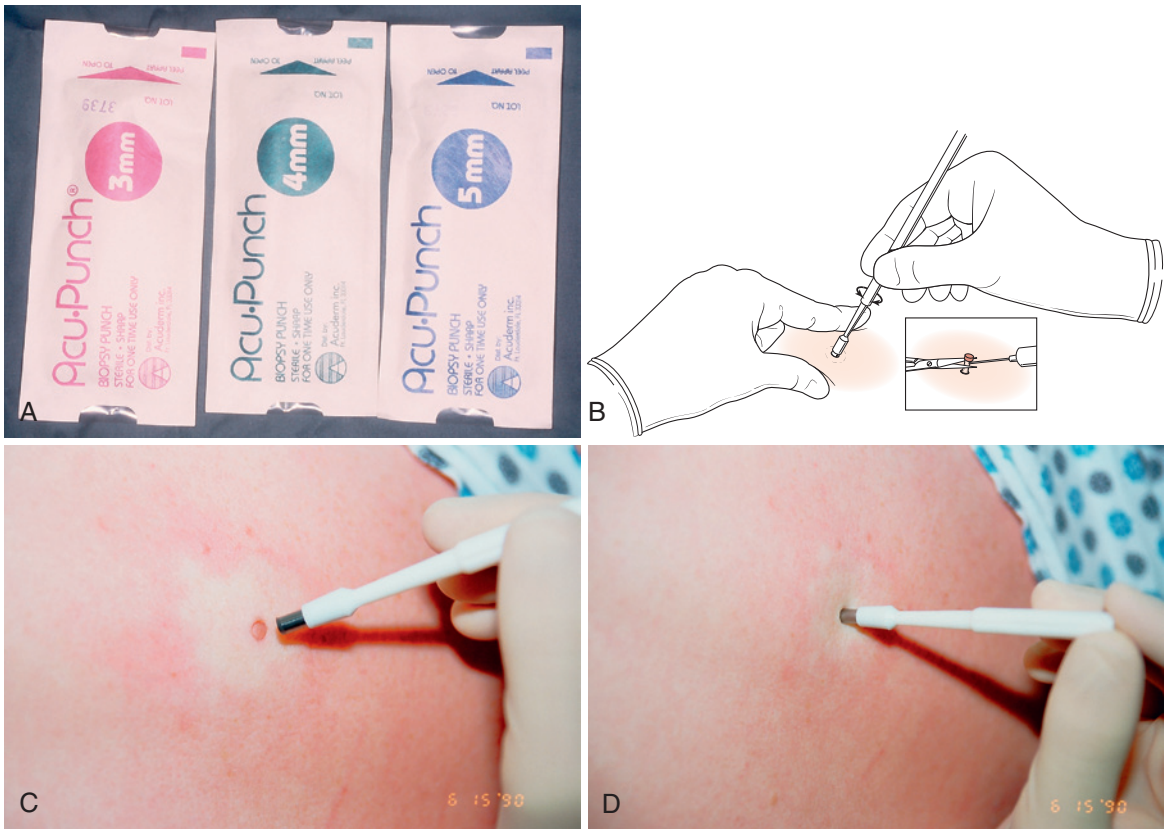

FIGURE 58.7 **A,** Different size punches (3 mm, 4 mm, 5 mm). **B,** Illustration that shows how the cutting punch creates a cylinder of tissue that can then be lifted up and cut loose. **C, D,** The core of tissue can be lifted up by fine forceps or by piercing it with the tip of a hypodermic needle.

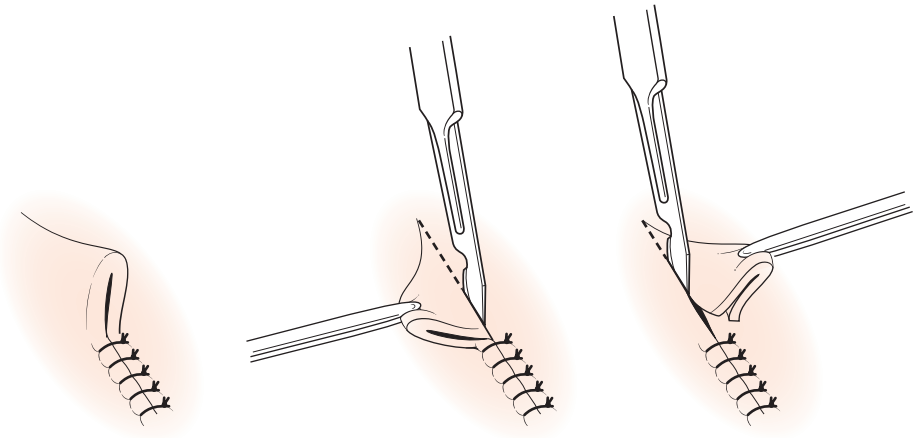

FIGURE 58.8 Method of "dog-ear" excision following elliptical excision of a lesion.

FIGURE 58.9 **A,** The margin around a pigmented lentigo maligna lesion is marked prior to infiltration of local anesthetic. **B,** Resulting soft tissue wound. **C,** If clear clinical margins are ensured, a flap reconstruction may possibly be performed; this shows the outline of a Limberg transposition flap. **D-H,** However, always select the simplest and most effective method of wound closure. Wound edge undermining reveals that the wound can be closed directly. Subcuticular wound closure is performed after deep dermal closure, and dog-ear excision; the wound is supported by adhesive strips. Final outcome is shown in **H**.

My preferred treatment is to shave the wart down to the level of the surrounding epidermis. A discrete edge is then viewed with magnification loupes and the entire wart is sharply curetted from the surrounding normal epidermis. Because this is an entirely epidermal lesion (i.e., the basal epidermal layer is not involved), reepithelialization occurs rapidly. This is an excellent way of treating periungual and subungual warts, resulting in a low risk of residual nail or perionychial deformity.

Seborrheic Keratosis

These lesions are more common in middle-aged and elderly patients. Lesions are usually centrally located, thus are more frequently seen on the upper arm and chest than on the hands. The depth of pigmentation is related to the amount of sun exposure. Occasionally, they mimic melanoma and require diagnostic biopsy. Seborrheic keratoses are benign flat lesions that take on a characteristic greasy scale and appear to have been "stuck" onto the skin's surface (Figure 58.11). Because they are entirely epidermal lesions, treatment takes advantage of their superficiality and includes curettage, shave biopsy, or application of liquid nitrogen. Given that these treatments do not invade the dermis, the potential for scarring is minimal.

Sweat Glands

Eccrine poroma is a sweat gland lesion.[26] Because it arises from the eccrine duct within the epidermis, not in the deeper dermal region, it is truly an epidermal lesion. The lesion presents as a moist and red papule with a surrounding collarette and occasionally may be mistaken for a pyogenic granuloma. Eccrine poroma is said to be more common on the soles and the palms and may be totally epidermal, or it may straddle both dermis and epidermis. Malignant change is unusual. Treatment is surgical excision. Multiple palm and sole lesions may occur in the uncommon genetic hidrotic ectodermal dysplasia syndrome.

FIGURE 58.10 **A, B,** Bowen carcinoma. It is difficult to define the tumor margins by clinical inspection. Mohs surgery is performed **(C, D)** and skin grafting done **(E),** with the long-term outcome shown in **F** and **G**.

PIGMENTED EPIDERMAL LESIONS

Pigmented Macules

Lentigines are benign pigmented macules with increased melanocytic activity.[46,55] Unlike freckles, they do not fade in the absence of sun exposure. A simple lentigo (lentigo simplex) appears during childhood, is usually less than 5 mm in diameter, and may occur on both sites sun-exposed and those not exposed to sun. Solar lentigo is also called *senile lentigo* and is common on the forearm and dorsum of the hand at sun-exposed areas. There is associated solar damage in the dermis, as can be seen by histologic solar elastosis. Their incidence increases with age and may resemble melanoma; thus, diagnostic biopsy may be required. Otherwise, specific treatment is unnecessary, though laser therapy may be helpful if the patient is bothered by cosmesis.

Melanocytes

Melanocytic nevus is a benign proliferation of melanocytes. Nevi, or simple moles, are the most common tumors in humans. Few are present at birth but begin to appear soon after, reaching their greatest incidence in young adults.

Junctional nevi have nevus cells confined to the dermoepidermal junction, and intradermal nevi have these nests in the dermis alone. Most nevi in younger patients are junctional and flat. In adults, most are intradermal and elevated. Compound

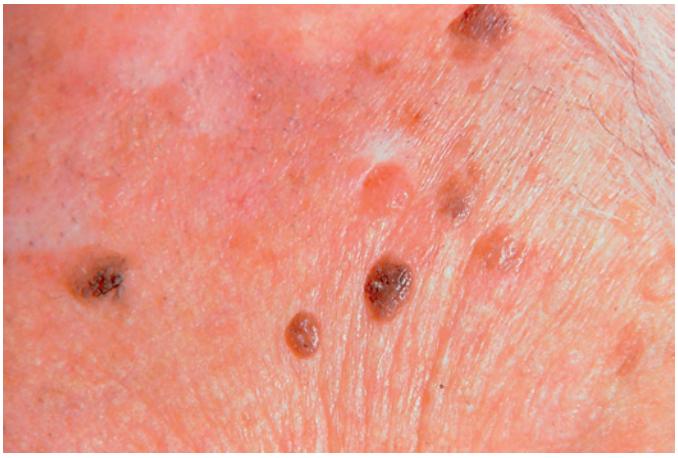

FIGURE 58.11 Characteristic appearance of seborrheic keratoses on dorsum of the hand.

nevi have nevus cells at both locations. It is the junctional component of both junctional and compound nevi that can, more rarely, transform into malignant melanoma; however, most melanomas do not arise out of preexisting nevi. Unlike melanocytes in the basal layer of the epidermis, nevus cells do not have dendritic processes (except in a blue nevus).

Melanocytic nevi may be either acquired or congenital. The latter are classified according to size (e.g., small, medium, or giant), and the former are classified according to pathologic findings (e.g., common mole, Spitz, blue, and atypical/dysplastic).

Moles

Most common moles (nevi) do not require any specific treatment unless malignant transformation is suggested by enlargement, darkening pigmentation, or ulceration—"ABCD": asymmetry, border irregularity, color variation, diameter greater than 6 mm. Palmar nevi were thought to be prone to malignant transformation, but this view has changed. Incidences of palmar nevi occur in 13% of whites and 29% of blacks, making routine excision of nevi in these locations both impractical and unnecessary.

Giant hairy congenital nevi occur most often on the face and bathing trunk area but can occur on the upper extremity (Figure 58.12). It is unclear what the precise risk is for malignancy developing in giant congenital nevi. A systematic review suggests a range of 0 to 9%.[46] The highest risk of malignant transformation with these lesions is actually during childhood and prepuberty, unlike the general incidence of melanoma, which is after puberty. Smaller congenital nevi are generally excised. However, excision of larger nevi may be less practical and require use of skin expansion, flaps, or skin grafting to close large wounds. Where excision is not feasible, periodic cancer surveillance and biopsy of suspicious areas must be done.

Benign Juvenile Melanoma

With spindle (or Spitz) nevus, which has also been called benign juvenile melanoma, the incidence of malignant transformation is no greater than with other compound nevi. The color ranges from pink to purplish-red, and the minority are darkly pigmented. Treatment is total excision.

Blue Nevus

This contains dermal melanocytes that produce melanin, and unlike the intradermal nevus, these melanocytes also have dendritic processes. Dermal melanin scatters shorter wavelengths of light, producing a blue color. It is more commonly found on the dorsum of the hand as a solitary lesion and arises in adolescence or early adulthood. Malignant degeneration is unusual.

Dysplastic Nevus Syndrome

This occurs in both sporadic and familial forms (Figure 58.13). There are multiple atypical nevi varying from 10 to more than 100, occurring mostly on the upper trunk. Lesions are often greater than 1 cm in diameter with irregular and variegated colors. Microscopic appearance is characteristic with large, atypical melanocytes that are spindle or epithelioid in type. The papillary dermis shows fibroplasia. It is impractical to excise all the lesions. Excision of a representative lesion can confirm a pathologic diagnosis. Such patients must be carefully observed and suspicious lesions excised.

Acral nevi (nevi occurring on the thickened palmar skin) can have histologic findings that may mimic dysplastic nevi.

Longitudinal Melanonychia

This term refers to the dark streaking of the nail caused by melanin deposits in the nail plate. Acral nevi that involve the nail matrix can present in this way. In dark-skinned patients, longitudinal melanonychia is common and is simply caused by increased melanin production by normal melanocytes. A longitudinal full-thickness nail bed biopsy is required for a suspicious lesion after removal of the nail plate and repair of the hyponychial nail fold and nail bed. Suspicious new lesions for potential melanoma include those in older patients (50–70 years), a longitudinal band >3 mm in width, change in lesion color and size, involvement of a single digit, nail dystrophy, and extension to the periungual skin (Hutchinson sign) (Figure 58.14).

DERMAL LESIONS

Such lesions are often elevated to be classified as macules or papules and nodules.[25,43] The following list describes some.

- *Dermatofibroma* (histiocytoma) is a fibrous tumor that involves the dermis. They most frequently occur on the extremities. It is usually solitary, slow growing, and firm and attached to overlying skin but freely mobile in relation to deeper subcutaneous tissues. They may have a depressed central "umbilication." Occasionally, dermatofibroma may be dark brown and be clinically confused with malignant melanomas. When indicated, simple excision can be done (Figure 58.15).
- *Digital fibrokeratoma* (acral fibrokeratoma) usually occurs on the acral surfaces of the hands. They are characteristically a hornlike projection with a raised collar of skin at the base. The overlying epidermis is hyperkeratotic and the dermis demonstrates increased fibrosis. They may mimic fibromas, eccrine poromas, and pyogenic granuloma. Treatment is by excision, though reappearance may occur.
- *Epidermal inclusion cysts* arise from occluded pilosebaceous follicles, with some arising from traumatic displacement of

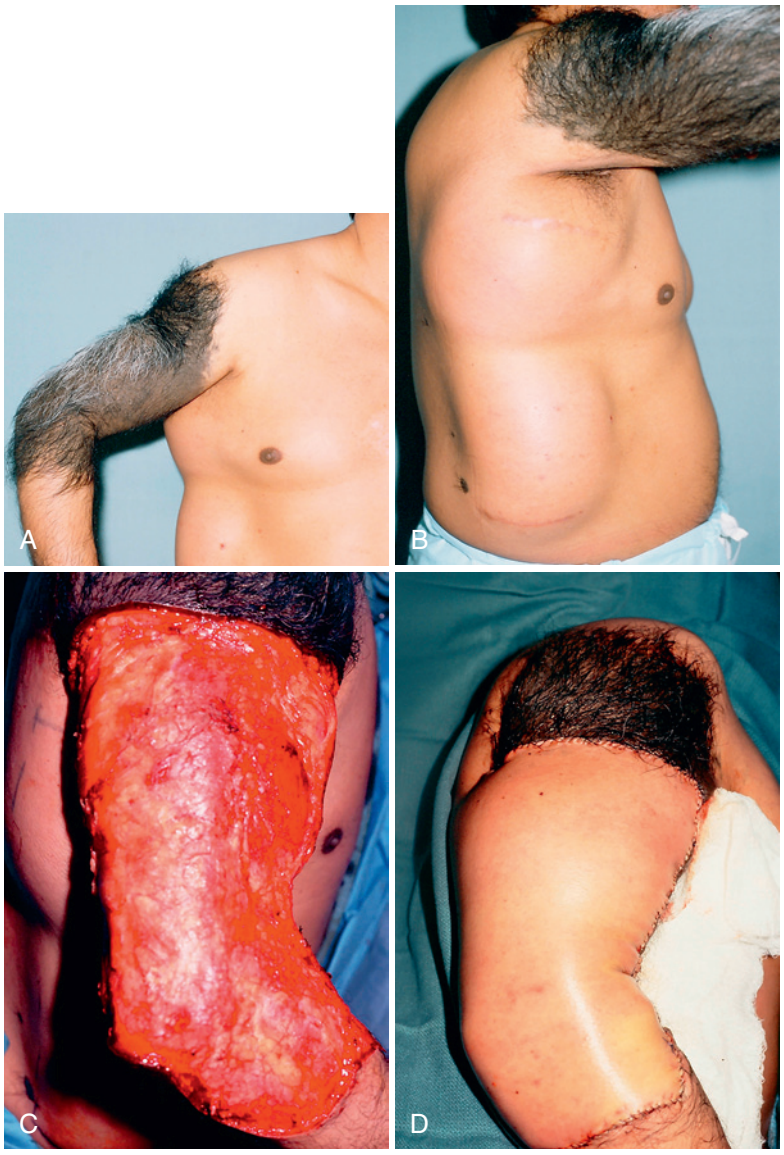

FIGURE 58.12 **A,** Arm giant hairy nevus. **B,** Large tissue expanders have been placed in the lateral chest wall. **C,** Most of the lesion is able to be excised at the first stage and a large wraparound chest wall pedicle flap is used for reconstruction **(D)**.

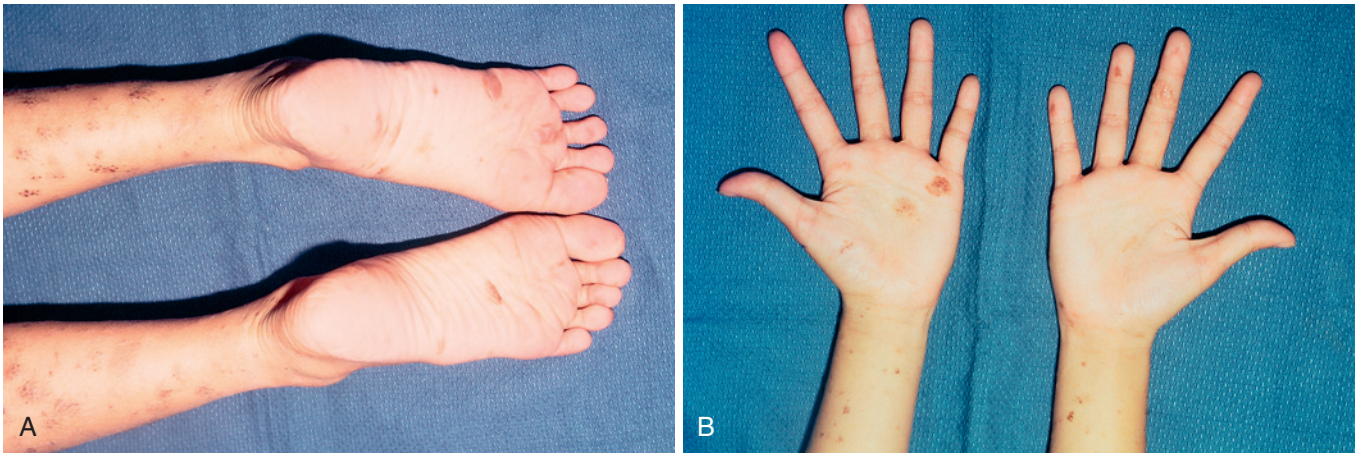

FIGURE 58.13 **A, B,** Child with multiple dysplastic nevi on trunk and upper and lower extremities, including plantar and palmar surfaces (acral nevi).

FIGURE 58.14 **A,** Nail has become completely involved by dark pigmentation. **B,** Nail plate has been removed to reveal germinal matrix nail bed pigmentation. Biopsy showed cellular atypia but no invasive melanoma. This was treated by nail bed surgical ablation and full-thickness skin grafting. **C,** Subungual melanoma showing Hutchinson sign with pigmentation encroaching on the proximal eponychium.

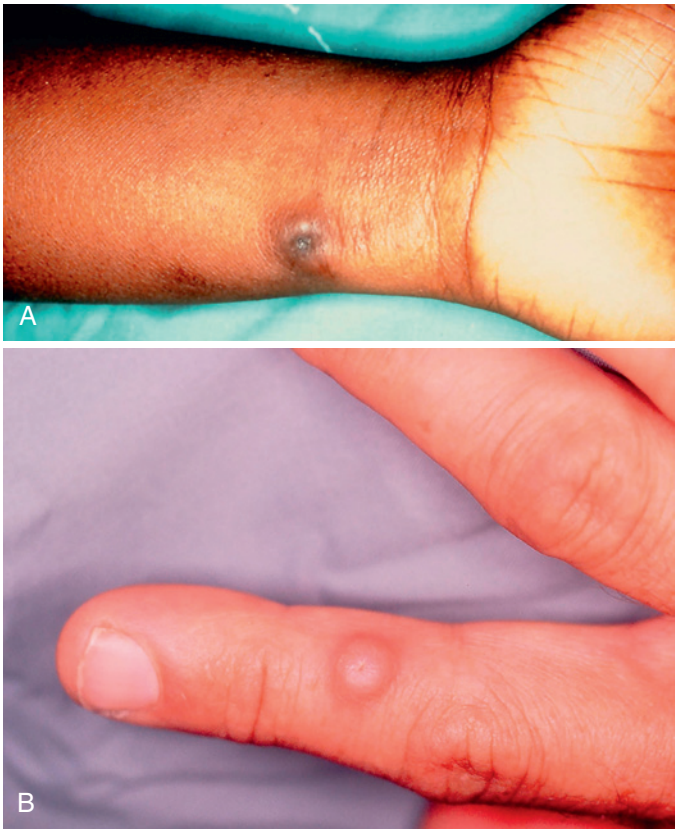

FIGURE 58.15 **A,** Dark-colored dermatofibroma showing central "umbilication." **B,** Finger dermatofibroma.

epidermal cells into the dermis (Figure 58.16). The skin is elevated over the underlying lesion and adherent to it. Central keratin-filled punctum may be seen. They are asymptomatic but may become secondarily infected. The preferred treatment is excision to include the entire epidermal lining.

- *Pilomatricoma* (or calcifying epithelioma of Malherbe) occurs as a solitary tumor in the upper extremities of children and young adults (Figure 58.17, *A, B*). It is usually a nondescript small dermal nodule (0.5-cm diameter), and the foci of calcification are seen histologically. Treatment consists of surgical excision
- *Neurofibroma* may occur as an isolated dermal lesion or as part of a more diffuse neurofibromatosis (Figure 58.17, *C–E*)
- *Infantile digital fibromatosis* occurs at the tips of the fingers (but not the thumb). These may be single or multiple, as "kissing" lesions on adjacent digits (Figure 58.18). They may cause functional deformity. Histologically, there are characteristic eosinophilic cytoplasmic inclusion bodies. Wide excision is required to minimize return but risk of recurrence is high.

NONHEMANGIOMATOUS VASCULAR LESIONS

These lesions can be excised; smaller ones can be destroyed with electrosurgery, laser, or silver nitrate cautery; descriptions follow. Incompletely removed lesions may reoccur.

- *Telangiectasias* are fine linear vessels on the skin's surface. They are common and may be normal, occurring especially

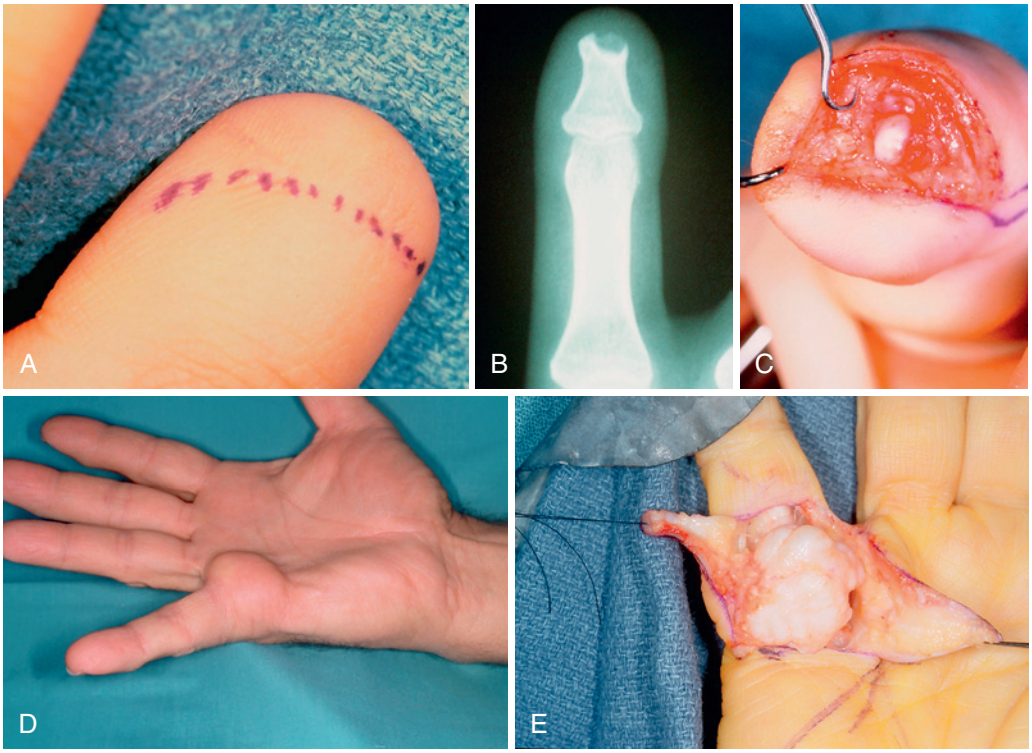

FIGURE 58.16 **A,** Patient who had prior fingertip traumatic amputation now presents with an apical finger mass. **B,** Radiograph shows pressure indentation of the distal phalanx. **C,** Fingertip inclusion cyst is excised. **D, E,** Palmar finger inclusion cyst.

in the elderly on sun-damaged skin. Their significance may lie in their association with other diseases such as collagen vascular disorders.

- *Pyogenic granuloma*[65] is a proliferation of capillaries arising at the site of prior trauma, often is relatively trivial. An associated infection may occur, but the condition is not an infectious process. Pyogenic granulomas have a friable surface and bleed easily (Figure 58.19). They occur most frequently on distal extremities, probably because of minor trauma at the sites. Spontaneous resolution is unusual.

PREMALIGNANT, SKIN CANCER ASSOCIATED, AND INDETERMINATE BEHAVIOR LESIONS

Cutaneous Horns

These arise from underlying epidermal lesions, most commonly actinic keratoses (Figure 58.20).[34,46] They are not premalignant, but as many as 10% have underlying squamous cell carcinomas, and extremely rarely a BCC. Numerous other lesions may give rise to cutaneous horn outgrowth (e.g., keratoacanthoma, sebaceous adenoma, seborrheic keratosis, and verruca). Because of the possibility of malignancy, biopsy is required together with excision of a 1 to 2 mm margin of normal skin. Subsequent treatment then depends on the underlying lesion.

Porokeratosis

These lesions are characterized by a surrounding sharply raised keratotic and horny rim.[1,36] Histologically, there is a rim of parakeratosis and often have an autosomal-dominant inheritance. About 13% transform into squamous cell carcinomas. There are several subtypes, including a Mibelli with raised plaques (Figure 58.21), disseminated superficial actinic (DSAP), linear, and punctate. All may occur on the hand and upper extremity. Because of their association with premalignancy, treatment modalities include cryosurgery, topical 5-fluorouracil, or imiquimod.

Keratoacanthoma

This is a benign, self-limited epithelial tumor, usually occurring on sun-exposed, hair-bearing skin.[25,46,58] It closely resembles squamous cell carcinoma, both clinically and histologically. A firm, erythematous papule appears initially and rapidly enlarges up to 2 cm or more in diameter over several weeks. The characteristic central crater of the lesion is filled with a keratinous plug (Figure 58.22).

Large lesions, even though indurated, are often freely moveable over the underlying structures. Common for such lesions, a regressive phase begins, the central plug is expelled, and the lesion heals spontaneously with a scar. It is believed to arise from proliferation of pilar epithelium. The evolution and regression of the lesions are felt to be related to the hair cycle. Treatment is generally complete excision, especially when the lesion is first recognized and small. Some prefer to call this lesion SCC keratoacanthoma type; thus, for this reason as well, surgical excision is the preferred treatment even though metastases are rare.

Keratoacanthomas may have an aggressive course with metastasis and cannot be distinguished from SCC under such circumstances. The cause, however, for confusion may be an initial mistake in diagnosis, and the histopathologic interpretation of keratoacanthoma may be problematic.

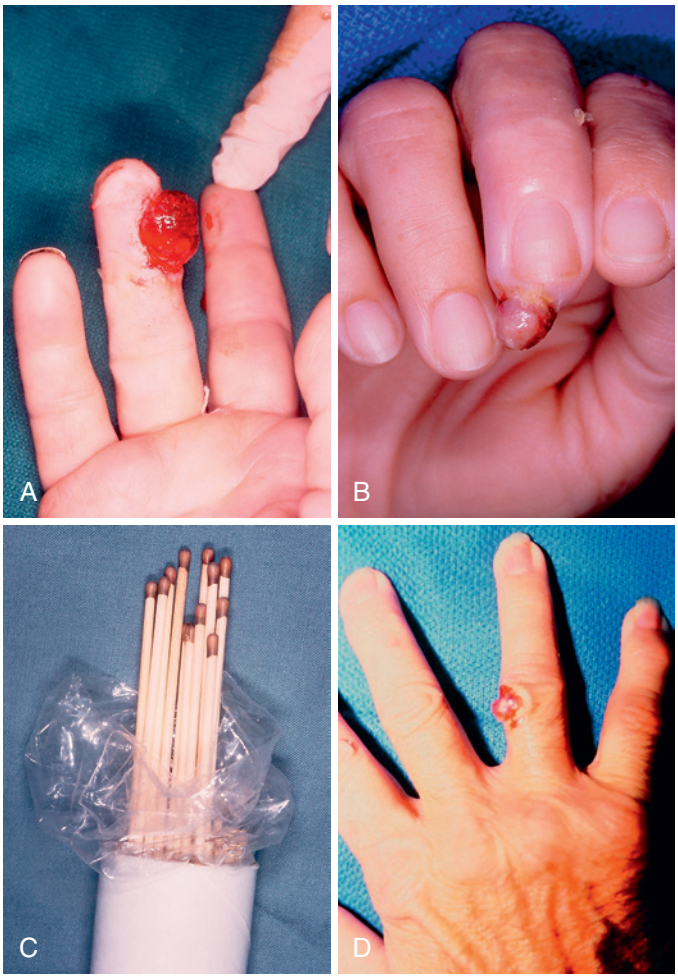

FIGURE 58.19 **A, B,** Pyogenic granulomas are common on the fingers. They have friable surfaces that bleed on contact. **C, D,** Silver nitrate sticks may be used to treat smaller lesions.

Distal Digital Keratoacanthoma

This is a rare, destructive form of keratoacanthoma of the distal subungual tissue.[5] As such, it does not occur in hair-bearing skin. Like a true keratoacanthoma, it does exhibit very rapid

FIGURE 58.21 Extremity porokeratosis of Mibelli.

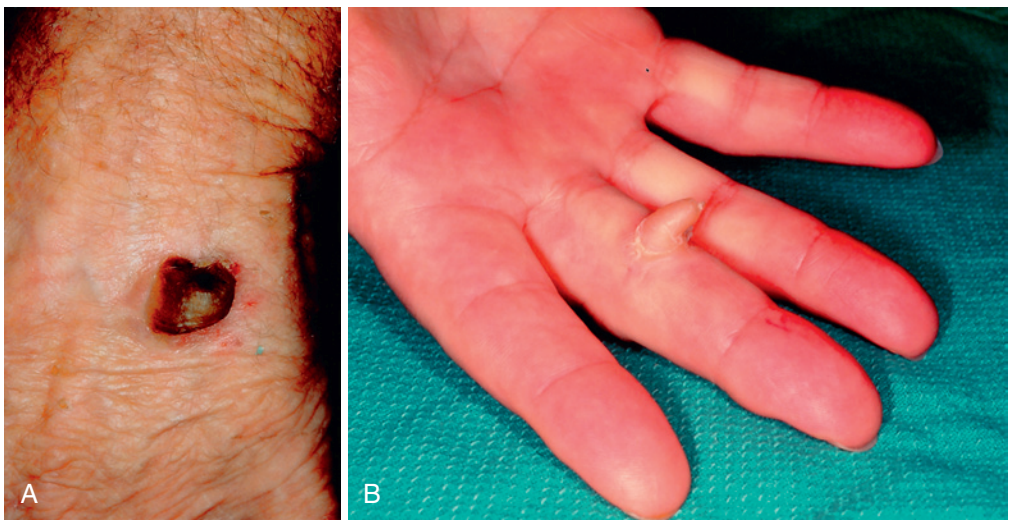

FIGURE 58.20 **A, B,** Examples of cutaneous horns on the hand and finger.

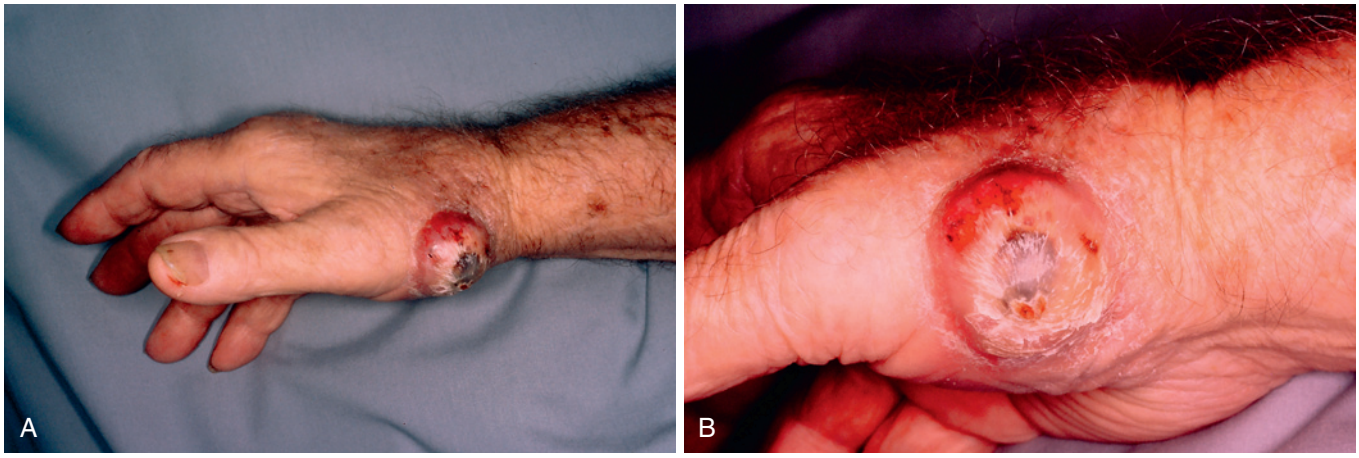

FIGURE 58.22 **A, B,** Keratoacanthoma at dorsal base of thumb. It shows the characteristic central keratinous plug.

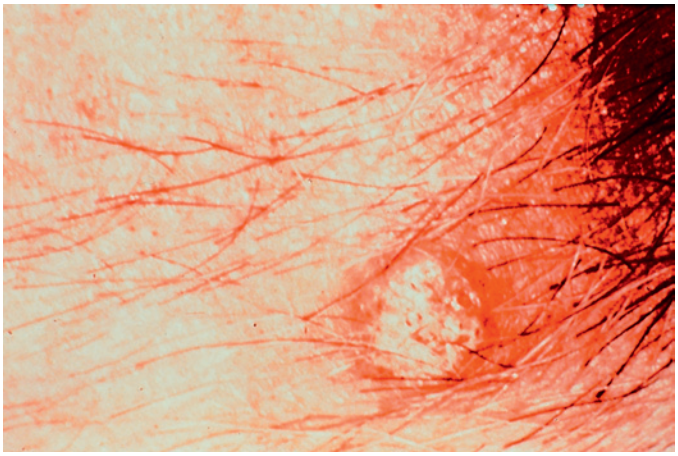

FIGURE 58.23 Scaly lesion of actinic keratosis.

growth. It causes nail bed distortion and may even result in bone destruction. Spontaneous regression has been reported, but it is probably a low-grade carcinoma. If one cannot conclusively rule out SCC, distal digital amputation is warranted.

Actinic Keratosis

The most frequently occurring premalignant cutaneous condition is actinic keratosis[15,42]; it is also called solar or senile keratosis. Lesions are rough and scaly with an erythematous border (Figure 58.23). Histology shows hyperkeratosis and areas of parakeratosis. The granular layer of the epidermis is usually absent, and there is an atypical cellular pattern. The basement membrane is thickened but intact. They occur in genetically susceptible people—for example, frequently older males of Celtic heritage—and a history of sun-exposed sites (e.g., hands and forearms). They must be differentiated from chronic eczema, psoriasis, and Bowen disease. Estimates suggest that invasive SCC develops in fewer than 10% of patients with actinic keratosis.

For individual lesions, treatment may involve cryotherapy and electrodesiccation with curettage. In situations of severe sun damage and multiple areas of actinic keratoses, topical treatments spread over a wider area are more suitable. These may include 5-fluorouracil, dermabrasion, trichloroacetic acid chemical peel, and photodynamic therapies. Lesions resistant to treatment with 5-FU may contain foci of invasive SCC.

Arsenical Keratosis

This occurs secondary to exposure to inorganic arsenic compounds either through ingestion or contact in the agricultural industry.[42] It usually manifests on the arms and soles of the feet and is rarely seen in the United States.

Bowen Disease

An intraepidermal SCC (or carcinoma in situ), Bowen disease[29,42] may become invasive after many years in fewer than 10% of the population. Squamous cell carcinoma arising from Bowen disease is more aggressive than carcinoma arising from actinic keratosis, and metastases develop in up to one-third of patients. Chronic sun exposure is etiologically related.

Lesions are irregular plaques with thickened and hyperkeratotic surfaces (Figure 58.24) and are usually erythematous. They must be differentiated from psoriasis, eczema, verruca, chronic fungal infections (especially when involving the perionychium), actinic keratosis, and superficial BCC. Surgical excision with a margin of normal tissue is the most effective treatment.

Mohs micrographic surgical techniques may be helpful because the clinical boundary of the lesion may be difficult to define. Because of deep follicular involvement, curettage and topical applications (e.g., 5-FU) may be less effective. Distal digital lesions (Figure 58.25) with significant nail distortion may be treated best by fingertip amputations. Large surface-area wounds remaining after lesion excision may be most effectively treated by skin grafting.

SYNDROMAL CONDITIONS ASSOCIATED WITH SKIN CANCERS

Gorlin Syndrome

Basal cell nevus syndrome[42,50] is also called Gorlin syndrome (Figure 58.26). Typical nevi are reddish-brown, papular, and may number up to many thousands that appear after puberty. Lesions may become invasive BCCs. Patients also have a characteristic facies, palmar, and plantar pits; brachymetacarpia;

and occasional neurologic abnormalities (e.g., mental impairment and medulloblastoma).

Xeroderma Pigmentosum

This is a genodermatosis that is an autosomal recessive defect in which the DNA repair mechanism for ultraviolent (UV) light damage is impaired. Skin and eyes are intolerant to UV light.[42] With sunlight exposure, an exaggerated sunburn reaction occurs; that is, the skin thickens and there is subcutaneous atrophy. The prognosis is dismal. Sun protective clothing is required, as well as avoidance of UV exposure. Patients develop multiple malignant epithelial tumors and melanomas during the first decade of life (Figure 58.27).

Other unusual conditions include Bazex syndrome, which is inherited as an X-linked dominant trait and results in multiple BCCs, hypotrichosis, and hypohidrosis. Haber's syndrome is a familial variant of Bowen's lesions, generally appearing in the covered areas of the body.

FIGURE 58.24 Palmar Bowen carcinoma.

BASAL CELL CARCINOMA

Although BCC is the most commonly occurring skin cancer, it is relatively rare on some anatomic sites (e.g., the hand).[45] Squamous cell carcinoma (SCC) is much more common than BCC at this site. BCC arises without a precursor lesion and is locally aggressive and recurrent; however, metastasis is rare. BCCs arise from the basal layer of the epidermis and from pilosebaceous adnexae. The characteristic cell has a large basophilic nucleus with minimal cytoplasm. Tumor cells at the periphery of any nest of cells are oriented with long axes perpendicular to the nest, giving a "picket fence" appearance. In the so-called morpheaform cancer, there is significant dermal collagen that compresses tumor cells into cords.

Differential diagnosis includes factitious ulceration, eczema, actinic keratosis, psoriasis, and fungal infection. Nodular pigmented basal cell carcinoma may mimic melanoma in appearance, but still behaves clinically as a well-circumscribed nodular BCC.

BCCs are distinguished primarily as circumscribed and diffuse lesions.[28,59] Nodular and circumscribed lesions generally are less virulent, and Jacobs et al were the first to differentiate

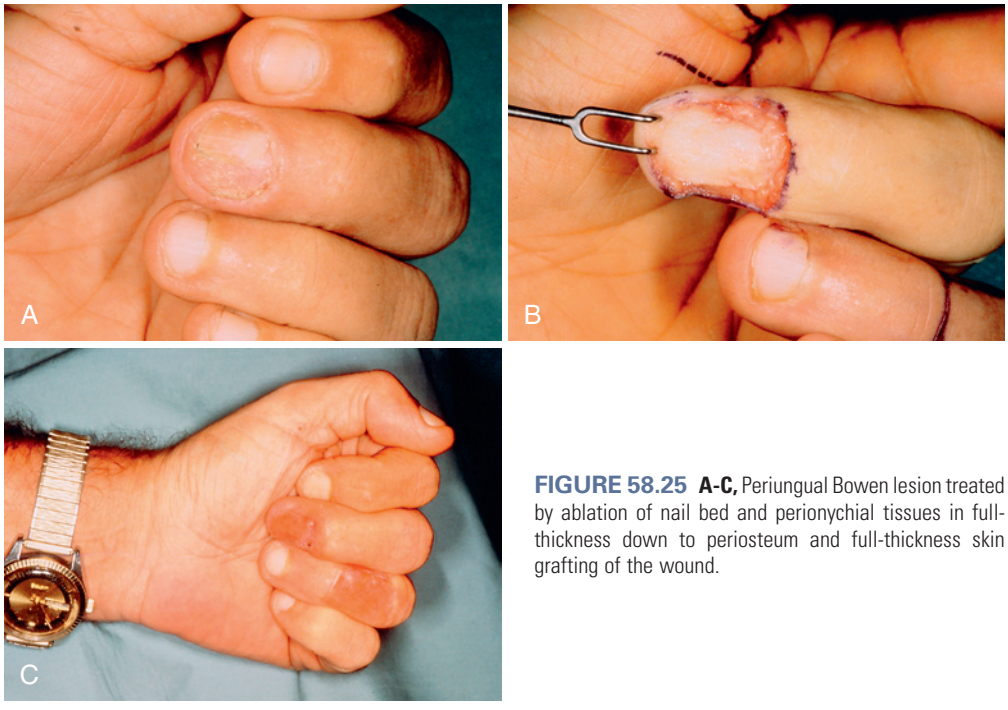

FIGURE 58.25 **A-C,** Periungual Bowen lesion treated by ablation of nail bed and perionychial tissues in full-thickness down to periosteum and full-thickness skin grafting of the wound.

TABLE 58.1 Classification of Basal Cell Carcinoma

Circumscribed	Diffuse
Nodular	Superficial spreading
Nodular ulcerative	Morpheaform (sclerosing)
Adenoid	Infiltrating
Cystic	Eccrine and apocrine epithelioma
Fibroepithelioma of Pinkus	

tumor type and tumor behavior (Figure 58.28). Within the two groups, circumscribed and diffuse, BCC in turn is classified according to degree of differentiation and depth of invasion, which is clinically noted with fixation to deeper structures.

Classification of BCCs

Nodular and ulcerative are the most common types of BCC (Table 58.1). Of the diffuse types, superficial spreading characteristically may occur on the trunk and upper extremities (Figure 58.29). Overall, this type of spreading is the next most common form of BCC.

Solid (Nodular) BCC

This is the most common form of basal cell carcinoma. It may ulcerate, which is called nodular ulcerative. It is dome-shaped with well-defined borders, is often a pink-red papule, and has a "pearly" appearance with telangiectasias. Although nodular BCCs may be histologically poorly differentiated, their growth pattern is circumscribed.

Adenoid BCC

This type of basal cell carcinoma has strands of tumor islands that resemble tubular structures surrounded by myxoid stroma.

Cystic BCC

This type of basal cell carcinoma has spaces in the tumor island secondary to degeneration of tumor cells. When "adenoid" areas are also present, the lesion is called "adenoid cystic." These large lacunae have a distinct macroscopic appearance, and cysts may rupture, allowing fluid to reach the lesion's surface (see Figure 58.28).

Diffuse basal cell carcinomas have a higher recurrence rate than circumscribed lesions because they extend insidiously into the dermis beyond the clinically visible or palpable border.

Superficial BCC

This type of basal cell carcinoma has been called multicentric because discrete foci seem to be present. However, three-dimensional histological reconstruction reveals that the apparent multiple foci are actually connected. This BCC is not easily treated and has a higher recurrence rate because of its extension beyond clinically apparent borders. Superficial BCC is scaly, crusted, erythematous, and level with the skin's surface. It may be ringed by a raised "pearly" border that slowly expands. Confusion with eczema, actinic keratosis, psoriasis, and fungal infection may occur.

Morpheaform (Sclerosing) BCC

This is quite rare on the hand but more common on the face. It is a firm plaque surrounded by "scar" tissue, and lateral spread has been reported as much as 7 mm beyond the clinically apparent tumor border.[56] Dense, fibrous stroma precludes treatment by curettage.

Treatment of BCC

Curettage and electrodessication is the most common method of treating BCC but is reserved for primary lesions less than 1 cm in diameter. Hand extremity lesions are amenable to this form of treatment. Well-defined lesions can also be treated by

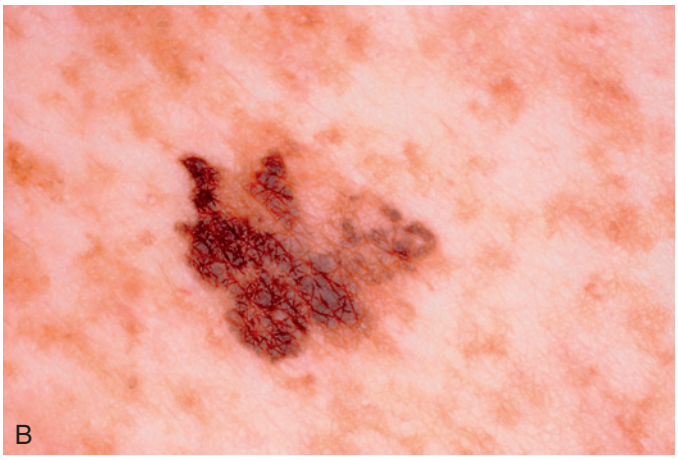

FIGURE 58.27 **A, B,** Patient with xeroderma pigmentosum has developed melanoma.

cryosurgery.[32] A potential risk is neuropathy due to uncontrolled depth of freeze, so this form of treatment should be avoided on digits and around the ulnar nerve at the elbow.

Although cure rate for curettage and electrodesiccation, and for cryosurgery for small lesions, has been reported to be as high as 97%, an inherent disadvantage is lack of microscopic verification of complete tumor removal.[64,31] Surgical excision offers a greater than 90% cure rate[27,44] (Figure 58.30). Loupe magnification allows more accurate visual assessment of tumor borders. Mark out the tumor borders before local anesthetic injection to avoid tumor distortion.

A 2-mm surgical margin may be sufficient for a less than 1 cm diameter nodular lesion. However, for lesions up to 2 cm, a 3 to 5 mm margin is more appropriate and should extend deep into subcutaneous fat. Lesions greater than 2 cm and those with aggressive growth patterns (e.g., morpheaform and superficial "multicentric" BCC) may require resection margins of 10 mm (where practically possible),[16,40] but this should be reserved for larger and infiltrative lesions.

Frozen sections of tumor margins is expensive and not recommended for every suspected BCC. If microscopic margins are found to be involved on permanent pathologic assessment, reexcision will not affect the likelihood of cure. However, for the higher risk lesions already discussed, frozen sections of margins are recommended and even a potential recourse to Mohs micrographic surgery. If flap reconstruction is planned, always ensure that margins are uninvolved by tumor, either through frozen section or while awaiting the results of a permanent section; meanwhile maintain a moist dressing (Figure 58.31).

Therapeutic topical 5-FU or imiquimod does not offer an acceptable cure rate for treatment of BCC.[35]

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma does have premalignant precursors (e.g., actinic keratosis), as well as the in situ variant (Bowen disease).[2] SCCs may also arise de novo, are more aggressive than BCCs, and metastasize more frequently. Fair skin, previous history of sunburns, blue eyes, and blond or red hair increase the risk of SCC. Additionally, immunocompromised patients, especially those with renal and heart transplants, are 65% more likely to develop SCC. These patients may also have multiple and more aggressively behaving squamous cell carcinomas (Figure 58.32).

Unlike BCC, where tumor type is the principle prognosticator for treatment, the following are more important factors influencing the prognosis of SCC[10,23,24,41,44,54]:

- *Broader grades of differentiation*—These are graded 1 through 4 based on the ratio of differentiated to undifferentiated cells. Grades 3 and 4 (50% and 75% of undifferentiated cells, respectively) are twice as likely to recur and three times more likely to metastasize than grades 1 and 2.
- *Location*—Example: paronychial SCC has a high incidence of local recurrence but a low metastatic rate.
- *Tumor size*—T1 indicates lesion size less than 2 cm, T2 is 2 to 4 cm, and T3 is greater than 4 cm. SCCs of a size greater than 2 cm are twice as likely to recur and three times as likely to metastasize than tumors less than 2 cm.
- *Tumor depth*—Some physicians feel this to be the most important factor determining whether SCC will metastasize. SCCs more than 4 mm deep or extending into the subcutaneous tissue (Clark level 5) are the most likely to recur and metastasize.
- *Perineural invasion*—This is a poor prognostic sign for both recurrence and metastasis and indicates a need for postexcision radiation therapy. There is a rate of 47% recurrence, 35% metastasis to regional nodes, and 15% distant metastasis. Perineural invasion is often asymptomatic but may be associated with pain.

Thus, high-risk lesions are those that show rapid growth of greater than 2 cm; have depth of invasion on biopsy of 2 mm or more, or at least Clark level 4; have poor histologic differentiation; and show perineural invasion. Low-risk SCCs can be treated by cryotherapy, electrodesiccation and curettage, photodynamic therapy, or excision. The margin of excision for

FIGURE 58.28 Clinically different basal cell carcinoma subtypes: **A,** pigmented; **B,** superficial ulcerative; **C,** adenoid cystic; **D,** superficial spreading; and **E,** sclerosing (morpheaform).

FIGURE 58-29 **A-D,** Superficial spreading basal cell carcinoma of forearm is excised and then treated with fasciocutaneous bilobed transposition flap; there is a good final healed outcome following frozen section confirmation of clear margins intraoperatively.

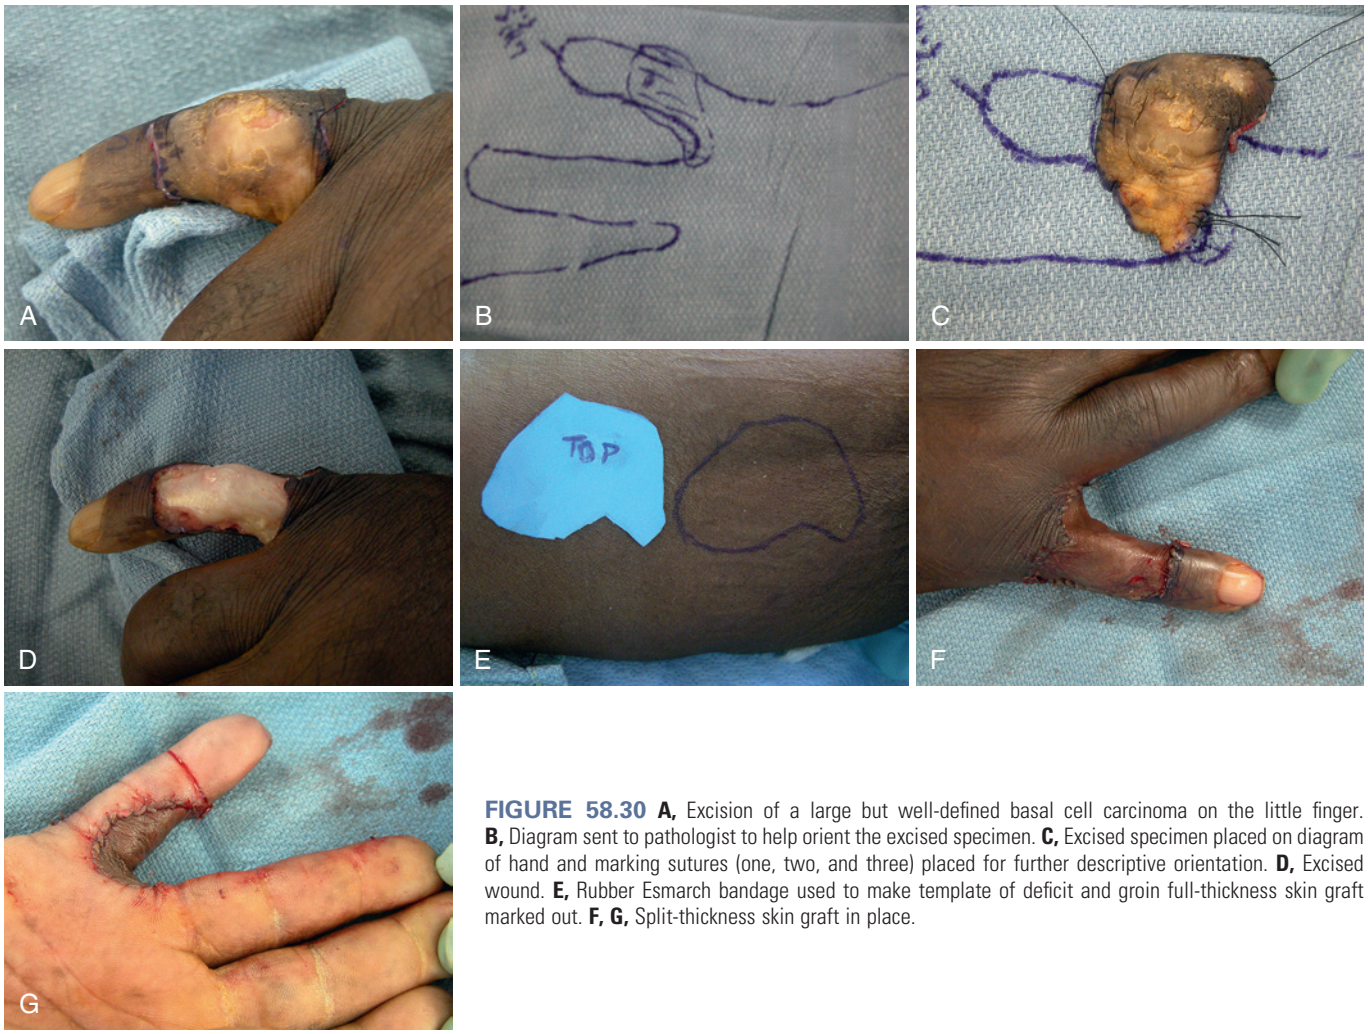

FIGURE 58.30 A, Excision of a large but well-defined basal cell carcinoma on the little finger. **B,** Diagram sent to pathologist to help orient the excised specimen. **C,** Excised specimen placed on diagram of hand and marking sutures (one, two, and three) placed for further descriptive orientation. **D,** Excised wound. **E,** Rubber Esmarch bandage used to make template of deficit and groin full-thickness skin graft marked out. **F, G,** Split-thickness skin graft in place.

low-risk lesions is 4 mm, and for high-risk SCCs it is at least 6 mm and down into subcutaneous fat or even to fascia (Figure 58.33).

Cure rates for surgery are about 92%. Mohs micrographic surgery may be indicated for the more high-risk lesions, especially for recurrent tumors, perineural invasion, poorly differentiated and deeply penetrating tumors, and in areas where tissue conservation is desired (e.g., on fingers).

Resulting excisional wounds may be able to be closed directly, but larger wounds can be covered with a skin graft. Local rotation flaps may be used; however, before realigning tissues the surgeon must be certain of free resection margins, either by frozen section or awaiting permanent section results. Amputation may be required to control aggressive tumors (Figure 58.34). Once again, periungual invasive SCC lesions may be confused with fungal infection, eczema, or Bowen disease (Figure 58.35).[37]

It is estimated that 2 to 5% of SCCs metastasize to axillary nodes. Elective node dissection or sentinel lymph node biopsy (SLNB) has not been shown to be of advantage in treating squamous cell carcinomas unless nodes are actually clinically enlarged because of the relatively low incidence of lymph node metastasis.[51] SCCs are slower to invade deeper tissues than are cutaneous malignant melanomas. Superficial dermis and epidermis are devoid of lymphatic drainage, making SCC less likely to spread via lymphatics. SLNB is under investigation for high-risk squamous cell carcinoma. If there are axillary node metastases, 5-year survival drops to 40%.

MELANOMA

There are several malignant melanoma morphologic subtypes. For cutaneous lesions thought to be melanoma, one may use the ABCDE acronym—asymmetric, border irregularity, color variation, diameter greater than 6 mm, evolving or changing—as a diagnostic guide (Figure 58.36). However, nodular melanomas grow vertically and may be greater than 6 mm and melanomas may be amelanotic.[17,21,22]

Such melanomas are subdivided into those with more rapid radial growth (i.e., lentigo maligna, superficial spreading, acral lentiginous) and those with a relative absence of radial growth with prominent vertical growth (nodular melanoma) (Figure 58.37). Vertical growth determines tumor depth and ultimate prognosis.

Clark's levels of invasion recognized the prognostic importance of vertical melanoma growth but was descriptive with

FIGURE 58.31 **A-D**, Open wound initially treated with moist dressings. Bilobed flaps may be very useful on the upper extremity because they can be transposed across the webspace. In addition, tissue can be taken from areas (i.e., those easily closed) of tissue laxity to areas where there is less laxity. This flap incidentally is also centered over the first dorsal metacarpal artery, thus ensuring good blood supply.

regard to invasion into the papillary dermis, reticular dermis, and finally into subcutaneous fat. We now use Breslow's millimeter depth of invasion thickness, which is measured from the epidermal basement membrane to the deepest melanoma tumor cells. Depth of invasion is difficult to accurately quantitate for subungual melanoma because the epidermal nail bed is compressed tightly against the dorsal periosteum of the distal phalanx.

Morphologic subtypes of melanoma, including superficial spreading, lentigo maligna (solar), acral lentiginous, subungual, nodular, amelanotic, and desmoplastic, are described next.

Superficial spreading melanoma makes up 70% of melanomas. Of all of them, it is the most likely to arise within or contiguous to a melanocytic nevus. There is a long, horizontal growth phase (6 months to 6 years) before vertical growth occurs; thus, these lesions have a better prognosis. Metastatic spread correlates with vertical invasion and rarely occurs during the early radial growth phase.

Lentigo maligna (solar) melanoma accounts for 4 to 10% of all melanomas. It is associated with elderly patients' long-term sun exposure. Thus, it occurs in the same areas affected by actinic keratoses, especially on the extensor aspect of the forearm. In situ melanoma is called lentigo maligna (sometimes Hutchinson's freckle). It is a flat macule that has a horizontal growth phase that lasts 1 to 2 decades. Once a vertical growth phase occurs and the dermis is invaded (often apparent clinically by papules in the lesion), the invasive melanoma is then called lentigo maligna melanoma. Histologic determination of margins may be difficult and often it is advisable to excise the lesion with at least 5-mm margins and await permanent histologic section confirmation before definitively closing the wound with a skin graft or flap.

Acral lentiginous melanoma makes up 2 to 8% of cutaneous malignant melanomas and occurs on the palmar surface and nail apparatus; it is not associated with sun exposure. This is the most common type of melanoma in people in whom melanoma is generally uncommon (i.e., African Americans, Asians, Hispanics). It has a long horizontal growth phase before vertical growth occurs. Diagnosis is often delayed because the lesions occur in areas not frequently examined clinically.

Subungual melanoma most commonly affects the thumb in the upper extremity. It may be mistaken for a subungual hematoma. Formal biopsy is required for a pigmented nail lesion that has persisted for more than 2 months.

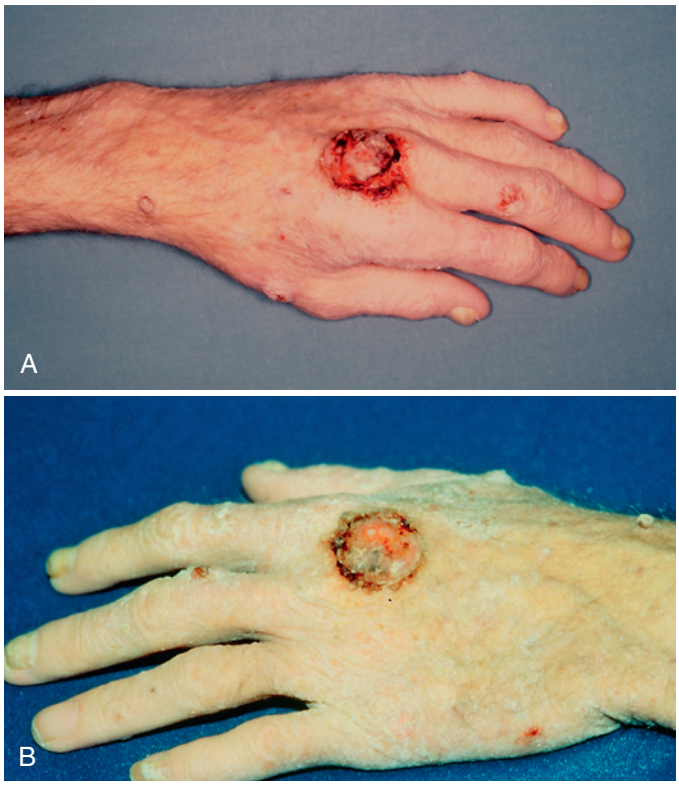

FIGURE 58.32 **A, B,** Renal transplant patient has multiple upper extremity squamous cell carcinoma.

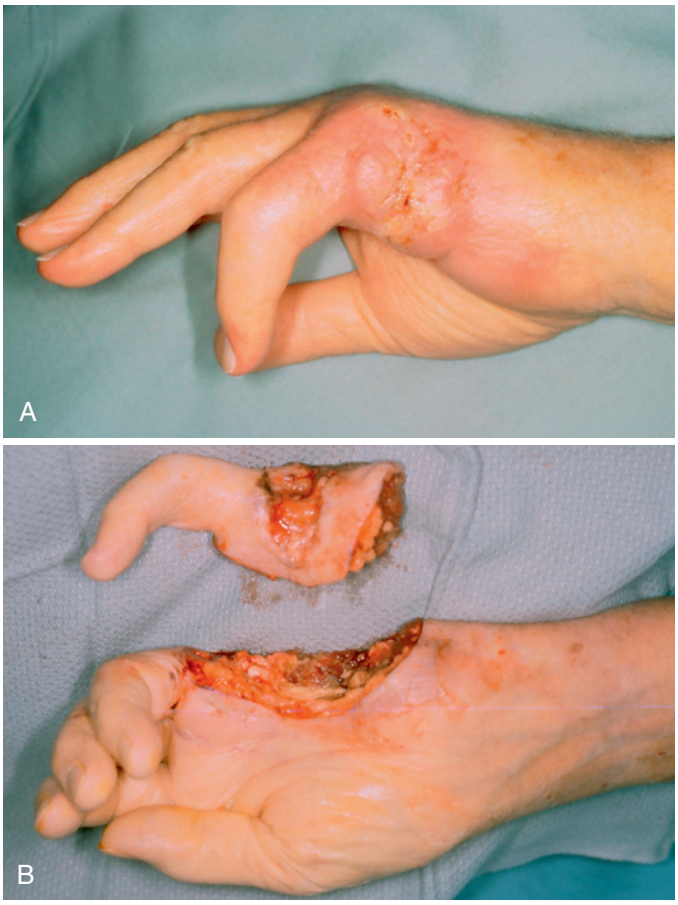

FIGURE 58.34 **A, B,** Squamous cell carcinoma invasive into bone and joint is best treated by digital ray amputation.

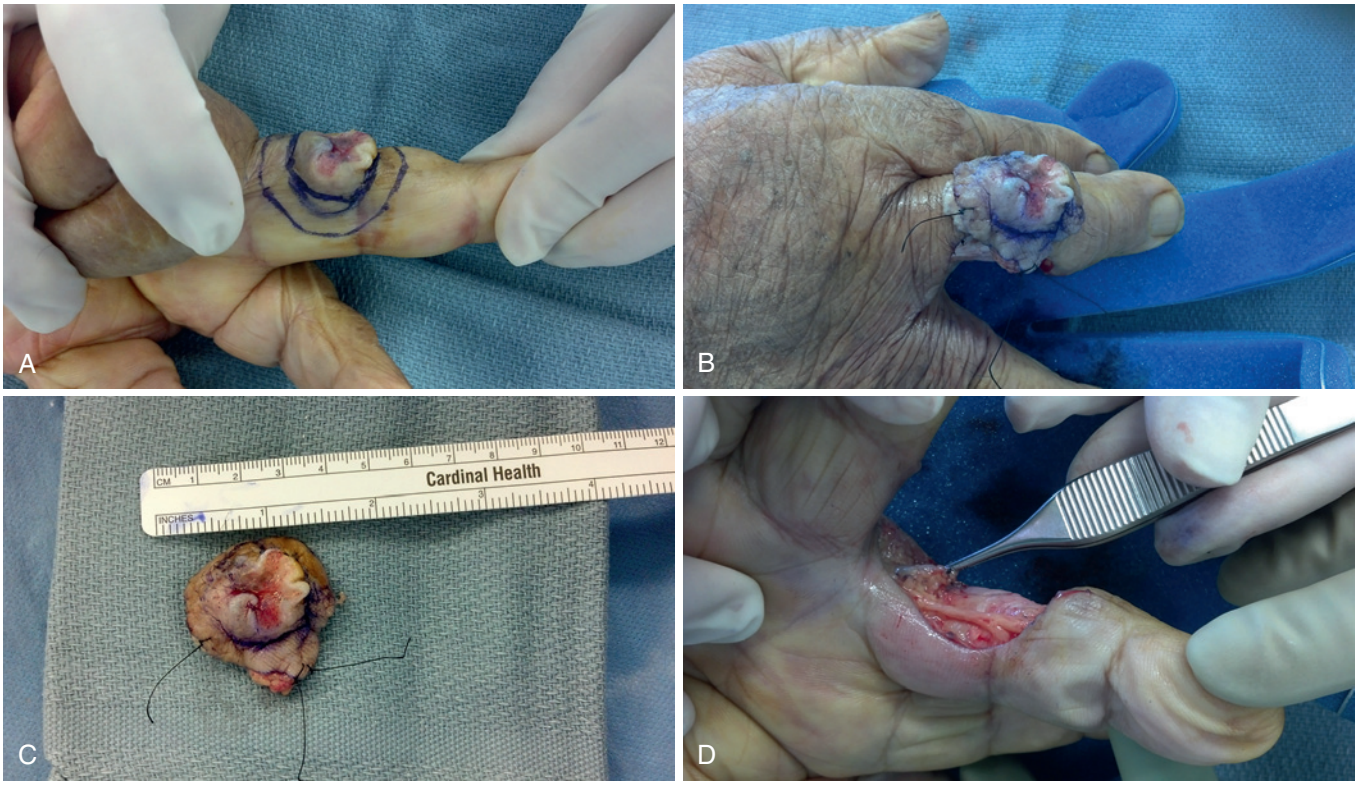

FIGURE 58.33 **A,** Digital squamous cell carcinoma is deeply adherent and measured. **B,** Excised lesion is orientated in situ and marking sutures are placed. **C,** Excised specimen showing marking orientation sutures. **D,** Resulting wound with exposed digital nerve.

Nodular melanoma accounts for 2 to 20% of melanomas. It is frequently thick at the time of diagnosis and thus has an increased metastatic potential. It generally arises de novo.

Amelanotic melanoma lesions may be gray or pink and devoid of dark pigmentation. They are a diagnostic challenge and can be mistaken for intradermal nevus or nodular BCC.

Desmoplastic melanoma occasionally may affect the hands. Histologically, it is similar to lentigo malignant melanoma but has a fibroblastic reaction in the dermis and neural invasion. Mean thickness at the time of initial clinical detection is 4.3 mm, but survival is more favorable for this tumor type than for other melanomas of equivalent thickness (5-year survival of 63% versus 48%).

FIGURE 58.35 Periungual squamous cell carcinoma.

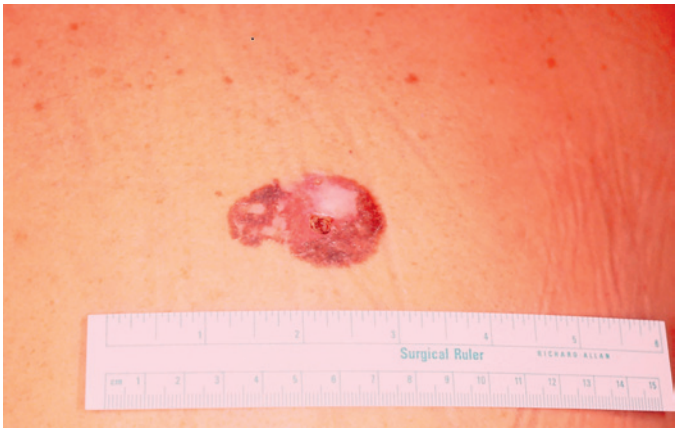

FIGURE 58.36 Superficial spreading melanoma showing irregular borders and variable pigmentation.

Prognosis and Staging

Independent prognostic indicators for patient survival with melanoma are Breslow thickness, macroscopic or microscopic ulceration, and lymph node involvement (determined by SLNB). Morphologic type, corrected for thickness, does not influence survival. Potential prognostic correlations exist for gender, mitotic rate, and truncal versus limb location (with the latter being more favorable).

Staging is determined by tumor size; regional lymph node metastases by the presence of micro- or macrometastases; by number of nodes involved; and, finally, by three subgroups of distant metastases—skin and soft tissue (best prognosis), lung, and other visceral metastases (worst prognosis) (Table 58.2). Elevated lactate dehydrogenase in any of the first metastatic subgroups upstages to the last subgroup.[3,20]

Laboratory investigations are unnecessary for early cutaneous melanoma (<1 mm thickness) in the absence of signs and symptoms to suggest metastatic disease. For larger melanomas, there are no uniform recommended initial staging evaluations, but these may include chest radiograph, blood count, liver function tests, and computed tomography (CT) scans. Positron emission tomography (PET) and CTs help identify developing metastases and facilitate decisions for surgical resection. Patients with melanoma possibly may be best evaluated in a multispecialty melanoma clinic.

Local Surgical Excisional Treatment

The Breslow depth classification assists in determining tumor excision margins.[4,20,44,61] In the 1980s, safety margins of 5 cm, independent of tumor thickness, were standard. Recommended excisional margins, based on Breslow tumor thickness, now are the following:

- In situ—2 to 5 mm (5-year survival, 95–100%)
- <1 mm—1 cm (5-year survival, 95–100%)
- 1 to 2 mm—1 to 2 cm (5-year survival, 80–96%)
- 2 to 4 mm—2 to 3 cm (5-year survival, 60–75%)
- >4 mm—3 cm (5-year survival, 50%)

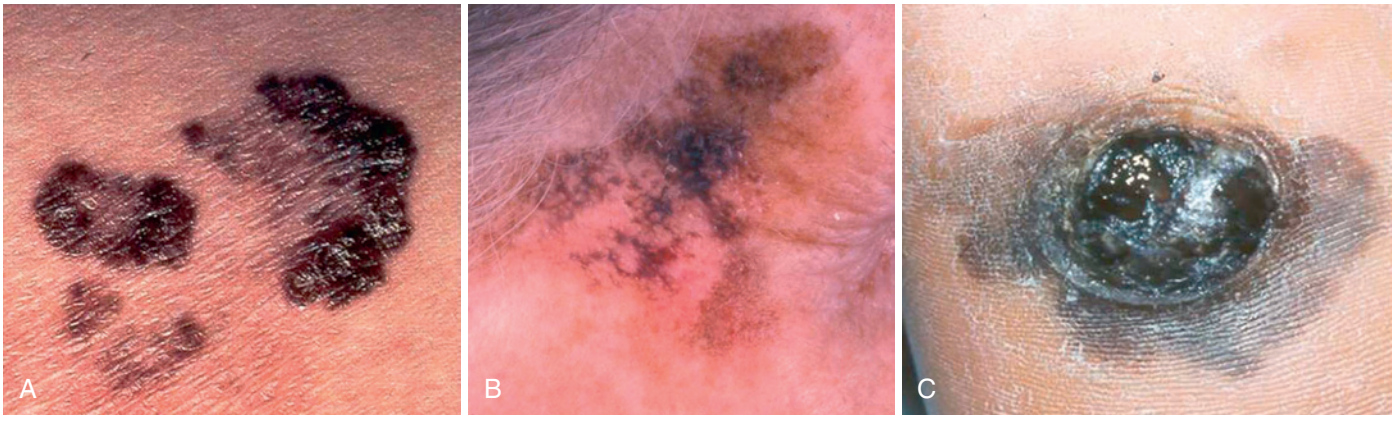

FIGURE 58.37 Different melanoma subtypes: **A,** Superficial spreading; **B,** lentigo maligna; and **C,** nodular.

TABLE 58.2 Tumor Staging

Tumor, Node, and Metastatic	Description*
Primary Tumor	
xT	Primary tumor cannot be assessed (e.g., shave biopsy or regressed melanoma)
T0	Primary tumor
Tis	Melanoma in situ
T1	Melanoma ≤1.0 mm
T2	1.01–2.0 mm
T3	2.01–4.0 mm
T4	>4.0 mm
Regional Lymph Nodes	
N0	No regional metastases
NX	Patients in whom regional nodes cannot be assessed (previously removed)
N1	1 metastatic node: (1) micrometastasis, (2) micrometastases
N2	2–3 metastatic c nodes: (1) micrometastasis, (2) macrometastases, (3) satellite and in-transit metastases without metastatic nodes
N3	4 or more metastatic nodes, or matted nodes, or satellite/in-transit metastases with metastatic nodes
Distant Metastatic	
M0	No detectable evidence of metastases
Mx	Presence or absence of metastases cannot be assessed
M1a	Metastases to skin, subcutaneous tissue, or distant lymph nodes
M1b	Metastases to lung
M1c	Metastases to all other visceral sites

*Presence of ulceration as determined by histopathology designates a tumor as Tb in contrast to a nonulcerated melanoma (Ta) and results in upstaging by one substage compared with nonulcerative melanoma.

Obviously, these measurements apply only to the peripheral margin because it is impossible to obtain equivalent deep margins on the hand. For in situ lesions, surgeons can excise through subcutaneous fat; however, for all other melanomas, extend the depth of excision to the hand's paratenon on the dorsum and to the forearm's fascia. Obviously, for deeper histological tumor extension, a more radical excision on the deep surface is required.

Subungual melanoma of an in situ type can be treated by surgical excision of the entire nail bed and paronychial region, and then covered with a full-thickness skin graft directly on the periosteum.[62] Invasive subungual melanoma is treated by amputation proximal to the next joint. Thus, if the distal phalanx is involved, amputate proximal to the IP joint of the thumb or the DIP joint of a finger. If a tumor extends to the middle phalanx, amputate proximal to the PIP joint. For functional reasons, a ray amputation may be the most appropriate.

Evaluation of Lymphatic Basins

Lymph node dissection is performed if there are palpable nodes that are histologically proven to be involved with metastatic melanoma.[11,38,39,44,48,49] This will probably not effect a cure, but it minimizes the morbidity of progressive malignancy in the axilla with tumor ulceration, pain from nerve plexus invasion, and lymphedema (Figure 58.38).

A randomized trial showed that SLNB patients who had a positive sentinel node and went on to complete lymph node dissection had an improved survival rate over those who had clinical observation and then only dissection when nodes were detected.[39] Sentinel lymph node biopsy is recommended for all lesions greater than 1-mm thickness in the absence of clinically palpable nodes.

SLNB is used to stage melanoma patients who are clinically node-negative (Figure 58.39). Lymph node staging is used to detect micrometastases for cutaneous melanoma with a Breslow tumor thickness of greater than 1 mm and for tumors of less than 1 mm if nonetheless of a Clark level 4 or 5. Thin melanomas of less than 1 mm account for about 70% of new cases, and SLNB generally is not recommended because the rate of micrometastases to nodes is less than 2%. For intermediate-thickness lesions, detection of micrometastasis by SLNB is the most important prognostic factor. However, it remains unclear, except for one study,[18,39] whether SLNB and subsequent radical axillary lymphadenectomy for positive nodes actually prolongs survival.

Isosulfan vital blue dye injection is done 10 minutes before surgical preparation of the patient. The use of both radiocolloid and mapping intraoperatively with a sterile gamma probe, combined with the blue dye injection, increases sentinel lymph node detection rates to more than 99% compared with 87% when only blue dye is used.[48] The morbidity associated with SLNB is obviously far less than with elective lymph node dissection (ELND), so formal node dissection can be targeted at specific patients who have a positive sentinel node biopsy (see Figure 58.39).

LESS COMMON MALIGNANT TUMORS

Merkel Cell (Neuroendocrine) Carcinoma

Merkel cells are in the basal layer of the epidermis and are associated with slow-adapting, pressure-sensitive sentry nerve endings. Merkel cell carcinoma[57,60] is a rapidly growing, painless and nontender intracutaneous nodule that can grow to as large as 5 cm in diameter. Treatment requires wide surgical excision and sometimes even amputation with regional lymphadenectomy. Some physicians recommend postoperative irradiation as well as chemotherapy. Local recurrence, distant metastases, and lymph node metastases are common (Figure 58.40).

Lymphangiosarcoma (Stewart-Treves Syndrome)

Lymphangiosarcoma[14,33,66] is a rare tumor that occurs in the upper extremity of patients with chronic lymphedema for more than 10 years following mastectomy with axillary lymph node dissection and irradiation. Initially, the tumor may not be obvious clinically and may appear simply as a bruise or as multiple purple skin papules; after that the tumor develops rapidly. Following biopsy confirmation, life-saving amputation in

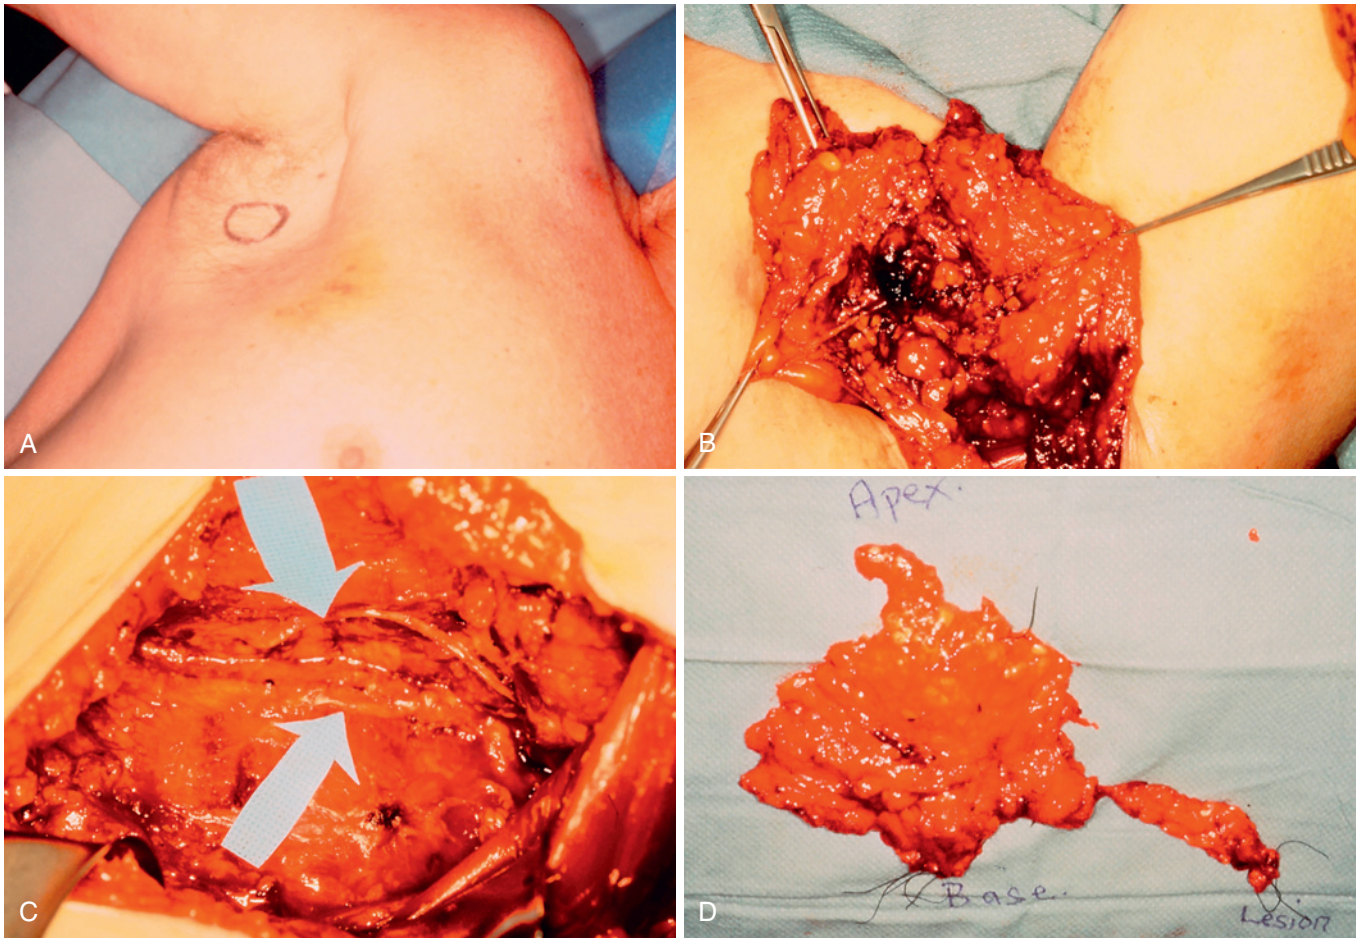

FIGURE 58.38 **A,** Patient with upper extremity melanoma and palpable axillary lymph node. **B,** Melanoma pigmentation is seen macroscopically in the involved node. **C,** Axillary dissection clearing all the way to the apical nodes (*arrows* point to axillary vessels and laterally to thoracodorsal nerve). **D,** Glandular axillary tissue removed as a single specimen (sutures oriented to the axillary specimen).

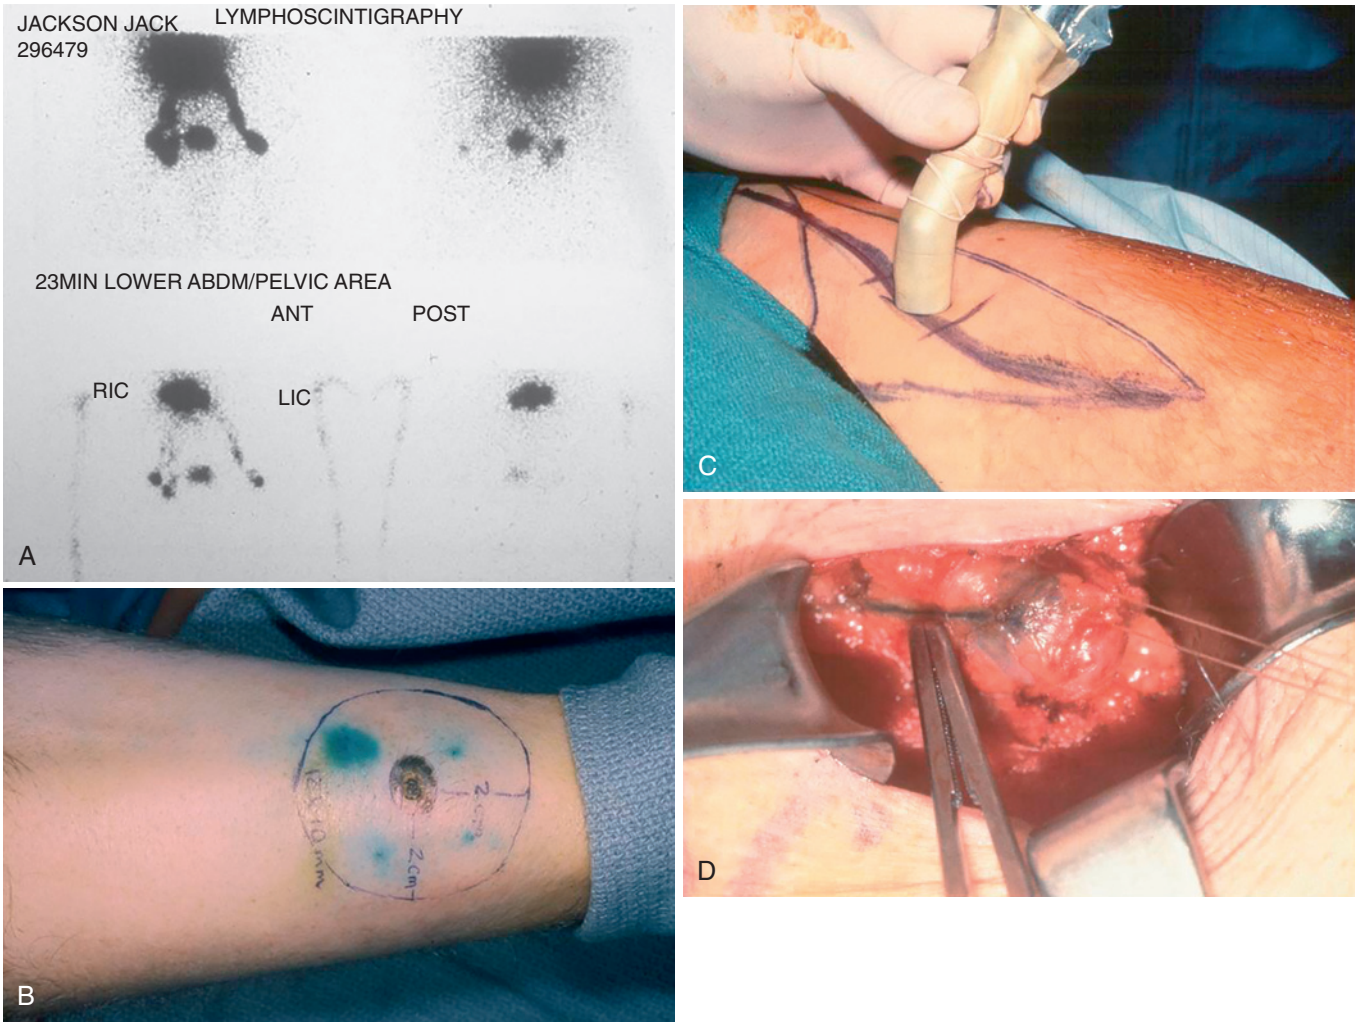

FIGURE 58.39 **A, B,** Sentinel lymph node mapping can be performed and facilitated by both intralesional injection of a vital dye and radiocolloid. **C,** A sterile probe detects the node with the highest radioactivity count. **D,** The sentinel node also takes up the vital dye stain.

conjunction with adjuvant chemotherapy is the preferred treatment.

Sweat Gland Tumors

Even so-called benign sweat gland tumors have a tendency to recur locally, and benign tumors may transform into a malignancy over time.[12,13] Treatment of the benign tumors must include excising a margin of surrounding normal tissue. Examples are eccrine poroma, chondroid syringoma, and eccrine spiradenoma. Tumors occur most commonly on the palm because this is where there is the highest concentration of sweat glands.

Malignant varieties of sweat gland tumors do occur but are rare, so there are no clear treatment guidelines. They develop painful ulceration, are locally invasive, and spread to lymph nodes and distant metastatic sites. Wide local excision is necessary as well as SLNB, with some recommending prophylactic regional lymph node dissection.

Human Immunodeficiency Virus

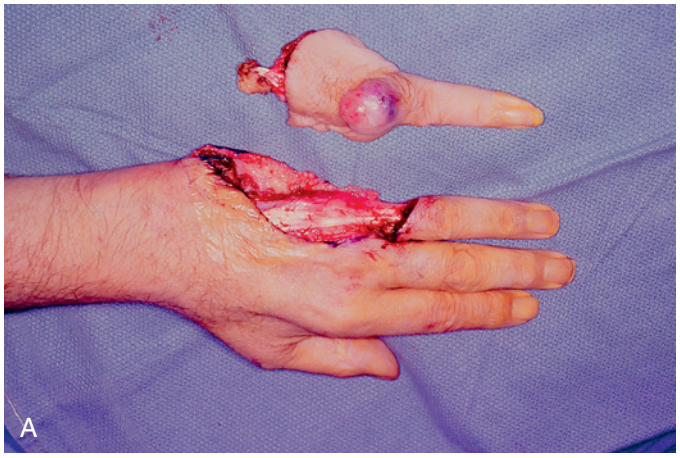
Patients with human immunodeficiency virus (HIV) have a higher risk of skin cancer, especially with a known viral etiology (e.g., Kaposi sarcoma)[6] (Figure 58.41). There is also a higher incidence of nonmelanoma skin cancers with a two-fold higher risk of BCC in HIV-infected Caucasian males, and a 2.6-fold higher risk of SCC in HIV-infected individuals irrespective of gender.[30] HIV virus levels and antiretroviral therapy are not related to this higher risk. Melanoma may also occur at higher rates among HIV patients.

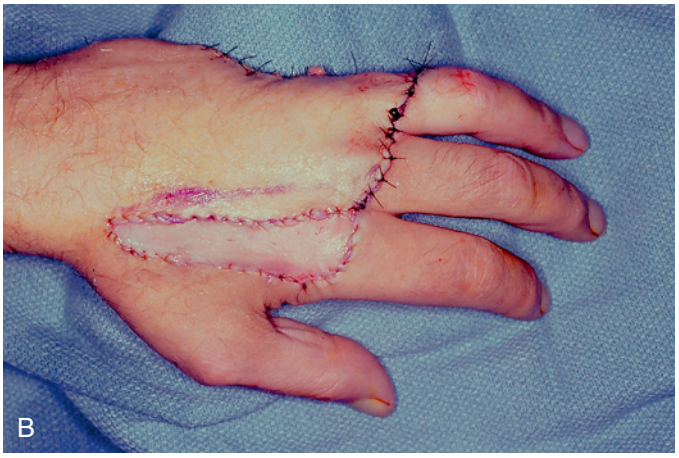
Dermatofibrosarcoma Protuberans

This is a locally invasive fibrosarcoma of the dermis (Figure 58.42) that has poorly defined clinical margins.[9,53] Treatment is wide resection followed by appropriate wound closure, most often with a skin graft. This is because the widely resected tumor often precludes direct wound closure and local flaps may be ill-advised unless the surgeon is certain of the clear clinical margins.

Metastatic Tumors

Tumors rarely metastasize from other sites to soft tissues or bones of the fingers or hand; however, always biopsy suspicious lesions (Figure 58.43).





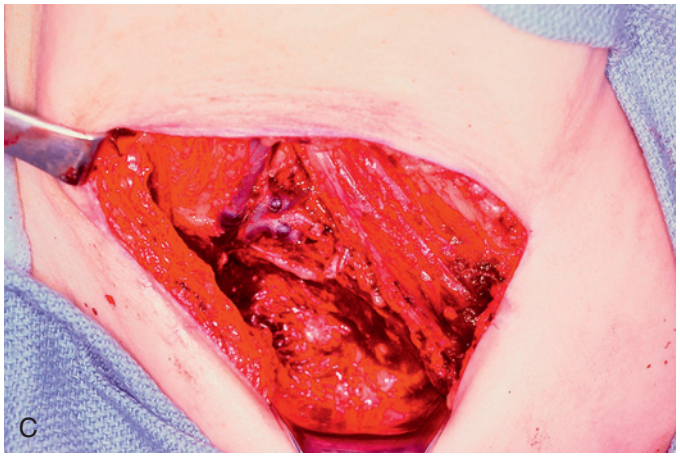


FIGURE 58.40 **A-C,** Merkel cell tumor treated by finger ray amputation, wound closure by dorsal hand transposition flap, and also axillary node dissection.

Bone and Soft Tissue Tumors

Edward A. Athanasian

Acknowledgment: I would like to acknowledge the excellent work of earlier authors who wrote and revised portions of this chapter in previous editions: Alexander C. Angeledes, Gordon B. McFarland, Jr., Waldo E. Floyd III, Richard J. Smith, Clayton A. Peimer, Harold M. Dick, and Owen J. Moy. The principles of management of aggressive and malignant tumors as described in great detail by these authors have changed relatively little. I have attempted to enlarge the focus of the chapter and update patient management principles, which have changed as the effects of adjuvant therapies have become better understood.

The purpose of this chapter is to present the most recent knowledge on specific benign and malignant bone and soft tissue tumors that may appear in the hand. Tumors occurring in the hand and forearm generally have unique growth patterns and potential for metastasis that may be different from those seen elsewhere in the body. Tumors in the hand are relatively uncommon, and most surgeons encounter them infrequently. Knowledge regarding treatment and care of hand lesions is often based on case reports, small case series, retrospective reviews, and a few large general case studies. Data from controlled trials are limited but have advanced the use of chemotherapy and radiation therapy and the treatment of soft tissue sarcoma. At times, the information available is both contradictory and controversial. It is important for the treating surgeon to thoroughly understand the specific characteristics of the tumor being treated, as well as the systemic treatment of the disease. Of greater importance, however, is knowledge and practice of the principles and guidelines for the treatment of patients with tumors.

The reader is strongly encouraged to understand and review the principles of staging, biopsy, resection, and amputation before treating all tumors, particularly those that are malignant. In no other aspect of hand surgery are the implications for uninformed decisions, judgments, or actions more serious than in the treatment of malignant bone or soft tissue sarcomas. Conversely, treatment based on up-to-date knowledge and a thorough understanding of the principles of care for local and systemic cancer maximizes the potential to save the patient's life. Only after this concern has been addressed can one focus on the task of salvaging or reconstructing a useful hand or limb. Regular review of treatment principles before treating patients for malignant tumors is imperative and helps ensure appropriate treatment.

DIAGNOSIS AND MANAGEMENT OF MUSCULOSKELETAL TUMORS

Neoplasms are usually classified into two categories: benign and malignant; in musculoskeletal tissues, malignancies can also be subdivided into low- and high-grade. Cellular growth in benign neoplasms usually proceeds at a much slower rate than in malignant tumors.

Malignant neoplasia is characterized by a rapid growth rate, atypical cellularity, and poor cell differentiation. Local growth is aggressive and infiltrative; there are only "pseudocapsules" through which the tumor must extend to form satellite lesions. Such tumors are likely to spread as blood-borne metastases, and local recurrence rates are high after excision unless a wide margin of normal tissue is included in the resection. Low-grade malignancies grow more slowly and infiltrate early but are less likely to metastasize than to recur locally. *Neither all generic categories nor isolated case illustrations are consistent with these classifications, however.*

Many benign tumors of the hand or forearm require no treatment, can be diagnosed clinically, and are asymptomatic. However, if a lesion increases in size or becomes symptomatic or if the physical or radiographic appearance suggests an aggressive process, appropriate staging studies, including obtaining tissue for diagnosis, must be performed.[38,53,56,134,180,181] Unfortunately, lumps and growths that look innocent may not necessarily be so. Surgeons need to be familiar with the range of possible diagnoses and generate a differential diagnosis for the individual patient under consideration. A physician is not justified in advising a patient that a mass should be "left alone" until the proper diagnosis is established by all appropriate means. Any tumor with an unclear diagnosis on the basis of nonsurgical evaluation should be sampled. If the biopsy proves the tumor to be benign, no further treatment may be necessary. If a malignant or an aggressive nonmalignant lesion is identified, however, further management is required.

Tumors that are symptomatic need to be diagnosed and staged. The clinical and family history, physical characteristics of the tumor, and data from laboratory and imaging studies provide at least the basis of a clinical impression. If the precise

diagnosis is unclear after a complete workup, a carefully planned biopsy is required to avoid the hazards of misdiagnosis and its complications.

CLASSIFICATION AND STAGING OF TUMORS

Management of hand and upper extremity tumors does not differ significantly from management of tumors in other parts of the musculoskeletal system. Correct treatment must always take into consideration the size and location of the growth, its histologic grade and clinical behavior, and its potential for metastases.[38,53,54,115,134,180,181] A thorough understanding of the general principles and guidelines is essential for accurate assessment and staging of tumors.

Histologic Grade and Surgical Staging

The histologic grade (G) of a neoplasm is determined by the malignant characteristics of tissue obtained by biopsy. An accepted classification is as follows:

G0: Benign

Gl: Low grade: few cells, much stroma, little necrosis, mature cells, <5 mitoses per high-power field

G2: High grade: many cells, little stroma, much necrosis, immature cells, more than 10 mitoses per high-power field

Benign tumors can be classified into three stages[53]:

- Latent, stage I tumors do not usually require treatment; they may heal spontaneously or remain unchanged.
- Active, stage II benign neoplasms grow within a limited zone and are contained by natural barriers; if surgery is required, these tumors are most often controlled by intralesional or marginal excision.
- Locally aggressive, stage III benign tumors may both grow and spread beyond natural barriers; excision usually requires a wide surgical margin or en bloc resection for local cure.

To avoid confusion and differences of opinion about malignant bone tumors, it has become important to establish specific grading criteria for tumors. A classification scheme based on a modified staging system for bone sarcomas was established by the American College of Surgeons Joint Committee on Cancer and End Results Reporting in 1977. It was proposed by W. F. Enneking at the University of Florida and accepted by the Musculoskeletal Tumor Society (MSTS) in 1979 (Tables 59.1 and 59.2). Although this staging system was developed for bone sarcomas, it has also been used to describe and stage soft tissue sarcomas, particularly in the orthopedic surgical community. A comparison of the MSTS system and the fourth and fifth editions of the American Joint Committee on Cancer (AJCC) system has found the AJCC system to be more predictive of systemic relapse.[204] The AJCC staging system incorporates grade, size, depth, and the presence or absence of metastasis to determine the final stage of the lesion. This system should be used preferentially for staging of soft tissue sarcomas (Table 59.3).

The pathologist and surgeon must agree on a surgical grade (G1 or G2) of the malignancy based primarily on the histologic features of the tumor and also on its gross pathologic appearance, the clinical setting, and its radiologic appearance. The histologic grade is determined only after careful scrutiny of a representative biopsy specimen by an experienced musculoskeletal pathologist. Clinical and radiologic status are also important parameters for determining the final tissue diagnosis and surgical grade.

The two grades of malignant tumors differ with respect to their rate of metastasis and recurrence: G1 is a low-grade malignancy with a low likelihood of metastasis and frequent local recurrence, and G2 is a high-grade malignancy with frequent blood-borne metastases. The so-called low-grade malignant tumors can also metastasize but are typically less likely to do so early in their course. Assignment of a grade to a particular tumor is neither easy nor exact because grading criteria are not quantifiable. Cellular morphology, anaplasia, necrosis, mitoses,

TABLE 59.1 Surgical Stages

Stage	Grade	Site
IA	Low (G1)	Intracompartmental (T1)
IB	Low (G1)	Extracompartmental (T1)
IIA	High (G2)	Intracompartmental (T1)
IIB	High (G2)	Extracompartmental (T2)
III	Any (G) Regional or distant metastasis (M)	Any (T) Regional or distant metastasis (M)

TABLE 59.2 Surgical Procedures for Extremity Sarcomas

	SURGICAL METHOD			
Margin	Limb Salvage	Amputation	Planes of Dissection	Microscopic Appearance
Intralesional	Debulking, piecemeal excision/curettage	Translesional amputation	Within tumor (palliative)	Tumor at all margins
Marginal	Marginal en bloc excision	Marginal amputation	Within tumor "reactive zone"	Reactive tissue (± microextensions of tumor)
Wide	Wide en bloc excision	Wide through-bone amputation	Through normal tissue but within compartment	Normal tissue (± "skip lesions")
Radical	En bloc resection of entire compartment	Extraarticular disarticulation	Normal tissue extracompartmental	Normal tissue

Adapted from Enneking WF: Staging of musculoskeletal neoplasms. In Uhthoff UK, Stahl E, editors: *Current concepts of diagnosis and treatment of bone and soft tissue tumors*, New York, 1984, Springer-Verlag, pp 1–21.

and tissue of origin can also be influenced by clinical behavior. Tumors that are known to be exceptionally dangerous (e.g., synovial and epithelioid sarcoma) are most properly classified into a higher grade than their histology would indicate. Two other criteria are important: T, which represents the size and site of the tumor; and M, which designates the presence of detectable metastases.

Location (Site)

Regardless of size, if the tumor is limited to a single anatomic compartment, it generally will be resectable. At the same time, it will be possible to preserve the extremity, as is the case with highly malignant tumors involving the distal phalanges and other acral parts. The basis of defining a *compartment* is the recognition that certain natural anatomic barriers exist that will temporarily contain and delay the spread of a pathologic process such as infection and neoplasia. For example, an intraosseous tumor contained by the cortices and intramedullary canal of a tubular bone would be considered intracompartmental. However, if this tumor perforates into the surrounding soft tissues, it would then be considered extracompartmental because it has already crossed a natural barrier. Computed tomography (CT) and magnetic resonance imaging (MRI) enable us to estimate the size and location of a tumor, thereby permitting more accurate preoperative planning than was possible previously.

This concept also applies to soft tissue compartments, but not quite so neatly as with bone tumors. Tumors that involve a flexor tendon in the digit have, in theory, violated the entire compartment of extrinsic muscle. Tumors may have a propensity to spread proximally along the tendon to the muscle, much as a hematoma may track proximally after rupture of a flexor tendon by following the natural barriers of the tendon sheath and muscle fascia.

Metastases

The third criterion for classification of malignant tumors identifies patients in whom the tumor has already metastasized to other sites. The MSTS has three stages, with stage III including all patients with distant metastases, regardless of the other parameters (see Table 59.1). Lymph node involvement is always an important finding in that primary musculoskeletal neoplasms do not commonly spread to regional nodes. Because lymph node metastases develop in less than 5% of patients with sarcomas, the differential diagnosis of extremity tumors with possible nodal metastases must always be expanded to include carcinomas and melanomas. Metastases to lymph nodes are significantly more prevalent with rhabdomyosarcoma, epithelioid sarcoma, clear cell sarcoma, and angiosarcoma.

Once the appropriate staging studies are completed, the surgeon will know the anatomic characteristics (the size or "T") of the lesion and whether metastases (the "M") are absent or present. A differential diagnosis can then be formulated and the biopsy planned.

TABLE 59.3 American Joint Committee on Cancer Staging System for Soft Tissue Sarcomas

	Description
Stage I	
IA	Low grade, small (<5 cm), superficial or deep to fascia
IB	Low grade, large (>5 cm), superficial to fascia
Stage II	
IIA	High grade, small (<5 cm), superficial or deep to fascia
IIB	High grade, large (>5 cm), superficial or deep to fascia
Stage III	High grade, large (>5 cm), superficial or deep to fascia
Stage IV	Any metastasis to lymph nodes or distant sites

EVALUATION PROTOCOL

There are no precise physical characteristics that clearly distinguish aggressive and malignant tumors from benign and reactive lesions. The only definitive test is histologic evaluation of biopsy material. However, because hand tumors can produce such significant dysfunction and because inadequate or unnecessarily aggressive surgery also presents risks, biopsy must be the final step in obtaining a diagnosis. All nonsurgical studies should be completed before surgical biopsy (Figure 59.1).

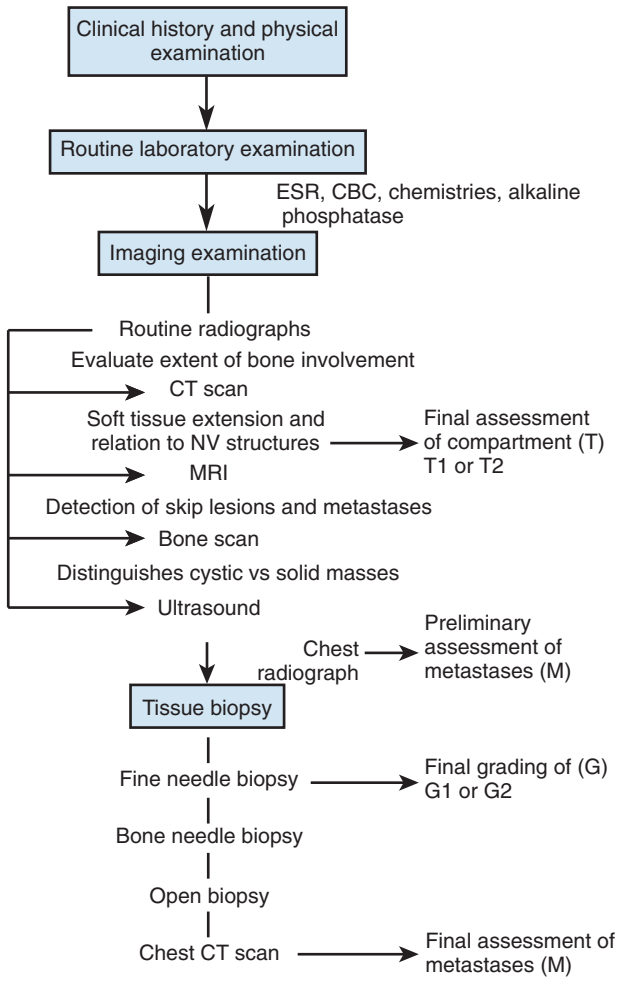

FIGURE 59.1 Suggested evaluation protocol for suspected musculoskeletal neoplasms. *CBC*, Complete blood count; *CT*, computed tomography; *ESR*, erythrocyte sedimentation rate; *MRI*, magnetic resonance imaging; *NV*, neurovascular.

Laboratory Studies

Laboratory studies include determination of the levels of serum calcium, phosphorus, blood urea nitrogen, and creatinine to evaluate the possibility of metabolic bone disease. Serum alkaline phosphatase and lactate dehydrogenase levels are elevated in some malignancies. Serum immunoelectrophoresis assists in determining whether multiple myeloma is present. The hematologic profile and the erythrocyte sedimentation rate are abnormal in the presence of many neoplastic and infectious processes. Urinalysis may detect an occult renal cell carcinoma that can metastasize to the hand. Antinuclear antibodies and rheumatoid factor may be positive in patients who have upper extremity swelling secondary to rheumatoid disease.

Diagnostic Imaging

A variety of diagnostic imaging techniques permit analysis and localization of the size and extent of the lesion and its impingement on normal anatomy. Although imaging does not typically offer a specific diagnosis, it provides important clues in the evaluation, analysis, and workup of a specific patient.

Plain Radiographs

Plain radiographs afford the best possible resolution and detail of bone and adjacent soft tissues. The anatomic region in question should be fully visualized on all radiographs, and this is achieved by taking an adequate number of views. Plain radiographs are initially performed to assess the presence and location of bone involvement. They may also be the most specific radiologic test for bone tumors.

Computed Tomography

Although conventional radiographs offer considerable spatial information, the higher resolution of CT produces images that are specifically useful in localizing small tumors within a bone and in identifying soft tissue extension or calcification within such growths. Because of its ability to discriminate varying densities, CT allows visual separation between the medullary canal, cortex, and surrounding soft tissues and thus often provides critical information concerning anatomic location (T) for tumor staging. Plain chest radiographs are always obtained before performing a biopsy on a suspected malignancy; chest CT scans are useful for staging histologically defined malignant tumors but are not routinely used for prebiopsy screening studies.

Scintigraphy

Radionuclide "bone scan" imaging can be very helpful in detecting primary and metastatic tumors. However, the phenomenon of increased radiopharmaceutical pooling (increased uptake) in a particular bone or soft tissue area is not at all specific or diagnostic. The technique has two time-variable phases. Within minutes after injection, conditions associated with increased vascularity show abnormally high uptake (i.e., trauma, infection, and neoplasia). Later, the isotopes are actively concentrated; in the skeleton, pooling occurs in woven (new) bone, so any process that forms immature bone would be associated with increased uptake on films taken 2 or 3 h after injection. Radioisotope scans are probably the most helpful to demonstrate lesions that may not have been suspected clinically or in anatomic sites not seen on initial images that focused only on the symptomatic region. These findings can be important in patient management, and they have the potential to alter biopsy or therapeutic plans significantly.

Magnetic Resonance Imaging

MRI is a technique that depends on sophisticated computers to produce excellent delineation of soft tissue contrast, as well as images in the axial, coronal, and sagittal planes. For MRI studies, electromagnets generate strong fields that cause cellular nuclei to "wobble" or "vibrate" at specific frequencies. A number of technical factors affect the MRI signal, including echo time (TE), pulse or repetition time (TR), longitudinal or spin-lattice relaxation (T1), and spin–spin relaxation (T2).

The majority of soft tissue tumors have a low signal intensity (i.e., appear darker) on T1-weighted scans and a high signal intensity (i.e., appear brighter or whiter) on T2-weighted studies. Specific problems, such as hematoma, lipoma (or liposarcoma), hemangioma, or conditions that involve hemorrhage into an existing tumor zone, are known to have high signal intensity on Tl-weighted scans. Obviously, the potential value of MRI is diminished in a region recently subjected to biopsy, trauma, or other surgery.

MRI is a superior imaging technique for assessment of the soft tissue extent of disease and is particularly beneficial in the evaluation of soft tissue sarcoma. The extent of intramedullary bone involvement also can be readily determined. This facilitates preoperative planning of the bone transection level during resection and may aid in identification of skip metastases that might otherwise not be identified. High-resolution CT offers the benefit of more accurate assessment of cortical bone involvement and may be the preferred technique for evaluating lesions involving the cortex of a given bone. CT is particularly beneficial in identifying occult osteoid osteomas.

Sonography

Sonograms produce images from a differential pattern of transmitted and received echoes. When compared with CT and MRI, sonography produces less detail with respect to precise anatomic relationships and tumor margins. The echo patterns of solid masses are nonspecific, but fluid-filled lesions can easily be differentiated from solid tumors. Sonograms are extremely inexpensive in comparison to the cost of CTs and MRIs and may be more useful than either for distinguishing reactive and cystic processes. Ultrasound guidance can be particularly useful for core needle biopsy of soft tissue lesions.

Biopsy

Biopsy is the last stage of diagnostic management. Such surgery should be planned as carefully as the definitive operation.[134,180] The exact technique used is influenced by the history, location, and size of the mass, as well as the experience of the surgeon and pathologist.

Needle Biopsy

Core needle biopsy has a limited role in the diagnosis of lesions in the hand and upper extremity. It can be useful in the assessment of subcutaneous lesions or in confirming the histology of a recurrent or metastatic lesion. Needle biopsy produces only a small and often fragmented tissue sample that may be

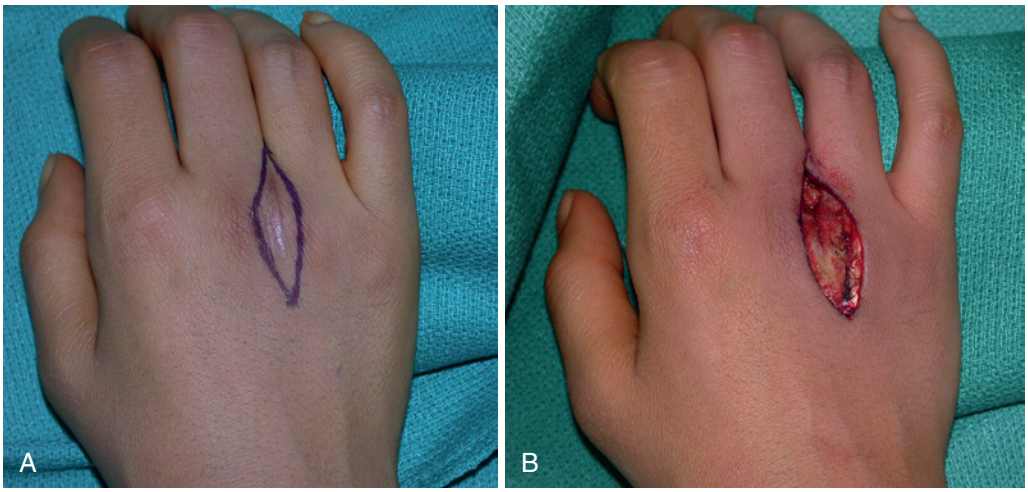

FIGURE 59.2 An open incisional biopsy was performed for a hand lesion. The biopsy site is contaminated with tumor cells **(A)**; the incision is oriented longitudinally and will be excised as part of the definitive procedure performed later **(B)**.

impossible to diagnose or grade accurately. Even if the core biopsy sample seems to clearly be diagnosable, the tissue volume may not be representative of the tumor and could lead to the possibility of overgrading or undermanagement.

Open Biopsy

Open surgical biopsy is a complex procedure, but one that plays a critical role in determining treatment outcome for aggressive and malignant tumors.[134,180,181] During the biopsy, the patient and surgeon must be prepared for the unexpected. Institutions or clinicians who are not prepared or able to complete all diagnostic studies and also provide definitive surgical and adjunctive medical management are best advised to refer patients *before* the biopsy is performed.

Hand surgery is most safely and efficiently performed in a bloodless field. The use of a pneumatic tourniquet is acceptable during both open biopsy and surgical treatment of tumors and neoplasms. Exsanguination of the limb before biopsy is contraindicated before inflation of the tourniquet because of the risk of seeding or dislodging tumor cells. An entirely satisfactory field is achievable by elevating the arm for 1 to 2 minutes before inflating the tourniquet. Likewise, the use of intravenous anesthesia (i.e., Bier block technique), a method that also requires pretourniquet exsanguination, is not appropriate for tumor biopsy or treatment of aggressive bone or soft tissue neoplasms.

A frozen section is necessary at the time that the biopsy is performed to determine whether an adequate specimen has been sampled so that permanent light and special microscopic evaluations can be carried out subsequently. It is rare to find a pathologist who can consistently provide accurate histologic analysis of a frozen specimen dependable enough to begin treatment.[134,181] The definitive treatment plan for malignant lesions is best decided on only after the results of all permanent sections, electron microscopic studies, and special tissue techniques are complete and reported. All biopsy specimens should be cultured, and all cultures should have tissue sent for microscopic examination.

Although plain chest radiographs are taken before biopsy, chest CT is performed to stage a diagnosed lesion. If the tumor is aggressive or malignant, the biopsy tract itself will be contaminated with tumor cells and must later be excised en bloc with the subsequent resection or amputation specimen. Preferred biopsy incisions are therefore longitudinal and carefully placed to permit complete excision of them without having to extend a dissection margin simply to accommodate a badly placed incision. As a simple rule, the biopsy should be placed in line with or immediately parallel to the incision that may be required for later attempted limb salvage (Figure 59.2). Transverse and Bruner-type incisions are specifically to be avoided.

Incisional Biopsy

Incisional biopsy is frequently the most appropriate technique for the diagnosis of bone and soft tissue masses. It requires excision of an adequate tissue sample that is minimally manipulated. Frozen sections are important to determine the adequacy of the specimen. The biopsy incision is located so that it affords the most direct route to the tumor, thereby ensuring that the fewest tissue planes are disturbed or contaminated.

The correct surgical technique for biopsy is different from standard typical surgical dissections. Biopsy involves a direct approach using a longitudinal incision through muscle and other tissues that overlie the mass. Biopsy technique does not include spreading or extensive and vigorous retraction, which has the potential to contaminate a widened area. However, adequate visualization during biopsy, as in any operation, is critical. Because the biopsy tract is contaminated with cells, an approach through a muscle sacrifices only one plane, whereas spreading techniques (i.e., moving muscles aside) contaminate not only the muscle that is retracted but also all surrounding structures. Perfect postsurgical hemostasis is essential to avoid hematoma, which can lead to the spread of cells beyond the primary site and biopsy tract. Once the wound is dry and hemostasis is secure after release of the tourniquet, the wound is closed, not drained. Other than taking steps to avoid pathologic fracture, postbiopsy surgical care is routine while the surgeon awaits the definitive histologic findings.

Excisional Biopsy

Excisional biopsy involves complete removal of a lesion through the reactive zone. An example would be excision of a giant cell

tumor of a tendon sheath or a lipoma. It is a technique that should be reserved for very small lesions (with a diameter of <1-2 cm) to avoid compromising subsequent surgical procedures. Extensive contamination of the operative field occurs with this type of biopsy. If this is done for a large tumor, the extent of contamination may increase the need for soft tissue coverage and increase the risk for both positive margins at definitive resection and subsequent local recurrence. Extensive contamination may preclude subsequent limb salvage and may commit the patient specifically to amputation as a result of the biopsy.

Primary Wide Excision

This type of biopsy requires excision of the tumor with a wide margin or cuff of surrounding normal, nonreactive, healthy tissue. This is an excellent oncologic procedure but requires sacrifice of an extensive amount of normal tissue. Primary wide excision is usually best reserved for very small lesions in which suspicion of malignancy is high and the risk of soft tissue contamination with other forms of biopsy is excessive, as might occur in the carpal tunnel. The decision of when to perform this type of biopsy is generally best made with the assistance of or by a musculoskeletal oncologist.

CRITICAL POINTS *Open Biopsy of Forearm and Hand Tumors*

Indication

- Lesions that cannot be diagnosed as benign on clinical and radiographic grounds.

Technical Points

- Review the case with a pathologist before biopsy and confirm the availability of that person.
- Draw limb salvage incisions or amputation flaps at the time of biopsy.
- Place a longitudinal biopsy incision mark in line with the limb salvage incision.
- Confirm that the biopsy incision will not compromise subsequent amputation flaps.
- Elevate the arm only for exsanguination without using an Esmarch bandage.
- Inflate the tourniquet to ensure a bloodless field.
- Dissect through one anatomic plane or muscle to limit the contamination field.
- Avoid extensive flaps or retraction to limit contamination.
- Incise directly into the tumor to remove a wedge for frozen section and permanent analysis.
- Culture all biopsy specimens.
- Confirm the presence of adequate lesional tissue on the frozen section.
- In most cases, defer definitive treatment of malignant lesions until permanent analysis confirms the diagnosis.
- Obtain perfect hemostasis before closure.
- If a drain is used, it should exit the patient immediately in line with the incision to limit contamination.
- Place sutures close to the wound edges to avoid additional skin contamination.
- Apply a bulky compressive dressing to avoid hematoma.

Postoperative Care

- Limit use of the limb until definitive treatment.

DEFINITIVE TREATMENT

General Plan of Tumor Excision

Benign Tumors

Nonaggressive, benign neoplasms are usually removed simply by marginal or intralesional operations such as curettage. If there is a question about the adequacy of resection of the tissue margins and the diagnosis is already confirmed, a frozen section may be of great assistance for intraoperative sampling of the margins.

Malignant Tumors

In the management of malignancies of the upper limb, preservation of function is secondary to eradication of the disease process. Hand surgeons who undertake management of a neoplasm must have a thorough understanding of the tumor's biologic behavior, its patterns of local and metastatic spread, and its response to radiotherapy and chemotherapy. Radiation therapy and chemotherapy may allow the surgeon to use less radical tumor margins so that amputation can be avoided and function maintained.[78,125] However, the risk of unnecessary sacrifice of tissue must be balanced against the need for adequate resection because local recurrence of sarcoma sometimes carries a grave prognosis. One of the major problems in assessing outcome has been the lack of a common procedural language regarding surgical methods; however, uniform use of the Enneking terminology, as recommended by the MSTS, provides such a means of communication (see Table 59.2).[53]

Treatment should not begin until a neoplasm has been diagnosed definitively and the results of all preoperative studies, including biopsy, are verified. The assumption that a problem can be "handled" by relatively simple extirpation in the absence of complete diagnostic data is neither justified nor defensible. The risks associated with soft tissue extension from a tumor-contaminated field are too great. Because most tumors are benign, cystic, and nonproblematic, the outcome of the few that are aggressive or truly malignant may be disastrous if surgeons become too casual or complacent. When a malignant tumor or aggressive nonmalignant lesion is identified, carefully planned treatment is required not only to preserve the maximal degree of hand function but also to save the patient's life. Function is secondary to survival.[38,70,134,183]

Hand surgeons who seek to treat a specific neoplasm must have not only a general understanding of the concepts and principles of tumor management but also detailed knowledge of the tumor's biology, histologic and clinical behavior, tendency to spread locally and widely, and potential response to adjunctive measures. All these considerations can have a significant bearing on proposed surgical margins and long-term function.[38,125,190] An inadequate resection that permits local recurrence may condemn the patient to a far worse prognosis than would otherwise have occurred.[55]

According to MSTS criteria, compartmental resection and radical excision cannot always be applied to the hand. Most hand tumors occur in spaces rather than in compartments, and although metacarpal excisions may remove a compartment for a stage IA or IIA bone tumor, extirpation of the entire flexor surface or above-elbow amputation would be required to remove the compartment if the neoplasm arose on a digital flexor. Presently, there are no data to support a conclusion that

the MSTS definitions should be applied uniformly to all parts of an acral compartment. Because the flexor tenosynovium is continuous in the thumb and little finger, but not in the index, middle, and ring fingers, there may be differences in management that can be used prudently with such variations in location.

A soft tissue tumor that develops along the dorsum of the wrist requires surgical extirpation of the extensors of several fingers or the thumb (or both), but not necessarily the entire muscle compartment proximally or distally. Functional restoration can be achieved with tendon grafts or transfers or with free muscle flaps. True radical excision may be impractical if function of any kind is to be salvaged in patients with lesions of the hand and forearm, and it may be that a 1- to 2-cm margin of normal tissue, especially with tumors that are sensitive to adjunctive measures, will be safe and allow secondary reconstruction.[158,162,183] The extent of surgical resection for aggressive tumors is dependent on their histologic diagnosis, location, and size. Remote tissue reconstruction, except when provided by microvascular transfer, should be avoided because of the risk of transferring malignant cells using tissue or flap pedicles.

Principles of Excision for Specific Sites

Distal Phalanx

Malignant soft tissue tumors in the distal phalanx commonly involve skin and bone (Figure 59.3). Safe removal may require excision at the distal interphalangeal (DIP) joint; occasionally, a lesser segment may need to be excised when the lesion, such as a nail bed carcinoma, is more superficial and slow growing. A small portion of dorsal or palmar skin might be used as a local flap to cover the middle phalanx after disarticulation of the DIP joint. In such instances, the distal phalanx and DIP joint are sacrificed if the lesion involves or threatens enough tissue while retaining the tissues at a safe distance from the tumor site. Indeed, if the tumor involves both the dorsal and palmar surfaces of soft tissue as well as bone, a more proximal transosseous amputation through the middle phalanx is required. In every case, the proximal end of the excision margin should be sampled and inspected by frozen section at surgery and later by permanent-technique histology to ensure the safety of the level of removal.

Malignant distal phalangeal lesions require removal with an appropriate cuff of contiguous soft tissue. Lower-grade bone tumors can be managed by distal phalangeal amputation that includes a soft tissue cuff 1 to 2 cm proximal to the intraosseous tumor, a level that requires transosseous resection through the middle phalanx. It is unlikely that such lesions can be safely removed by DIP disarticulation alone. Patients with pathologic fractures or extracompartmental extension usually require removal of the finger at or proximal to the proximal interphalangeal (PIP) level or even ray resection.

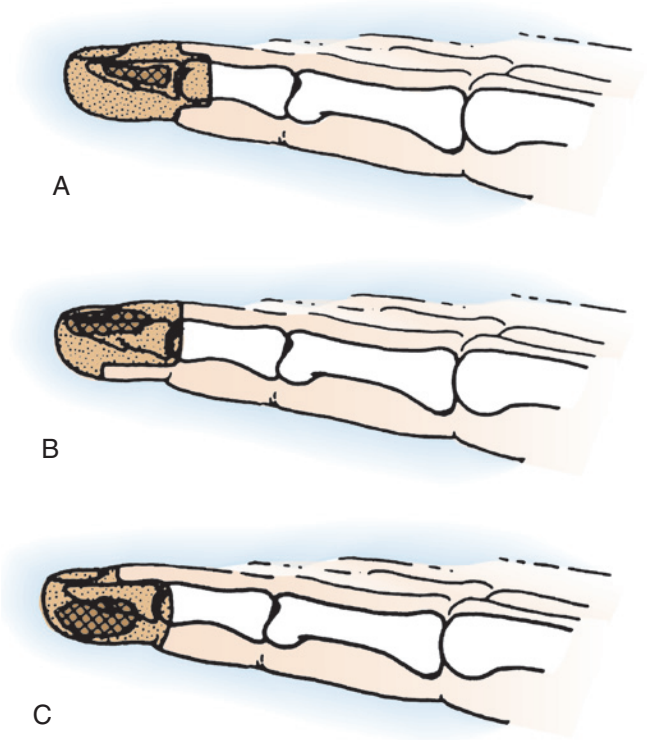

FIGURE 59.3 Malignant lesions of the terminal segment of the finger generally require amputation at or proximal to the DIP joint. **A,** Intraosseous distal phalangeal tumors are amputated at or proximal to the joint along with combined dorsal and volar flap closure. **B,** Dorsal lesions are treated by appropriate tumor excision with volar flap closure. **C,** After removal of a palmar tumor, dorsal flap closure may be possible.

Middle Phalanx

Malignant and aggressive soft tissue tumors in the middle phalanx and those proximal to the region of the DIP joint require amputation at the metacarpophalangeal (MP) joint or metacarpal level or ray resection (Figure 59.4). In this instance, MP joint disarticulation should allow at least a 2- to 3-cm margin of normal tissue; however, functional and aesthetic considerations strongly recommend ray resection (Figure 59.5). In theory, bone tumors involving the proximal and middle phalanges can be excised and replaced with bone graft if the lesion is not aggressive and has not extended into soft tissues. However, ray resection is actually a far more practical and functional alternative if both the proximal and middle phalanges are involved. For malignant tumors that have spread beyond bone because of fracture or slow, progressive extension, ray amputation is clearly indicated. MP joint disarticulation is rarely a safe, practical, functional, or aesthetic choice for treating tumors at these levels.

Thumb lesions are unique. Although lesions distal to the interphalangeal joint are often best treated by amputation,

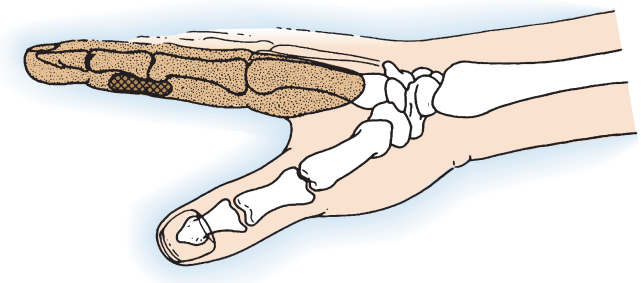

FIGURE 59.4 Tumors of soft tissue at the middle phalangeal and proximal interphalangeal joint level are best treated by ray resection.

FIGURE 59.5 **A,** Axial magnetic resonance imaging demonstrating synovial sarcoma following radiation involving third and fourth metacarpal. **B,** Fourth ray resection was performed with en bloc resection of the diaphyseal third metacarpal. **C, D,** Volar and dorsal incisions for ray amputation and fillet flap marked. lesions at the proximal phalanx level may be amenable to wide excision and extensive reconstruction. This can be done safely while adhering to the principles of wide excision and subsequent extensive reconstruction, which may require bone and microsurgical soft tissue reconstruction.[141]

First Metacarpal

First metacarpal malignancies can be treated by wide excision and autogenous or allograft replacement (Figure 59.6). Achieving wide margins may require excision of surrounding soft tissues and adjacent joints or bones. Reconstruction with metacarpal allograft, or by fibula or iliac autograft, may be considered in appropriate circumstances. Autografting should be done with a second, separate surgical setup and clean gowns and gloves to avoid cross contamination of the bone donor site. Because osteoarticular allografts may be unstable, arthrodesis may be required at the trapeziometacarpal articulation. Alternatively, suspension may be appropriate if trapezium resection is required.

With extensive soft tissue contamination, more radical resection may be required, including the entire first ray and possibly portions of the web and second metacarpal, to gain a safe margin. If part of the second metacarpal is resected, the "floating index finger" thereby produced can be considered for direct pollicization if sacrifice of the entire second ray is not required.

Finger Metacarpals

Aggressive and malignant bone tumors of the second through fifth metacarpals generally require en bloc bone excision. A more important treatment decision may be whether removal of

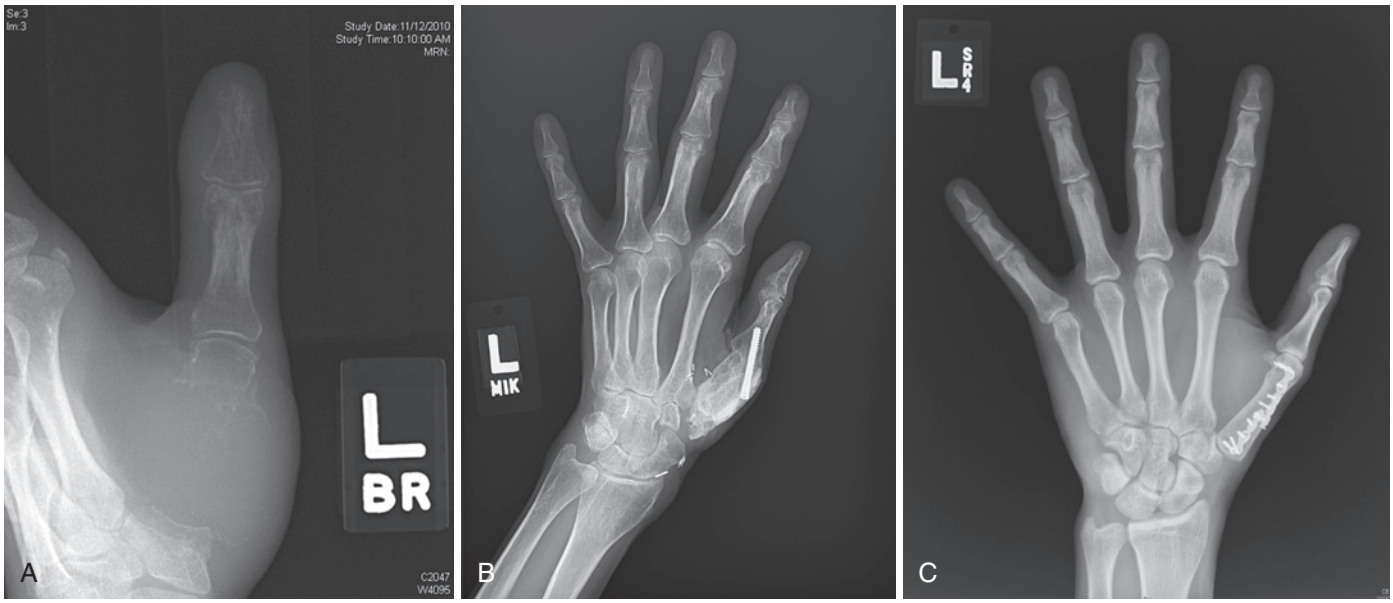

FIGURE 59.6 **A,** A grade 3 giant cell tumor (GCT) of the thumb metacarpal is treated with wide extraarticular resection including the trapezium and base of the proximal phalanx. **B,** Thumb metacarpal is reconstructed with a large iliac crest graft with metacarpophalangeal joint arthrodesis and proximal suspension. **C,** Long-term follow-up of diaphyseal segment reconstruction using iliac crest bone graft for a grade 2 chondrosarcoma. Small blade plates facilitate internal fixation of small periarticular fragments.

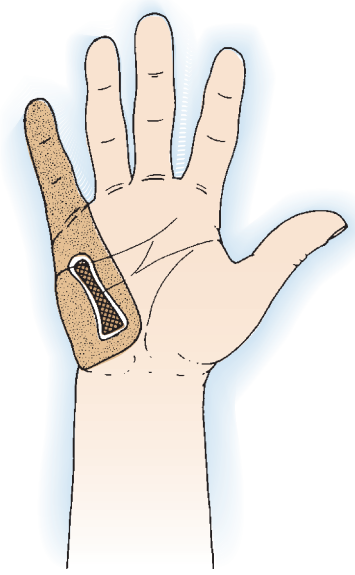

FIGURE 59.7 Malignant tumors of the fifth metacarpal can be treated by ray excision.

one metacarpal alone is possible or whether removal of an entire ray or pair of rays is best. Ray excision is usually best for lesions of the second and fifth metacarpals (Figure 59.7). With the additional consideration of ray transposition, the principles governing removal of the third and fourth rays are no different from those governing the second and fifth. If bone graft has been used for reconstruction, carpometacarpal arthrodesis and MP ligament reconstruction or silicone arthroplasty may be practical. Whatever level is chosen for reconstruction, it is essential that an adequate, safe margin of normal tissue first be excised en bloc with the tumor.

Aggressive tumors of the second through fifth metacarpals that have invaded soft tissue or sustained pathologic fractures often require excision of not only the involved ray but also the contiguous ray or rays radial and ulnar to the involved digit. A malignant tumor of the second metacarpal that extends into soft tissues may necessitate removal of the second and third rays or the first through third rays while preserving the soft tissue of the middle finger as a fillet flap to resurface the radial side of the hand. A similar technique can be used for tumors of the ulnar side of the hand. If the second, third, and fourth rays must be removed, the best strategy is usually to osteotomize and supinate the fifth metacarpal to provide effective oppositional pinch and grasp with the thumb. If a tumor of the fourth metacarpal requires removal of the third through fifth rays, the radial aspect of the middle finger or a fillet of that digit on its radial neurovascular pedicle can be used to close the ulnar side of the hand. Tumors of the fifth metacarpal may require excision of the fourth and fifth rays. Skin coverage may be possible by using a fillet flap from the ring finger.

If a malignant tumor has broken into the midpalm and extends across the metacarpals, removal of all digital rays may be needed to gain an adequate soft tissue margin. Retention of a sensate and relatively mobile thumb may be considerably more aesthetic and functionally satisfactory than a forearm- or wrist-level amputation. However, if a tumor extends proximally from the metacarpal level, a more proximal level of hand, wrist, or forearm amputation is required for safe tumor management.

Soft tissue tumors in the palm or on the dorsum of the hand generally require at least partial hand amputation. If treated by only local or limited excision, the chance of recurrence and metastasis may be enhanced; below-elbow amputation is necessary to treat these larger tumors. It is unusual for an aggressive soft tissue tumor to be adequately removed by a truly local en bloc excision. At a minimum, aggressive soft tissue tumors, such

as bone tumors, require ray resection or removal of multiple rays (Figures 59.8 through 59.10). Central palmar lesions generally require sacrifice of three rays; those on the border are more likely than those in the center to be salvageable by removing just two rays. In the presence of proximal, broader, and larger lesions, all four digits or the entire hand may have to be sacrificed to save the patient.

Wrist and Distal Forearm

Malignancies of the proximal palmar surface of the hand and volar aspect of the wrist often require amputation. A dissection that attempts to "salvage" the median nerve or one or two flexors in the middle of an expanding tumor or reactive zone is only likely to spread the disease. Correct surgical and medical principles for tumor removal and care should be taken (Figures 59.11 through 59.13).

Tumors that arise on the dorsum may allow preservation of the hand if staging studies show that the lesion has not penetrated into the palm and the excision margin verifies a safe plane of normal tissue. Isolated intraosseous carpal lesions that have not invaded soft tissue are rare but can be excised locally. The carpal bones are intraarticular, so the onset of symptoms is generally associated with synovitis and joint invasion; therefore, below-elbow amputation or complete en bloc excision of the entire radiocarpal articulation and carpus is likely to be necessary.

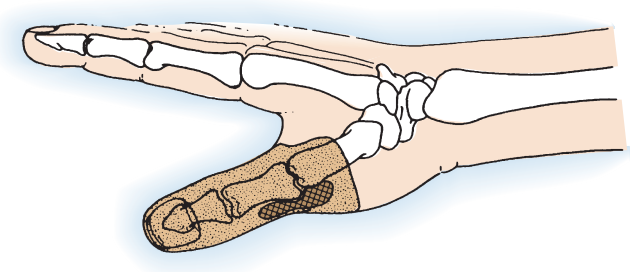

FIGURE 59.8 Malignant soft tissue tumors adjacent to the thumb metacarpophalangeal joint require amputation through the metacarpal. More aggressive and extensive tumors may require removal of the entire ray, possibly contiguous with the second metacarpal.

Growths on the volar aspect of the distal part of the forearm frequently require above- or below-elbow amputation because it is not easy to excise a tumor adequately and still preserve function in and distal to this region after removal of all flexor muscles and tendons, the median and ulnar nerves, and vessels. If a tumor arises in a location that does not specifically involve the ulnar nerve and artery, it may be possible to save a portion of the hand and wrist along with the neurovascular bundle and to consider later reconstruction after longitudinal hemiamputation. Treatment of tumors arising on the radial side of the distal end of the forearm varies according to the size and exact location of the lesion (Figure 59.14). In many situations, as is true of lesions on the volar side, amputation is probably preferable when all criteria are considered. Tumors on the extreme ulnar side of the wrist can be handled in a way that mirrors those on the radial aspect, although lesions in the extreme end of the ulna may be amenable to wide excision of the distal ulna (Figure 59.15).

Intracompartmental lesions within the distal radius or ulna can be treated by wide excision of the bone and arthrodesis or autograft replacement. In such situations, transosseous excision must include biopsy of the medullary canal from the retained segment or segments. When tumors have invaded tissues or crossed compartments extensively, above- or below-elbow amputation may be required.

Wherever a tumor is located, treatment must be individualized to achieve the goal of functional restoration without risking local recurrence and later distant spread. Because of a lack of control over the site and the origin of the neoplasm, the surgeon's responsibility is confined to intelligent management and treatment by adhering to the proper principles of care.

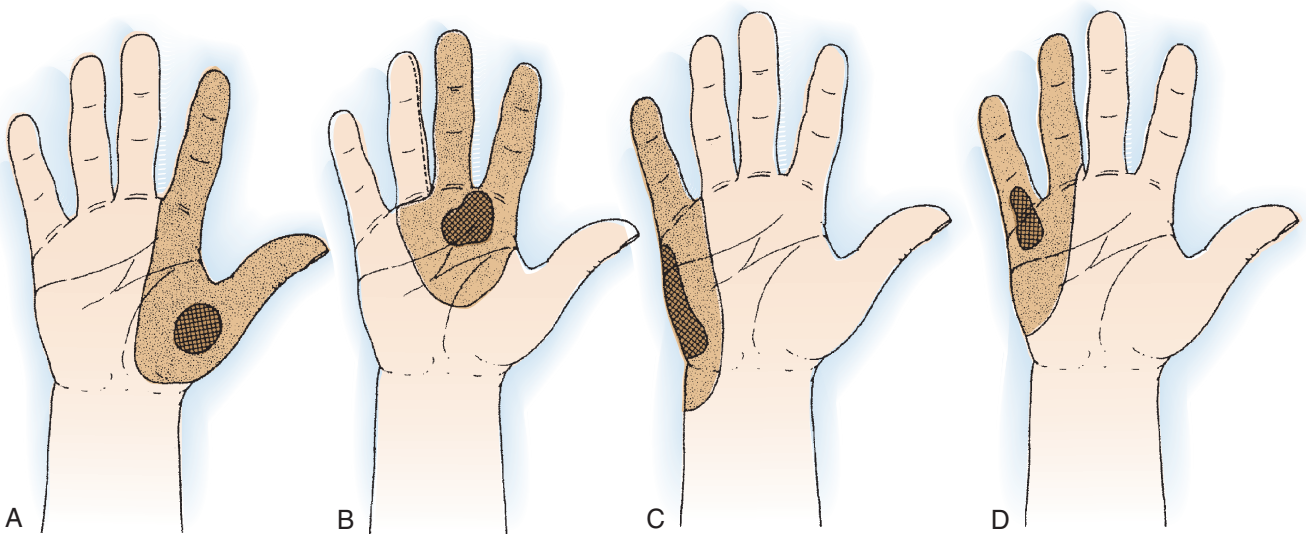

FIGURE 59.9 **A,** Tumors located between the first and second metacarpals may require amputation of both rays for adequate local control. **B,** Tumors between the second and third metacarpals require removal of both rays. **C,** Lesions of the ulnar border of the hand can be treated by resection of the fifth ray and local flap or skin graft closure. **D,** Large and more aggressive lesions or those extending more radially may need removal of both the fourth and fifth rays.

BENIGN SOFT TISSUE LESIONS

Ganglions and Mucous Cysts

Clinical Characteristics

Ganglion cysts are the most common soft tissue tumors of the hand. These mucin-filled cysts are usually attached to the adjacent underlying joint capsule, tendon, or tendon sheath. Ganglions are most prevalent in women and generally occur (70%) between the second and fourth decades of life. They are not rare in children[201] and have been reported from the first to the eighth decades. Ganglions usually occur singly and in very specific locations; however, they have been reported to arise from almost every joint of the hand and wrist (Table 59.4). The less common ganglions are often associated with other conditions of the hand (e.g., bossing of the second and third carpometacarpal joints, de Quervain disease, and Heberden nodes of the DIP joint).

Ganglion cysts have also been reported to cause clinically symptomatic pressure on the median and ulnar nerves of the

hand.[177] Because of their high incidence and prevalence, ganglion cysts should readily be recognized by most hand surgeons. Other conditions that cause diffuse swelling over the dorsum of the wrist, such as extensor tenosynovitis, lipomas, and other hand tumors, also must be considered in the differential diagnosis. The history, physical examination, techniques of transillumination, and aspiration should allow a conclusive diagnosis in most instances.

Patients usually seek medical attention because of the cosmetic appearance of the mass, pain, weakness, and concern for potential malignancy. A specific antecedent traumatic event is present in at least 10% of cases, and repeated minor trauma may be an etiologic factor in their development. There is no obvious correlation with patient occupation. Malignant degeneration has never been reported; however, malignant soft tissue tumors are frequently misdiagnosed as ganglion cysts. Ganglions can appear quite suddenly or develop over a period of several months. They may subside with rest, enlarge with activity, and rupture or disappear spontaneously. Although

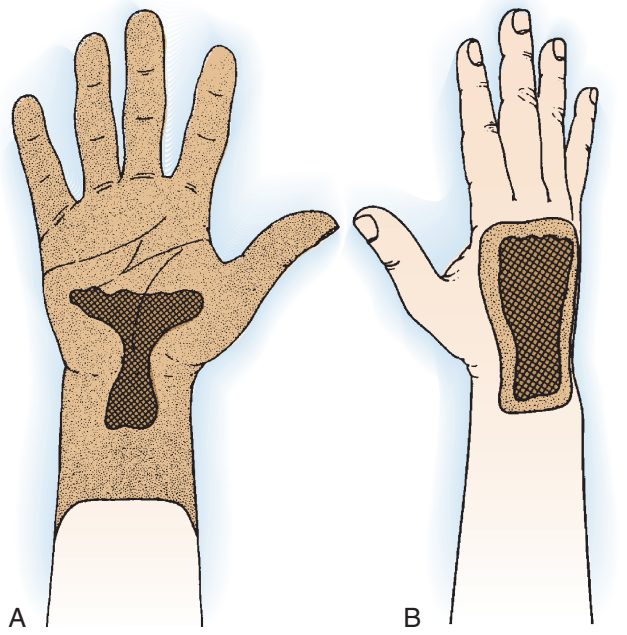

FIGURE 59.11 **A,** Tumors on the proximal volar aspect of the palm often involve the flexor tendons and median and ulnar nerves; forearm- or wrist-level amputation is usually required. **B,** Lesions on the dorsum of the hand may not necessarily invade vital neurovascular structures and can be adequately resected en bloc, followed by secondary reconstruction.

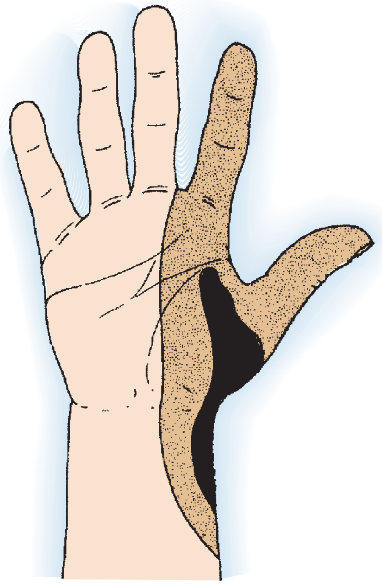

FIGURE 59.13 Aggressive tumors of the radial side of the distal part of the forearm may require amputation of the thumb and index rays, as well as the contiguous radial side of the wrist at a minimum.

recurrences are infrequent with proper excision,[9,66] >50% may recur if incompletely excised.

Radiographs of the involved region are often unremarkable, although intraosseous cysts are occasionally present at the wrist. Osteoarthritic changes are commonly seen with cysts at the DIP or carpometacarpal joints. Communication between the wrist joint and cyst has been demonstrated with arthrograms but not with cystograms. A one-way valvular mechanism[96] has therefore been postulated to connect the wrist joint to the cyst.

ANATOMY

The microscopic description of ganglions is well known. The main cyst may be single or multiloculated and appears smooth, white, and translucent. The wall is made up of compressed collagen fibers and is sparsely lined with flattened cells without evidence of an epithelial or synovial lining.

The capsular attachment of the main cyst reveals mucin-filled "clefts," which have been shown by serial sections to intercommunicate[9] through a tortuous continuous duct connecting the main cyst with the adjacent underlying joint. The stroma surrounding the intracapsular ducts may show tightly packed collagen fibers or sparsely cellular areas with broken collagen fibers and mucin-filled intercellular and extracellular lakes. No inflammatory reaction or mitotic activity has been noted.

The contents of the cyst are characterized by a highly viscous, clear, sticky, jelly-like mucin made up of glucosamine, albumin, globulin, and high concentrations of hyaluronic acid. In some cases, the mucin may be blood tinged. The contents of the cyst are decidedly more viscous than normal joint fluid.

Pathogenesis

Since Hippocrates offered the first recorded description of "knots" of tissue containing "mucoid flesh," numerous speculative theories with little scientific basis have abounded. This became especially apparent when 18th- and 19th-century anatomists offered the following hypotheses: (1) synovial herniation (Eller, 1746) or rupture through the tendon sheath, (2) synovial dermoid or rest caused by "arthrogenesis blastoma cell nests" or embryonic periarticular tissue (Hoeftman, 1876), (3) new growths from synovial membranes (Henle, 1847), and (4) modifications of bursae or degenerative cysts (Vogt, 1881).

Until recently, the most widely accepted theory, initially postulated by Ledderhose (1893) and popularized by Carp and Stout,[32] was mucoid degeneration. The fibrillation of collagen fibers, accumulation of intercellular and extracellular mucin, and decreased collagen fibers and stroma cells supported this

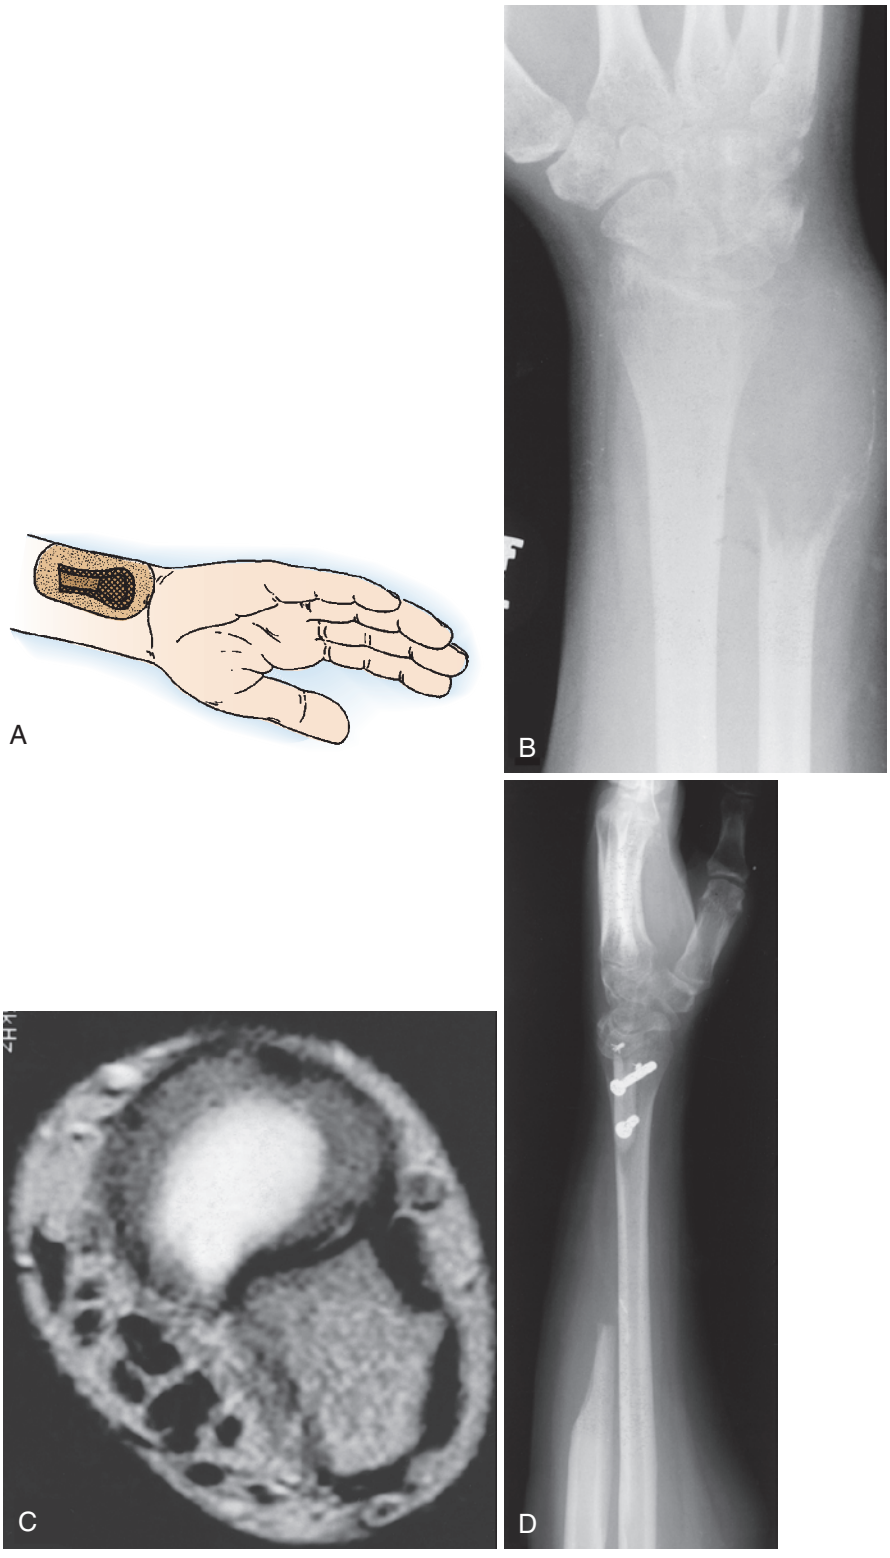

FIGURE 59.15 **A,** Intraosseous tumors of the distal ulna can be managed by en bloc excision. No bone reconstruction is needed in most cases. Tumors with soft tissue extension **(B, C)** may require excision of the ulnar cortex of the radius en bloc with the ulna, as was required with this malignant fibrous histiocytoma. **D,** A portion of the remaining ulna was used to augment the radius and support the lunate facet.

theory. Mucoid degeneration does not, however, explain why the degenerative process is self-limited and solitary and generally occurs in adolescents and young adults and why the fluid recurs after aspiration or incomplete excision.

Nonoperative Treatment

Nonsurgical methods of treatment are usually considered initially because of the limited associated morbidity and possibility of success. Nonsurgical treatment has included digital pressure, injections of hyaluronidase or sclerosing solutions, subcutaneous tenotome dissection, and cross fixation with a heavy suture. Historical folk medicine has mentioned rupture with a mallet or Bible, methods that need not be considered except for their historical interest. Observation has been advocated in the pediatric population because of the high likelihood of spontaneous resolution.[201]

Aspiration of the ganglion, puncture of the cyst wall, and instillation of lidocaine (Xylocaine) and betamethasone (Celestone) into the capsule or tendon sheath attachments reduce the mass and may alleviate symptoms for varying periods.[186] Aspiration may provide long-term relief and has been reported to be effective in 20 to 30% of patients with wrist ganglions. Injection and aspiration of volar wrist ganglions must be approached with caution because of the proximity of the radial artery. Marked subcutaneous atrophy and skin depigmentation may be seen after injection with triamcinolone (Kenalog), which should be avoided.

The most effective nonsurgical treatment is patient reassurance. An explanation of the condition and assurance of its nonmalignant nature are often the only treatment sought or required. Surgery is best reserved for patients with persistently symptomatic ganglions.

Operative Treatment

Open procedures are most commonly done for excision of ganglion cysts. Treatment principles include attempts to minimize scar formation and loss of range of motion. Data on arthroscopic approaches to both dorsal and volar carpal ganglion cysts have been published.[90,130,148,179] The technique appears to be effective with a risk for local recurrence comparable to the historic risk for recurrence after open procedures. Recent comparative studies have evaluated the relative risks and benefits of open versus arthroscopic treatment and demonstrated similar outcomes.[52,101]

Dorsal Wrist Ganglion

Clinical Characteristics. The prototype of all ganglions of the hand is the dorsal wrist ganglion, which accounts for 60 to 70% of all hand and wrist ganglions. The main cyst is usually located directly over the scapholunate ligament (Figure 59.16) and is easily seen and diagnosed. The cyst may occur anywhere else between the extensor tendons, however, and can be connected to the ligament through a long pedicle (see Figure 59.16). Failure to identify this pedicle and excise its attachment to the scapholunate ligament increases the likelihood of recurrence. Careful preoperative palpation of the cyst with digital compression often reveals its extent and the direction of the pedicle. Transillumination or aspiration confirms the diagnosis preoperatively. Although ganglions have been reported in other carpal joints, they are rare and attachments to the scapholunate joint must be ruled out before a dissection is considered complete. Review of the patient's preoperative radiographs to rule out an interosseous component is wise.

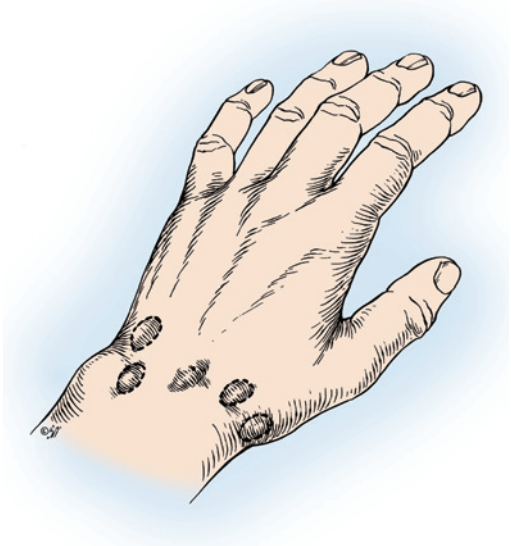

FIGURE 59.16 A few of the many possible locations of dorsal wrist ganglions. The most common site is directly over the scapholunate ligament. The others (*dashed circles*) are connected to the scapholunate ligament through an elongated pedicle. (Copyright © Elizabeth Martin.)

FIGURE 59.17 Transverse incision over the scapholunate ligament **(A)** used to expose the typical dorsal ganglion. An additional incision **(B)** was made to expose a more distant cyst. The main cyst and pedicle are mobilized, passed under the extensor tendons, and delivered through incision at **A**. (Copyright © Elizabeth Martin.)

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. Most dorsal ganglions can be approached through a transverse incision over the proximal carpal row, but a modified incision or second transverse incision may be necessary for ganglions not directly over the scapholunate ligament (Figure 59.17). The diagnosis of ganglion cyst should be made before commitment to a transverse incision because this type of incision is not readily incorporated into a limb-sparing

incision in the event of a subsequent diagnosis of a malignant soft tissue tumor. Typically, a dorsal ganglion appears between the extensor pollicis longus and extensor digitorum communis tendons, which are retracted radially and ulnarly, respectively (Figure 59.18).

The main cyst and its pedicle are mobilized down to the underlying joint capsule. With the wrist in volar flexion, the joint capsule is opened along the border of the radius and scaphoid's proximal pole (Figure 59.19). The capsule is elevated and retracted distally to expose the capsular attachments to the scapholunate ligament (Figure 59.20). Smaller intraarticular cysts are often seen attached to the scapholunate ligament. The capsular incision is then continued around the ganglion, but all capsular attachments to the ligament are left intact (Figure 59.21). The capsular incision is extended more laterally if any

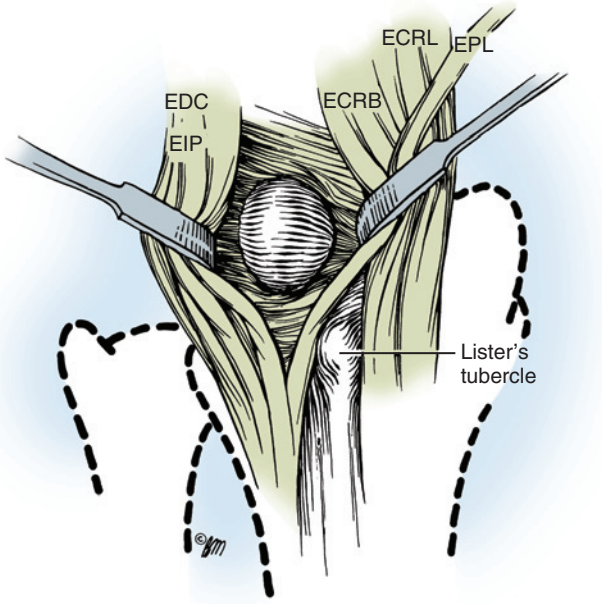

FIGURE 59.18 The dorsal ganglion exposed and mobilized between the extensor pollicis longus (EPL), extensor carpi radialis longus (ECRL), and extensor carpi radialis brevis (ECRB) radially and the extensor digitorum communis (EDC) and extensor indicis proprius (EIP) ulnarly. (Copyright © Elizabeth Martin.)

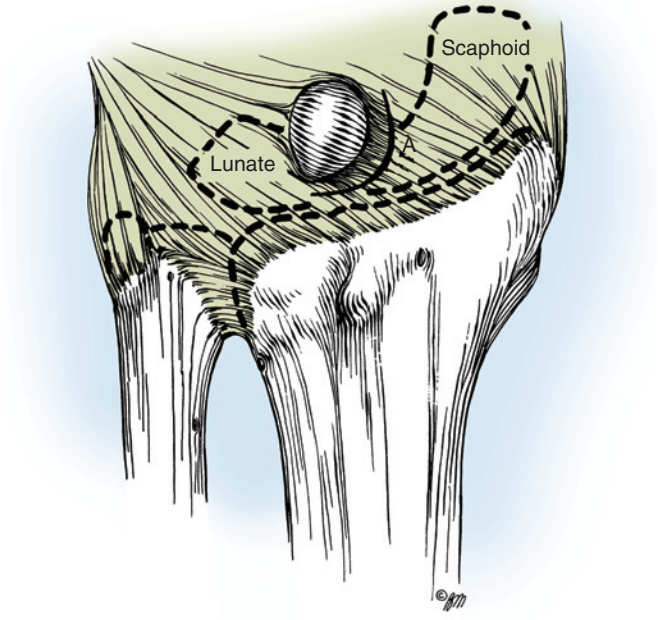

FIGURE 59.19 The initial incision through the joint capsule *(A)* to expose the scapholunate ligament attachments and intracapsular cysts *(B)*. (Copyright © Elizabeth Martin.)

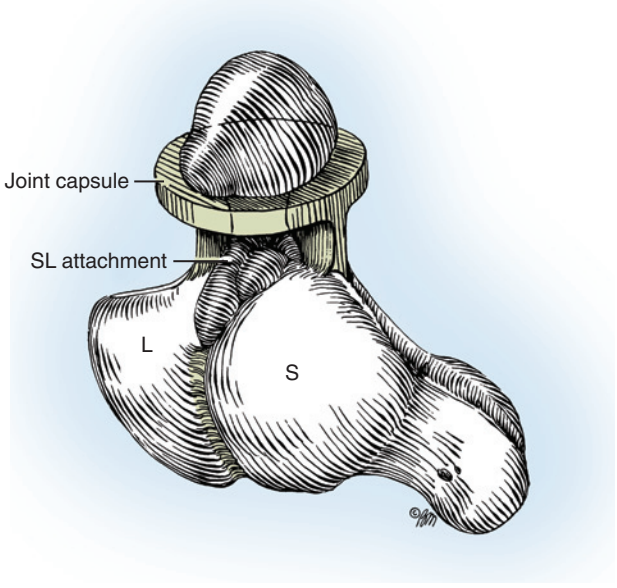

FIGURE 59.21 The ganglion and scapholunate (SL) attachments are isolated from the remaining, uninvolved joint capsule (not shown). *L*, Lunate; *S*, scaphoid. (Copyright © Elizabeth Martin.)

capsular ducts, which can be identified by small amounts of mucin drainage, are encountered during the dissection. The ganglion and its capsular attachments are then tangentially excised off the scapholunate ligament (Figure 59.22).

A small, mucin-filled duct is invariably seen piercing the transverse fibers of the scapholunate ligament. This duct appears to connect the underlying scapholunate joint with the main cyst. Synovial and capsular attachments along the distal margin of the scapholunate ligament are also excised to give an unobstructed view of the head and neck of the capitate (Figure 59.23). If the ganglion ruptures and its anatomic features are lost during the dissection, it should continue until all attachments to the scapholunate ligament have been excised. The excised portion of the joint capsule usually measures approximately 1.0 to 1.5 cm. It is neither necessary nor desirable to cut into the scapholunate ligament, nor is curettage of the scapholunate joint necessary.

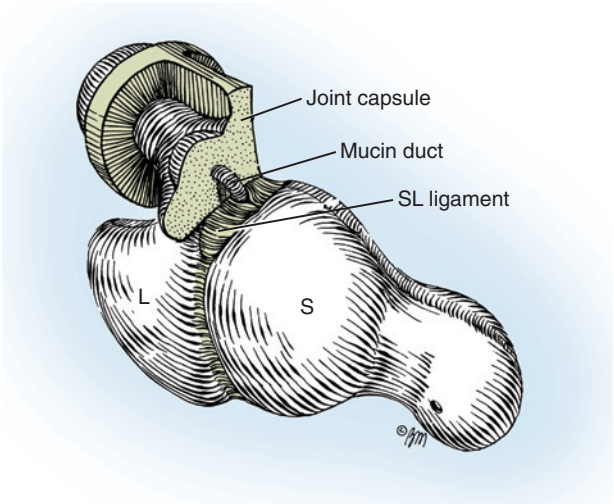

FIGURE 59.22 Tangential excision of the ganglion and attachments off the fibers of the scapholunate (SL) ligament. A minute mucin duct piercing the fibers of the SL is invariably cut during this dissection. *L*, Lunate; *S*, scaphoid. (Copyright © Elizabeth Martin.)

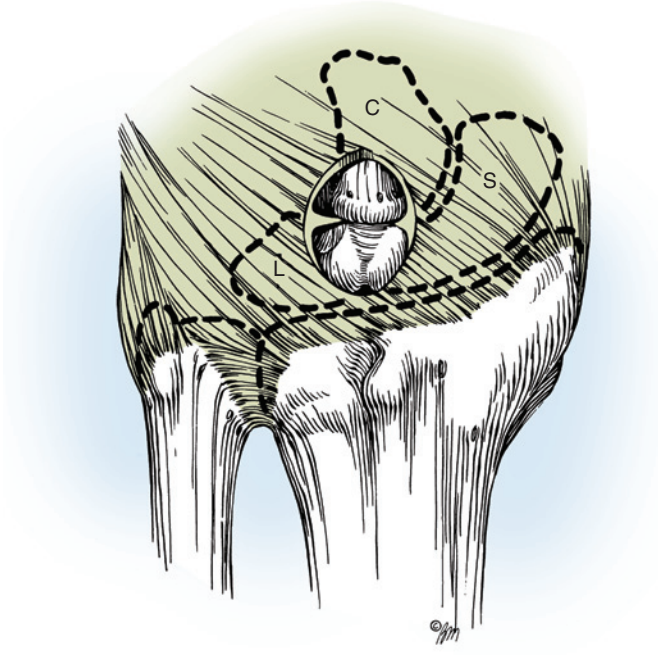

FIGURE 59.23 Completed excision of all attachments to the scapholunate (SL) ligament and the immediate vicinity. Synovial tissue between the ligament and the head of the capitate (C) has also been excised. Note that the SLs remain intact. *L*, Lunate; *S*, scaphoid. (Copyright © Elizabeth Martin.)

The tourniquet is released and hemostasis obtained, then the wound is closed and a dressing applied. Attempts to close the joint capsule either primarily or with fibrous flaps are contraindicated. Subcuticular closure with a monofilament, nonabsorbable pull-out suture may minimize scar formation. Splinting the wrist in slight flexion may reduce postoperative flexion loss.

Postoperative Care. A bulky dressing extending from the proximal part of the forearm to the MP joints is applied and the hand elevated. Early finger motion is encouraged. The dressing and sutures are removed between 7 and 10 days postoperatively. Wrist motion should be initiated and encouraged, especially volar flexion. Hand therapy is continued until a full range of motion has been obtained.

Complications. Early recurrences, the most common complication of ganglion surgery, are usually the result of inadequate and incomplete excision and rarely should occur. Ganglions appearing at the same site years after excision may in fact be new ganglions. Stiffness of the wrist can be avoided by early motion, physical therapy if necessary, and splinting of the wrist in slight flexion during the immediate postoperative period. It is imperative that early volar flexion be stressed. To avoid keloid or hypertrophic scars, longitudinal incisions across the wrist joint should be avoided. Awareness and respect for the sensory branches of the radial and ulnar nerves prevent neuroma formation, which often defies effective treatment. I have not seen avascular necrosis of either the lunate or scaphoid or scapholunate dissociation after the surgical technique just described.[9] Ganglions and sprains of the intercarpal ligaments can occur concomitantly after trauma to the wrist and must be distinguished preoperatively. Identification of concomitant wrist pathology may be facilitated with arthroscopic treatment.

Occult Dorsal Carpal Ganglion

Unlike protruding dorsal ganglions, smaller, occult dorsal ganglions are easily overlooked and can often only be palpated with the involved wrist in marked volar flexion. Comparison with the opposite normal wrist is helpful. An occult ganglion may be the cause of unexplained wrist pain and is disproportionately tender. MRI is useful in confirming the diagnosis and differentiating pain related to scapholunate ligament injury. Dorsal ganglions occasionally do occur in association with an underlying scapholunate diastasis, and they may be blamed for the carpal instability after their excision.

Dorsal prominence of the proximal pole of the scaphoid secondary to intercarpal instability may be confused with a painful occult ganglion and must be diagnosed with appropriate radiographic studies to avoid a delay in proper treatment. Excising the ganglion alone might not alleviate all the patient's preoperative pain. Excision of the posterior interosseous nerve at the level of the radiocarpal joint may help alleviate the pain and add to the patient's postoperative comfort. If other causes of wrist pain and tenderness, especially directly over the scapholunate ligament, can be excluded, an occult dorsal ganglion is best initially treated conservatively by immobilization

and steroid injections directly into the dorsal capsule, which can also aid in diagnosis.

In cases in which further diagnostic studies are necessary, some authors have found the use of MRI and ultrasonography helpful.[153] Chronic tenosynovitis of the extensor tendons can be confused with a dorsal wrist ganglion but can be easily distinguished by the diffuse nature of the swelling and the puckering seen with digital extension, the so-called tuck sign.

Volar Wrist Ganglion

Clinical Characteristics. The second most common ganglion of the hand and wrist is a volar wrist ganglion (18-20%). The majority of volar ganglions occur either directly over the distal edge of the radius or slightly more distally over the scaphoid tubercle. The former arises from the capsular and ligamentous fibers of the radiocarpal joint and occurs under the volar wrist crease between the flexor carpi radialis and abductor pollicis longus tendons (Figure 59.24). The main cyst may be intertwined with bifurcating branches of the radial artery, thus making delicate dissection imperative. The other type of volar ganglion arises from the capsule of the scaphotrapezial joint.

Although volar ganglions may appear small clinically, they can be surprisingly extensive at surgery. Multiloculated cysts extending under the thenar muscles, along the flexor carpi radialis tendon, into the carpal canal, and under the first extensor compartment adjacent to the dorsal branch of the radial artery and as far dorsally as the first web space may be encountered. These extensions can often be appreciated preoperatively by careful palpation and digital compression of the ganglion.

It is important to assess the patency of the radial and ulnar arteries. The Allen test should be performed routinely and ulnar artery occlusion excluded. The surgeon must be aware of the importance of preserving the radial artery, particularly in patients with a radial-dominant circulation.

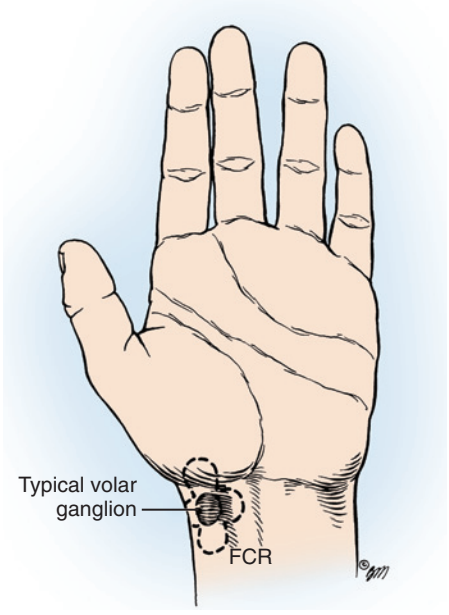

FIGURE 59.24 Typical location of a volar wrist ganglion. Possible subcutaneous extensions (*dashed lines*) are often palpable. *FCR*, Flexor carpi radialis. (Copyright © Elizabeth Martin.)

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. Although the surgical technique of excision of a volar ganglion is similar to that for a dorsal ganglion, exposure and precise identification of the capsular attachments of a volar ganglion are more difficult. The incision must be planned to allow for extension into the carpal tunnel or base of the thenar muscles (Figure 59.25). Longitudinal incisions allow for optimal visualization.

With the skin flaps retracted, the forearm fascia is incised longitudinally and the dome of the cyst identified and mobilized. Particular care should be taken to identify and protect the radial artery, which is frequently intimately attached to the wall of the ganglion and may even be completely encircled by the ganglion (Figure 59.26). Loupe magnification aids in this dissection.

The pedicle is traced to the volar joint capsule (usually the scaphotrapezial or radiocarpal ligament). The joint is opened

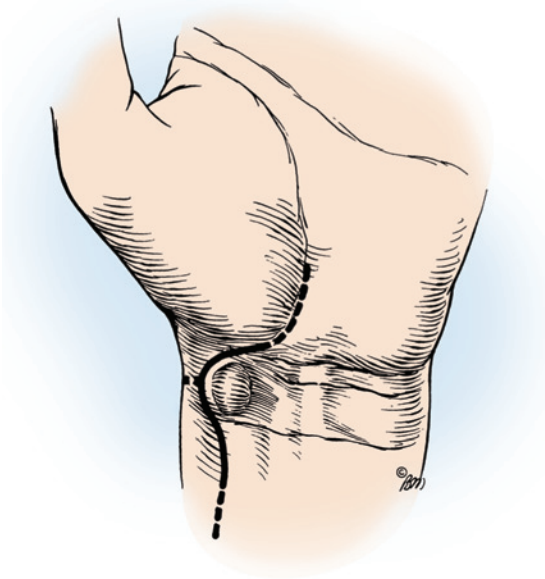

FIGURE 59.25 The usual incision to expose a volar wrist ganglion. Extensions proximally, distally, and even radially are possible (*dashed lines*). Care must be taken to avoid injury to the palmar cutaneous branch of the median nerve if the incision is extended. (Copyright © Elizabeth Martin.)

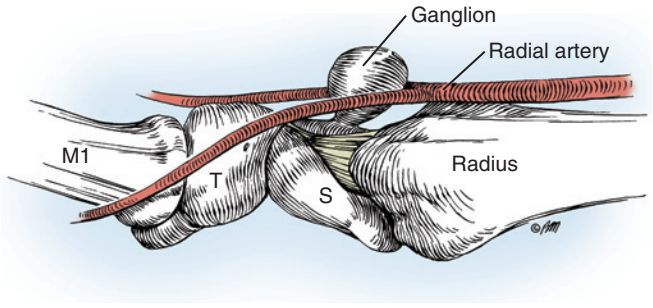

FIGURE 59.26 The usual relationship of the ganglion to the radial artery and volar joint capsule. *M1*, First metacarpal; *S*, scaphoid; *T*, trapezium. (Copyright © Elizabeth Martin.)

and explored and the capsular attachments are excised (approximately 3 ± 4 mm). Once the ganglion has been excised, the surrounding tissues can be compressed digitally to rule out further mucin-filled pockets. If unidentified extensions are present, they must be excised. Hemostasis, wound lavage, and a simple skin closure (preferably subcuticular) complete the operation. Again, capsular closure is unnecessary and only delays early mobilization.

Postoperative Care. A bulky bandage and elevation of the hand ensure early postoperative comfort. Follow-up care is similar to that for dorsal ganglions, and motion of the wrist should begin within the first 2 weeks after surgery.

Complications. The complications are similar to those of dorsal ganglions. Unexpected branches of the radial sensory or lateral antebrachial cutaneous nerves may be injured and lead to troublesome neuromas. Extensions of the routine incision into the carpal canal must avoid injury to the palmar cutaneous branch of the median nerve. Injuries to the radial artery can be repaired microscopically. Some authors recommend leaving a portion of the cyst wall attached to the artery to avoid arterial injury. Stiffness of the wrist is less common than with dorsal ganglions, but it can occur if early motion is not encouraged. Unpleasant scars are not an uncommon problem on the volar aspect of the wrist and often defy "plastic" revisions. Curved incisions appear to consistently provide more attractive scars, especially near the volar wrist creases (see Figure 59.25).

Volar Retinacular (Flexor Tendon Sheath) Ganglion

Clinical Characteristics. The third most common ganglion (10-12%) of the hand is the volar retinacular one, which arises from the proximal annular ligament (A1 pulley) of the flexor tendon sheath. This ganglion is invariably a small (3-8 mm), firm, tender mass palpable under the MP flexion crease (Figure 59.27). The cyst is attached to the tendon sheath and does not move with the tendon. Needle rupture followed by a steroid injection and digital massage to disperse the cyst's contents can frequently delay or obviate the need for surgery. Several attempts at conservative treatment are recommended before surgery, with the patient's understanding that recurrences might happen. The proximity of the digital nerves must be taken into account.

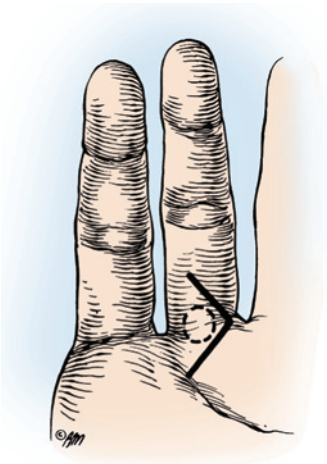

FIGURE 59.27 Volar retinacular ganglion palpable over the proximal tendon sheath and an incision for easy exposure. (Copyright © Elizabeth Martin.)

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. The ganglion is approached through an oblique incision over the mass (see Figure 59.27). Transverse incisions do not allow adequate exposure without undue skin traction and are not easily incorporated into an extensile incision, which also must allow identification and mobilization of the radial and ulnar neurovascular bundles. The ganglion can then be traced to the tendon sheath and excised with a small portion of the sheath (Figure 59.28). After skin closure, a simple dressing is applied and early motion allowed.

Mucous Cyst

Clinical Characteristics. A mucous cyst is a ganglion of the DIP joint that generally occurs between the fifth and seventh decades.[39] The earliest clinical sign may be longitudinal grooving of the nail, without a visible mass, caused by pressure on the nail matrix (Figure 59.29). Usually, however, the patient is seen after the cyst has enlarged and attenuated the overlying skin. The 3- to 5-mm cyst typically lies to one side of the extensor tendon and between the dorsal distal joint crease and eponychium. The patient often has Heberden nodes and

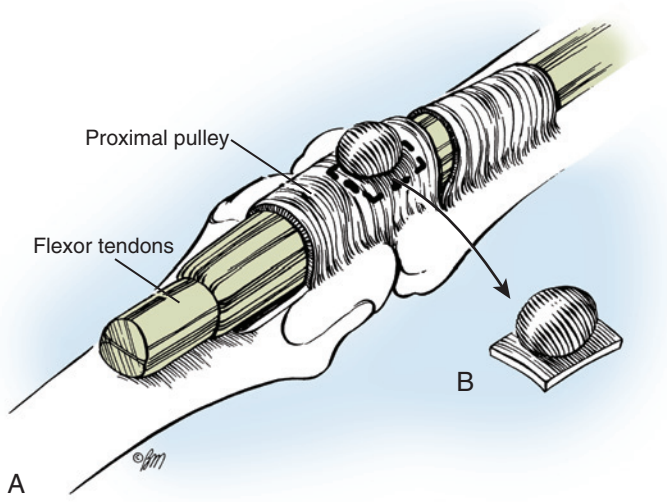

FIGURE 59.28 **A,** Volar retinacular ganglion in situ on the proximal annular ligament (A1 pulley) of the flexor tendon sheath. **B,** Excised specimen with a surrounding margin of tendon sheath. (Copyright © Elizabeth Martin.)

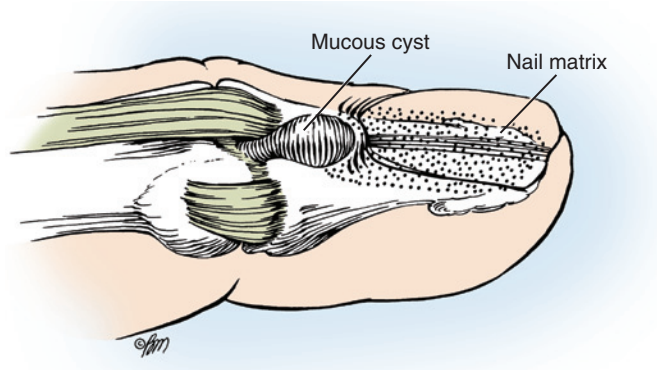

FIGURE 59.29 An early mucous cyst resting on the nail matrix may cause longitudinal grooving of the nail in some cases. (Copyright © Elizabeth Martin.)

radiographic evidence of osteoarthritic changes in the joint. The cyst and osteophytes both should be treated to ensure a satisfactory result.[51]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. The cyst historically has been approached through an "L"-shaped or curved incision (Figure 59.30, *A*), and any attenuated or involved skin that cannot be easily separated from the cyst wall is excised elliptically (see Figure 59.30, *B*). The cyst is mobilized, traced to the joint capsule, and excised with the joint capsule (Figure 59.31, *A*). From a practical point of view, however, all soft tissue between the retracted extensor tendon and adjacent collateral ligament needs to be excised and the DIP joint left exposed (see Figure 59.31, *B*). Care should be taken to not disturb the insertion of the extensor tendon or nail matrix. With the joint extended and the tendon retracted dorsally, the opposite side is explored and occult cysts or hypertrophied synovial tissue is excised. Osteophytes can be excised with a rongeur (Figure 59.32). Skin closure may require rotation and advancement of a dorsal skin flap[112] or a full-thickness skin graft.

An alternative and my current preferred approach is to make a transverse incision centered over the DIP joint. The base of the mucous cyst is identified and excised while leaving the distal and superficial portion of the cyst intact. Osteophytes and joint capsule are excised and the skin closed. The remaining portion of the cyst will involute over the course of several weeks, and the skin complications seen with marginal excision are avoided. I have used this technique since its report by Gingrass and colleagues[79] and have not needed to perform any skin coverage. Patients must be educated preoperatively to expect slow resolution of the cyst. Personal experience has confirmed the results that were published in the report.

Complications. Recurrences may be because of inadequate excision of the ganglion's capsular attachments and failure to recognize extensions of it under the extensor tendon to the opposite side. The underlying arthritic process persists and can result in new ganglion formation. Relief of pressure on the nail matrix by decompression or excision of the ganglion usually restores the nail to its normal appearance. Stiffness rarely causes a functional problem.

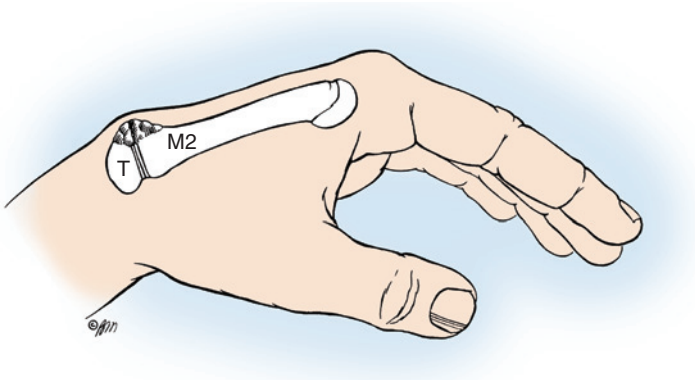

FIGURE 59.33 Carpal boss involving the second carpometacarpal (M2) joint. *T*, Trapezoid. (Copyright © Elizabeth Martin.)

Carpometacarpal Boss

Clinical Characteristics. Dorsal wrist ganglions can be confused with carpal bosses, which are osteoarthritic spurs or prominences that develop at the base of the second or third carpometacarpal joints (or both) (Figure 59.33). A firm, bony, nonmobile, tender mass is visible and palpable at the base of the carpometacarpal joints, especially when the wrist is flexed. Radiologically, the mass is best visualized with the hand in 30 to 40 degrees of supination and 20 to 30 degrees of ulnar deviation ("carpal boss view").

Bosses are more common in women, in the right hand, and between the third and fourth decades. The mass may be asymptomatic, or the patient may complain of considerable pain and aching. A small ganglion is associated with a carpal boss in 30% of cases, thus adding to confusion of it with the more common dorsal wrist ganglion. Every effort should be made to treat the carpal boss nonoperatively. Splinting, nonsteroidal antiinflammatory medications, and ultrasound-guided cortisone injections should be used or strongly considered prior to proceeding with surgery. The potential for persistent symptoms following surgery must be emphasized.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. The mass is approached through a transverse or oblique incision over the bony prominence (Figure 59.34). The extensor digitorum communis and extensor indicis proprius tendons are retracted ulnarward. A ganglion, if present, can be mobilized and excised with its capsular attachments. The osteophytes and carpometacarpal joints are approached through a separate longitudinal incision over each involved joint. Subperiosteal dissection exposes the involved joint to the adjacent osteophytes, which are then excised down to normal cartilage with small osteotomes. The dissection may involve the second and third carpometacarpal joints individually or all four opposing surfaces together (Figure 59.35). The surgical area is palpated through the skin to ensure excision of all palpable prominences. The capsule, periosteum, and any adjacent overlying tendon fibers (extensor carpi radialis longus, extensor carpi radialis brevis) are reapproximated over the joint with a few fine inverting sutures, which should not be palpable through the skin.

Postoperative Care. A cast or splint should be worn for 4 to 6 weeks to allow adequate ligamentous healing and pain relief.

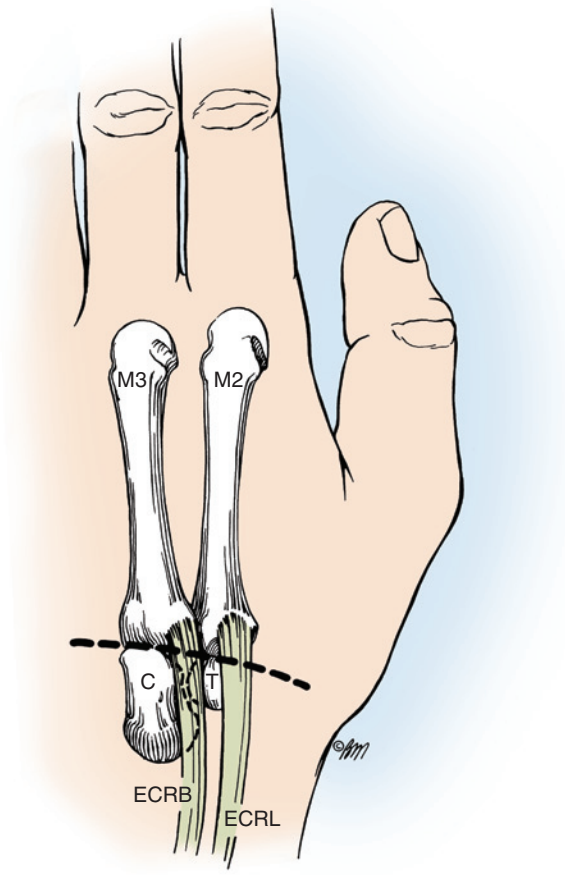

FIGURE 59.34 Incision for excision of a carpal boss, centered over the second (M2) and third (M3) carpometacarpal joints. *C*, Capitate; *ECRB*, extensor carpi radialis brevis; *ECRL*, extensor carpi radialis longus; *T*, trapezoid. (Copyright © Elizabeth Martin.)

Complications. The most common complication is persistence of a mass. Pain may persist unless all abnormal abutting surfaces have been excised. Dorsal wrist ganglions can occur over the carpometacarpal joints and must be distinguished from carpal bosses with an associated ganglion. Avoidance of injury to branches of the radial and ulnar sensory nerves is again stressed.

Ganglions of the Proximal Interphalangeal Joint

Clinical Characteristics. Similar to a mucous cyst of the DIP joint, ganglions also occur dorsally over the PIP joint on either side of the extensor tendon. They arise from the joint capsule and usually pierce the oblique fibers between the central slip and lateral band. These cysts are small (3-5 mm) and tender and may interfere with joint motion.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. A curved or longitudinal incision over the PIP joint exposes the ganglion (Figure 59.36). The lateral margin of the lateral band is released from the transverse retaining ligament and retracted dorsally to expose the PIP joint (Figure 59.37). The pedicle from the main cyst usually can be followed through the extensor system into the joint capsule. A small, elliptic incision through the oblique extensor fibers

mobilizes the cyst and pedicle. The entire joint capsule and synovial lining are excised between the collateral ligament and extensor insertion on the middle phalanx.

Postoperative Care. A simple skin closure and dressing followed by early motion are all that is required.

Ganglions of Extensor Tendons

Clinical Characteristics. Ganglions do arise on or within extensor tendons. They typically occur over the metacarpals and are distinguished by their proximal motion with the fingers in extension. They can, however, be confused with dorsal wrist ganglions, carpal bossing, or extensor tenosynovitis. The patient may complain of tenderness, aching, or snapping of the tendon with motion.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Operative Technique. The ganglion is approached through a transverse incision (Figure 59.38), and the intimate broad attachment to the extensor tendon is readily recognized. The ganglion should be dissected off the extensor tendon with all the synovial tissue surrounding the involved tendon. Rupture of the ganglion is difficult to avoid, but recurrences are rare.

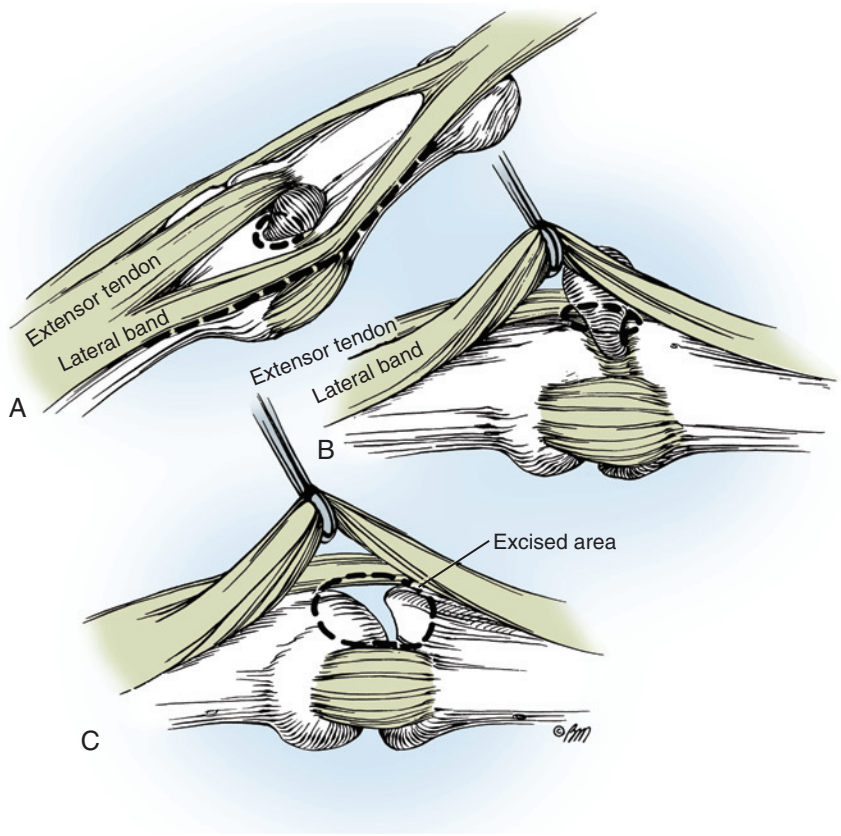

FIGURE 59.37 **A,** Proximal interphalangeal (PIP) ganglion in situ between the extensor tendon and lateral band. An incision along the lateral border of the lateral band and the base of the pedicle is illustrated with a dashed line. **B,** The lateral band has been released and elevated to expose the joint capsule and infratendinous portion of the cyst. **C,** Excision of the cyst and joint capsule reveals the exposed PIP joint. Miscellaneous Locations

Ganglions have been reported to occur in numerous other locations of the hand and wrist and are often associated with various conditions, including those described in the following subsections.

First Extensor Compartment (Dorsal Retinacular) Ganglion. Ganglions attached to the first extensor compartment, similar to volar retinacular ganglions, are seen in patients with acute stenosing tenosynovitis (de Quervain disease) (Figure 59.39). Therefore, in addition to releasing the tendons (see Chapter 56), the involved tendon sheath and the ganglion can be excised. Injury to the radial sensory nerve should be avoided, and a separate compartment of the extensor pollicis brevis may be present and require release.

Carpal Tunnel. Symptoms consistent with compression of the median nerve have been ascribed to ganglions arising from the volar carpus within the carpal canal.[110] A volar wrist ganglion also can extend distally and ulnarward to compress the median nerve. All carpal tunnel releases should be accompanied by exploration of the canal to rule out extrinsic masses, including ganglions.

Guyon Canal/Distal Ulnar Nerve. Ganglions within the ulnar canal (loge de Guyon) can compress the ulnar nerve and cause motor or sensory loss, or both.[177] These ganglions generally arise from joints around the hamate and dissect through the hypothenar muscles or along the motor branch. Ganglions in the palm can lead to isolated atrophy of the first dorsal interosseous muscle. Early excision is imperative and avoids permanent injury to the ulnar nerve.

Intraosseous Ganglions

Although rare and usually an incidental radiographic finding, intraosseous ganglions are increasingly being recognized as a source of wrist pain.[41] Surgical treatment is best delayed, however, until all other possible causes of the patient's discomfort have been excluded. When indicated, curettage and bone grafting adequately treat the condition. Careful exploration of the joint at the time of surgery helps rule out other undiagnosed causes of the patient's symptoms. Communication between the joint cavity and the intraosseous cyst has not been consistently demonstrated (Figure 59.40). The histologic features of intraosseous ganglions are identical to those of their soft tissue counterparts.

Epidermal Inclusion Cysts

Epidermal inclusion cysts are thought to result from traumatic implantation of epithelial cells into the underlying soft tissue or bone.[63,150] The cells grow over an interval of months to years to produce a painless swelling, most commonly in the fingertip. Erythematous and painful lesions have been described. These lesions most frequently occur in the distal phalanx of the left long finger and thumb in men in the third and fourth decades

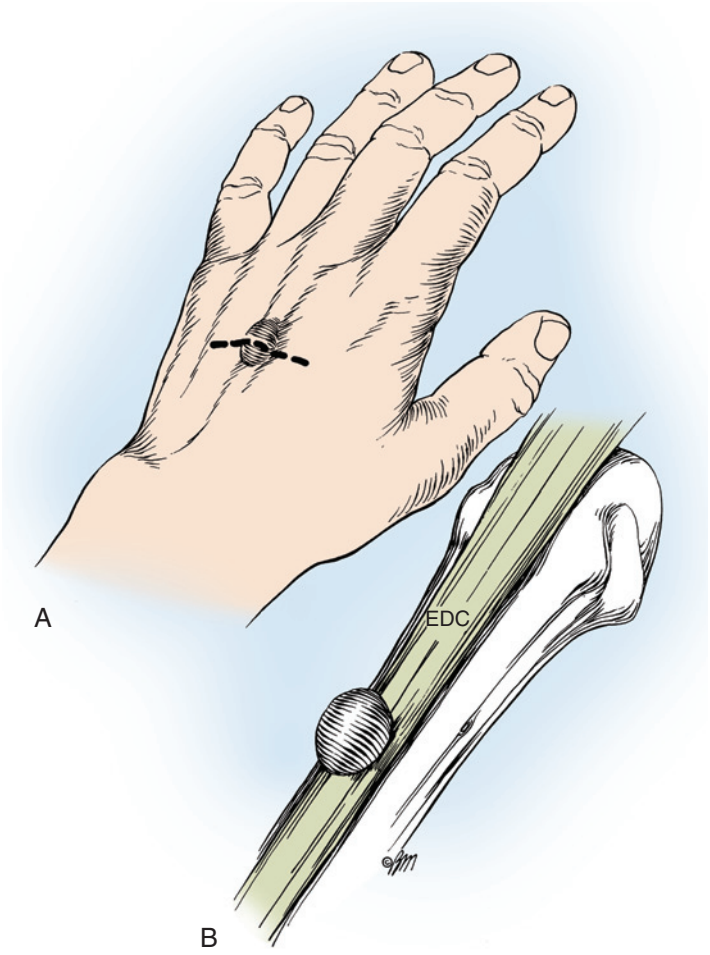

FIGURE 59.38 Extensor tendon ganglion. **A,** The ganglion, tendon, and overlying skin incision. **B,** The ganglion in situ on the extensor tendon. *EDC,* Extensor digitorum communis. (Copyright © Elizabeth Martin.)

of life. Epidermal inclusion cysts may be seen after traumatic or surgical amputation of the fingertip. Metacarpal involvement is rare, and there are no reported cases occurring in the carpus.

Patients typically note a slowly growing mass on the fingertip or thumb tip, even though a history of trauma (penetrating injury) may not be recalled. When confined to soft tissue, the cyst is usually well circumscribed, firm, and slightly movable. The differential diagnosis can be more difficult when the cyst involves bone, in which case radiographs generally show a well-demarcated lytic lesion (Figure 59.41). Occasionally, cortical penetration can be seen, and the lesion may mimic a malignant or infectious process. More than a fourth of reported lesions have been treated by primary amputation, before pathologic diagnosis, out of concern for an aggressive neoplasm or advanced bone destruction.

Patients with a lytic lesion of the distal phalanx should undergo biopsy before consideration of an ablative procedure. Epidermal inclusion cysts are readily treated by marginal excision or by curettage and bone grafting for lesions involving bone. In rare cases with advanced bone destruction, amputation may be an alternative. Recurrence is uncommon, and malignant transformation has not been reported.

Foreign Body Lesions

Foreign body lesions are traumatic reactive masses rather than true neoplasms. These lesions are a response to implanted foreign material.[8,49,89,173] The tissue's reaction to foreign material varies with the nature of the foreign substance deposited, the anatomic site involved, the duration of the implant, and the presence or absence of tissue hypersensitivity to the material.[89] This response is the host's method of isolating recognized extraneous substances. Glass, wood, and metal are the most common types of particulate matter associated with a foreign body reaction. These lesions are usually relatively superficial in location.

It is important to establish the cause of the lesion because the differential diagnosis includes malignant soft tissue neoplasms. A history of penetrating trauma or identification of a foreign body with radiographs or ultrasonography can provide this information.[8,173] It may be impossible to preoperatively distinguish between an inclusion cyst, a foreign body reaction, or a soft tissue neoplasm. Excisional biopsy of these relatively small lesions allows pathologic analysis and confirmation of the diagnosis and results in a cure for the problem.

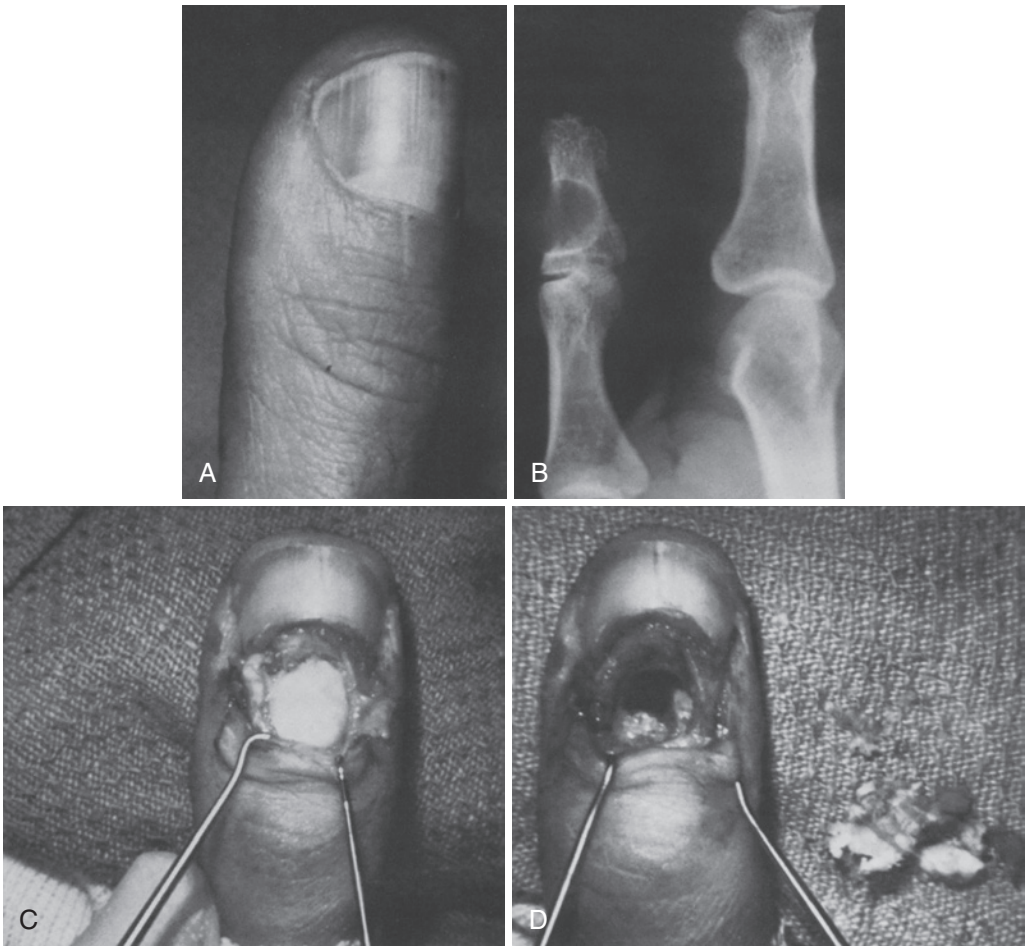

FIGURE 59.41 Epidermal inclusion cyst. A 53-year-old salesman reported that an enlarging deformity of the thumb **(A)** had progressed slowly for some time after a crush injury that occurred at least 18 months earlier. Radiographs showed a well-circumscribed distal phalangeal lesion with a reactive endosteal cortical rim **(B)**, typical of bone reaction to a slowly growing soft tissue tumor. **C, D,** Marginal excision revealed an epidermal inclusion cyst that was successfully treated by removal and phalangeal curettage.

Lipomas

Lipomas are common benign fat tumors that typically occur in several locations in the hand,[14,20,139] most commonly subcutaneously or intramuscularly. Lipomas have been reported to arise in association with tendon sheaths, in the carpal tunnel, in the Guyon canal, and in the deep palmar space. They are soft nontender masses that do not transilluminate. Symptoms of nerve compression may be noted if the tumor is in the deep palmar space or in proximity to a major nerve. Such lesions are frequently present for several years and may grow slowly. When the lesion is subcutaneous, it is readily recognized by its well-demarcated appearance and rubbery consistency. Plain radiographs may reveal a soft tissue shadow, and MRI may be particularly useful by demonstrating signal characteristics that are significantly suggestive of fat, which is often similar to surrounding subcutaneous fat.

Lipomas are usually well demarcated and are readily dissected from surrounding soft tissues, but occasionally the tumor may be immediately adjacent to nerves, thus making dissection difficult. When the patient's physical examination and radiographs are extremely suggestive of a lipoma, a small lesion can be treated by excisional biopsy. Deep lesions, such as those occurring in the carpal tunnel, should be studied preoperatively with MRI. If the signal characteristics are not clearly suggestive of lipoma, a small incisional biopsy should be done to establish the diagnosis and prevent operative contamination of major nerves. Marginal excision of lipomas is generally curative, although recurrence may be seen.

Lipofibromatous Hamartomas

Lipofibromas or lipofibromatous hamartomas are unusual tumors of peripheral nerves that most commonly involve the median nerve when seen in the upper extremity.[91,129] Rare instances of ulnar or radial nerve involvement have been reported.[95] Patients usually complain of slowly progressive swelling in the distal part of the forearm or palm, and symptoms of nerve compression may be present. The mass is most commonly noted in childhood or adolescence and is thought to be congenital or developmental in origin. MRI findings can be diagnostic. Surgical exploration reveals either diffuse fusiform swelling of the nerve without extension into perineural tissues or a more circumscribed area of involvement. The mass is closely associated with the nerve fibers and is not readily dissected free. Attempts at partial excision or interfascicular dissection frequently result in permanent loss of motor or sensory

nerve function and should be avoided in the presence of characteristic MRI findings.[91,161,191] Biopsy of a cutaneous branch of the nerve can be done to confirm the diagnosis if MRI findings are not diagnostic.[161]

Additional surgical treatment is directed only at decompressing the nerve. Spontaneous decrease in tumor size and improved nerve function have been reported after nerve decompression only. If the size of the lesion requires that it be excised, Houpt and associates have advocated complete excision and nerve grafting in children and immediate tendon transfers in adults.[91] Histologic examination of the lesion reveals nerve tissue with surrounding fat cells and a smaller component of fibrous tissue. Long-term follow-up of patients with such lesions has demonstrated slow but progressive loss of nerve function.[129]

Giant Cell Tumors of the Tendon Sheath (Pigmented Villonodular Tenosynovitis)

A giant cell tumor (GCT) of a tendon sheath is a benign soft tissue tumor and is the second most common tumor seen in the hand (after ganglions).[1,83,97,100,104,145] Several terms have been used to describe this lesion, including *localized nodular synovitis, fibrous xanthoma*, and *pigmented villonodular tenosynovitis. Giant cell tumor of the tendon sheath* is not a particularly good term because the lesion does not uniformly contain giant cells and is not necessarily associated with a tendon sheath. The tumor generally occurs on the volar surface of the fingers or hand, although dorsal involvement is not uncommon. There is a propensity for involvement of the radial three digits and the DIP joint region.[145] Clinically, the tumor is most often firm, nodular, and nontender. Because it grows slowly, it may be present for a long time before the patient is seen. A sensory deficit may be present when the lesion occurs in proximity to the digital nerves.

The lesion does not transilluminate, which helps distinguish it from a ganglion. Plain radiographs may demonstrate a soft tissue mass or pressure erosion of underlying bone.[104] Bone invasion, as can be seen with diffuse pigmented villonodular tenosynovitis, is not typical and suggests a more aggressive neoplasm. Actual bone invasion is rare but has been described.[198] Marginal excision is the recommended treatment, although the reported incidence of recurrence is 5 to 50%.[83,145] The high risk for recurrence is thought to be caused by the presence of satellite lesions or incomplete excision. Statistically significant risk factors for local recurrence include degenerative joint disease, location at the DIP joint, and radiographic evidence of pressure erosion.[166] If extensive joint involvement or degenerative changes are seen, arthrodesis may be necessary after excision. Radiation can be considered for multiply recurrent or aggressive lesions.[40] A malignant form of GCT of the tendon sheath has been adequately described.[100]

Schwannomas (Neurilemomas)

Neurilemoma, or schwannoma, is the most common benign nerve tumor occurring in the upper extremity.[50,164,169,189] This lesion arises from Schwann cells and produces a slowly growing, well-circumscribed, eccentric lesion in the peripheral nerve. Neurilemomas are most commonly seen on the flexor surface of the forearm or hand in the fourth, fifth, or sixth decades. Patients most frequently notice a painless mass, but less commonly there may be a neurologic deficit. Palpation or compression of the lesion can produce radiating pain in a specific nerve distribution. The lesion is often mobile in a transverse direction but not longitudinally. It is frequently misdiagnosed as a ganglion and may have a similar consistency.[164,169] MRI can be useful in delineating the lesion, but it may not be possible to distinguish neurilemoma from a neurofibroma or malignant peripheral nerve sheath tumor (Figure 59.42).[189]

Neurilemoma can be dissected free or "shelled out" from the surrounding nerve. Interfascicular involvement may be seen rendering dissection more difficult. Optical magnification and microsurgical techniques have been advocated to reduce the risk for postoperative neurologic deficit. The incidence of postoperative neurologic deficit is approximately 5 to 15%,[182] with a significantly greater risk of a deficit occurring with procedures done after incisional biopsy or recurrence.[50] In the overwhelming majority of cases, the lesion can be completely removed and neurologic symptoms, if present preoperatively, are improved. Recurrence is uncommon. Multiple lesions in a single peripheral nerve have been described. There are rare reports of malignant transformation.[4,74]

CRITICAL POINTS *Excision of Giant Cell Tumor of the Tendon Sheath*

Indications

- Same as for open incision biopsy.
- Suspected giant cell tumor of a tendon sheath.

Technical Points

- Same as for biopsy.
- When diagnosis is confirmed by biopsy or visual inspection, perform a marginal excision.
- Have a low threshold for intraarticular exploration or exploration deep into the volar plate.

Postoperative Care

- Advise the patient of the diagnosis and approximate 30% risk for local recurrence.
- Initiate range-of-motion exercises and remove the sutures at 7 to 10 days.

Neurofibromas

Neurofibromas are benign nerve tumors that arise within nerve fasciculi and are typically more difficult to excise than neurilemomas.[50] Solitary lesions may be seen, but multiple neurofibromas are more common in the setting of neurofibromatosis (von Recklinghausen disease). Symptoms and clinical findings may be similar to those seen with neurilemomas. At surgery, a more prominent nerve fascicle or group of fascicles can be seen entering and exiting the lesion if both proximal dissection and distal dissection are done under magnification.[50] Excision of the lesion requires transection of the entering and exiting fascicles. Postoperative neurologic deficit is more common than after excision of neurilemomas. Progression of motor and sensory nerve deficits has been noted after surgical treatment of plexiform neurofibromas in patients with neurofibromatosis.[50] Surgical treatment of neurofibromas in patients with neurofibromatosis should be reserved for lesions that are growing or producing progressive symptoms. There is a known risk for malignant degeneration of neurofibromas in patients with neurofibromatosis.

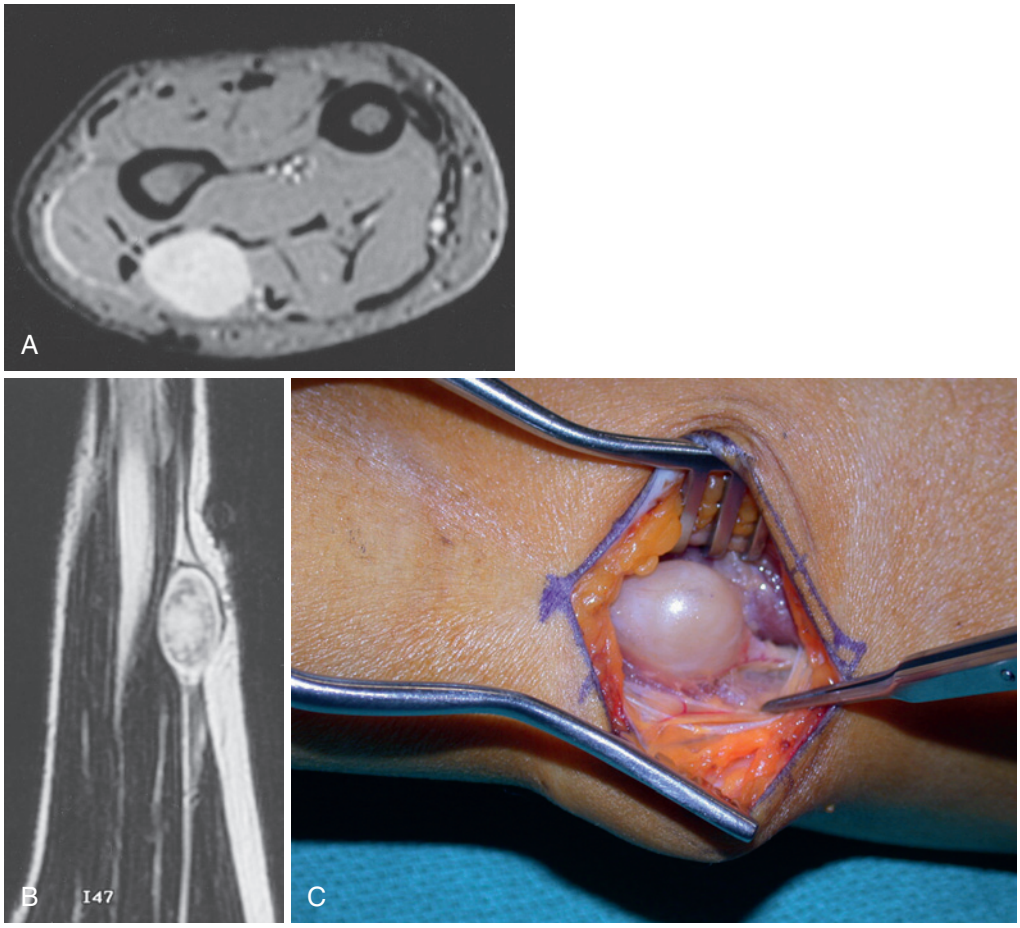

FIGURE 59.42 Axial **(A)** and sagittal **(B)** magnetic resonance images of a neurilemoma arising from the ulnar nerve. Intraoperatively, the lesion was readily dissected from the major portion of the ulnar nerve **(C)**.

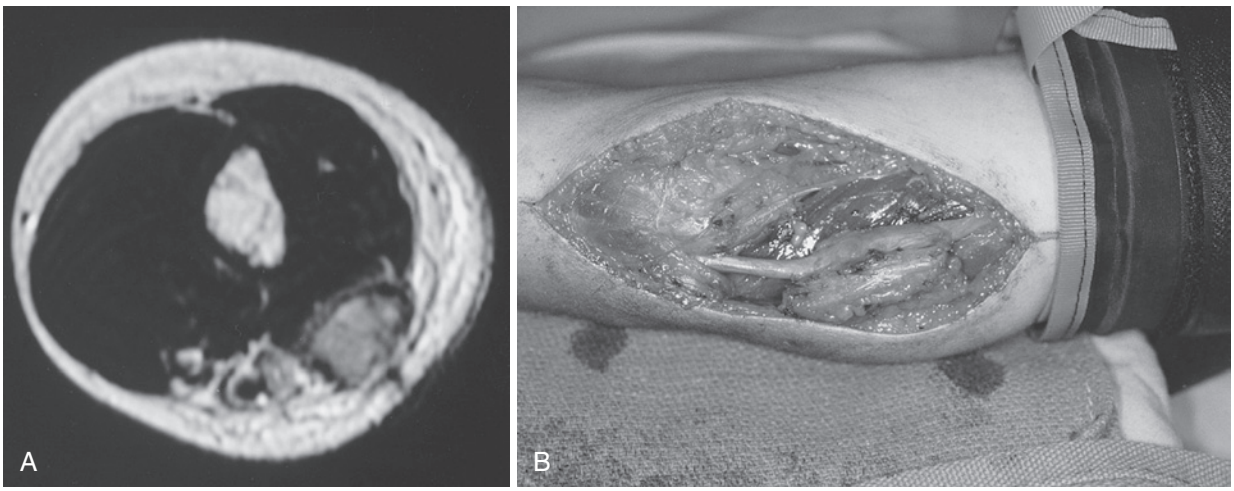

FIGURE 59.43 **A,** Axial magnetic resonance imaging demonstrating a lobulated granular cell tumor arising from the ulnar nerve. **B,** At surgery, the tumor was not able to be separated from the ulnar nerve just proximal to the medial epicondyle.

Granular Cell Tumors (Granular Cell Myoblastomas)

A granular cell tumor is a neoplasm that is rarely seen in the forearm and hand.[58,64,132] This lesion appears to arise from neural elements rather than from myoblasts, as originally believed, and it has been found to occur in close association with nerves (Figure 59.43).[58] Patients usually note a painless mass. Multicentricity has been reported in 10 to 15% of cases. Excision of the tumor has been curative, although there has been no critical analysis of the need for wide margins at excision. A malignant variant of a granular cell tumor has been

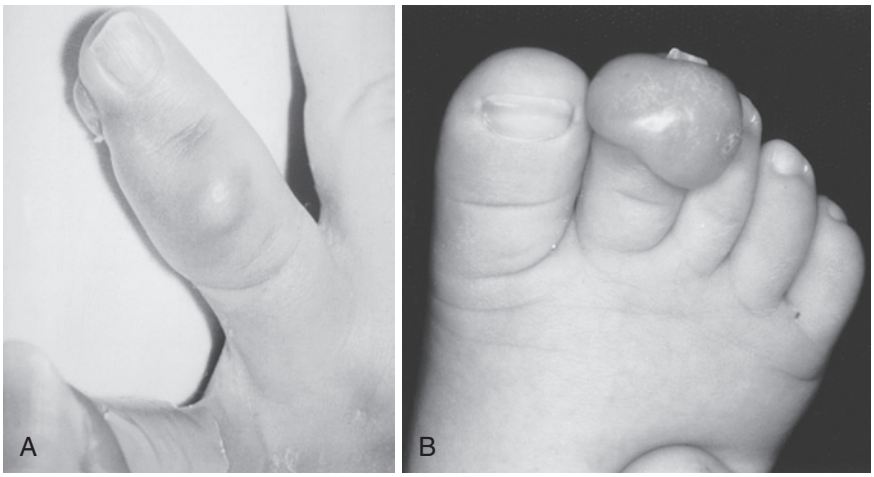

FIGURE 59.44 Digital fibroma during infancy occurs almost exclusively in the fingers **(A)** and toes **(B)**, usually in the first year of life. (Courtesy of Chris Unni, MD.)

reported; it is rare and difficult to distinguish from the benign lesion.[58] Malignant lesions are highly aggressive and require wide excision and consideration of systemic treatment.

Fibromatoses

Digital Fibroma of Infancy

Digital fibroma of infancy is a benign but very aggressive fibrous lesion seen virtually exclusively in the fingers or toes (Figure 59.44), with more than 80% of cases arising before the age of one.[19,61,94] Digital fibroma of infancy generally occurs in the region of the interphalangeal joints of the fingers. The lesions are usually small, dome shaped, skin colored, and painless. The true natural history of this condition is not known. Observation has documented progression with interphalangeal contracture, angular deviation, and bone deformity in severely affected children.[19,61] There are reports of spontaneous resolution of the skin lesions, with some patients having residual deformity.[19] Microscopic evaluation has demonstrated intracytoplasmic inclusion bodies, which has resulted in speculation of a viral or myofibroblast cause of the lesions.

Treatment has included observation, marginal excision, wide excision with coverage, and amputation. No documented cases of metastasis have been reported, but the incidence of local recurrence after excision is approximately 60%. Although no firm treatment guidelines exist, it seems prudent to observe these lesions until spontaneous resolution occurs or early signs of deformity or contracture are seen. Wide excision and skin grafting appear to give the best local control and functional results, but there is a significant risk for local recurrence and even subsequent involvement of adjacent digits.[61]

Juvenile Aponeurotic Fibroma

Fibrous lesions in the hand are commonly seen in childhood and adolescence and are frequently difficult to classify and treat. Juvenile aponeurotic fibroma, or calcifying aponeurotic fibroma, is a benign, aggressive fibrous lesion seen during childhood or adolescence that most commonly affects the palm.[3,34,107,114] This lesion is manifested as a small painless mass, often closely associated with tendons or neurovascular structures. The histologic appearance can be difficult to distinguish from fibrosarcoma.

Wide excision with sparing of functional or vital structures is the recommended treatment, but the recurrence rate has been reported to be higher than 50%.[34] On rare occasion, amputation has been necessary to control the disease. There is one reported case of metastasis after recurrence of juvenile aponeurotic fibroma in the hand, although the metastasis was classified as fibrosarcoma.[114] Local and systemic surveillance should be considered for patients with this lesion. Recurrent lesions can be observed if they do not produce functional impairment and the diagnosis is not in question.[34]

Nodular Fasciitis

Pseudosarcomatous fasciitis, subcutaneous pseudosarcomatous fibromatosis, and *infiltrative fasciitis* are terms that have been used to describe the entity currently called *nodular fasciitis*. It is an uncommon but well-described reactive lesion that is poorly understood and may simulate a sarcoma.[17,187] This lesion most commonly occurs on the volar surface of the forearm and rarely can occur in the hand and digits.[105] Patients usually note a rapidly growing small nodule that has been present for a very short time, frequently less than a month. There may be a history of local trauma and tenderness on palpation. The histologic appearance has been confused with fibrosarcoma and myxoid liposarcoma, which has led to overtreatment.[187] The diagnosis of nodular fasciitis is rarely anticipated preoperatively. The natural history of nodular fasciitis appears to be self-limited. Recurrence after marginal excision should raise the question of an alternative diagnosis because even incompletely excised lesions have not been noted to recur.[17] The most important issue in treating patients with nodular fasciitis is to differentiate this lesion from a soft tissue sarcoma to avoid unnecessary aggressive surgical treatment. Molecular genetic testing of pathologic specimens can assist in establishing a diagnosis as genetic studies have identified frequent presence of the USP6 gene rearrangement by interphase fluorescence in situ-hybridization (FISH).[155]

MALIGNANT SOFT TISSUE LESIONS

Soft Tissue Sarcomas

Soft tissue sarcomas are relatively rare in the hand and forearm.[28] Approximately 12,000 new cases of soft tissue sarcoma are diagnosed each year in the United States and only 15% of them occur in the upper extremity.[120] *The majority of these lesions share a common primitive mesenchymal origin.* For most patients no predisposing risk factor can be identified. Certain environmental and genetic risk factors have been implicated as potential causes of soft tissue sarcoma. Patients exposed to radiation[38] and forestry workers exposed to herbicides may have a higher incidence of soft tissue sarcoma. Genetic factors have been implicated in neurofibromatosis and Li-Fraumeni syndrome.[123]

In previous editions of this chapter, individual types of soft tissue tumors were described on the basis of their presumed cell of origin. It is important to recognize that specific cell origin or tumor differentiation of soft tissue sarcoma has limited value in predicting the behavior of a tumor. The biologic behavior of soft tissue sarcomas can be more accurately predicted by the lesion's histologic grade, which takes into account cell mitotic index, cellularity, tumor necrosis, and anaplasia. The most common histologic subtypes of soft tissue sarcoma seen in the hand are epithelioid sarcoma, synovial sarcoma, and malignant fibrous histiocytoma.[28] Histologic diagnosis can be useful in assessing its propensity for regional lymphatic spread.[68,165,185]

Clinical Picture

The clinical characteristics of the various types of soft tissue sarcomas in the upper extremity and hand can be similar. Most frequently, patients note a painless mass that may have been present for a long time with recent growth.[28,194] Less commonly, a painful mass may be reported. Epithelioid sarcoma is notable for manifestation as an ulcerating nodule that can be mistakenly treated for infection.[185] Soft tissue sarcomas in the hand are frequently misdiagnosed as infection, ganglion, and lipoma. This can lead to inappropriate treatment or to a delay in treatment.

Physical examination of a patient with a suspicious lesion includes careful assessment of size, location, depth, mobility, and relationship to major nerves, vessels, tendons, and bone. Regional lymph nodes are assessed. Plain radiographs are obtained and may demonstrate soft tissue calcification, fat density, or unexpected bone involvement, which can assist in making a diagnosis (Figure 59.45). MRI has become increasingly valuable in defining the pathologic anatomy, determining the local extent of disease, and aiding preoperative planning.

Biopsy

Soft tissue masses that are symptomatic, enlarging, or not readily diagnosed by physical examination should be considered for biopsy. Very small lesions that can be excised with a surrounding cuff of normal tissue can be treated by excisional biopsy before a known diagnosis. Large lesions or lesions in proximity to major nerves, vessels, or tendons are best treated with incisional biopsy. The decision of how to perform the biopsy is particularly important in the hand because of the compact nature of important soft tissues in the wrist and hand. Incisional biopsies or biopsies in which the tumor is inadvertently violated result in contamination of all tissues included in the exposure. Poorly planned biopsies may compromise the ability to perform limb-sparing surgery. It is best to plan the biopsy incision to be in line with or incorporated into the definitive limb salvage or amputation procedure that may be required in the event of a high-grade malignant diagnosis. Transverse, oblique, and zigzag (Bruner) incisions should specifically be avoided.

Staging

After the diagnosis of a soft tissue sarcoma, systemic staging should be done with CT of the chest and axilla. Soft tissue sarcomas of the upper extremity most commonly metastasize to the lungs or regional lymph nodes.[68,74] Lymph node metastasis occurs in less than 5% of soft tissue sarcomas of the extremities, however.[136] Epithelioid sarcoma is a notable exception, with a risk for regional lymph node metastasis as high as 42%.[22,162,165,185] Sentinel lymph node biopsy for epithelioid sarcoma, clear cell sarcoma, angiosarcoma, and rhabdomyosarcoma is currently being investigated and may play a role in the staging of patients with these diseases.[106,131] Soft tissue sarcomas are generally staged on the basis of grade, size, and the presence of metastasis. Prognostic factors that have been incorporated into the AJCC staging system include grade, size, depth, and presence of metastasis.[77] Histologic grade is particularly important in predicting the biologic behavior of the lesion and its risk for metastasis.[118] The tumor should also be staged with the MSTS staging system.[55]

Operative Treatment

Surgery is the primary form of local treatment for patients with soft tissue sarcoma. Treatment of either bone or soft tissue sarcoma requires the surgeon to think and plan for two parts of the operation: resection and reconstruction. At times, a two-team approach may be best. Resection of the lesion is of primary importance. Concerns regarding reconstruction must be given secondary consideration within the context of the particular patient or aggressiveness of the lesion. Compromise of resection margins out of concern for reconstruction increases the risk for local recurrence and may increase the risk for metastasis and death.[28,124,194] Positive margins in the treatment of soft tissue sarcomas in the hand are not readily salvaged or compensated for by the use of external beam radiation and have been found to be predictive of recurrence.[28,194]

The goal of surgery is complete removal of the tumor with a surrounding cuff of normal tissue. Wide excision with 2 to 3 cm of normal tissue surrounding the tumor has been advocated.[118,185] Deliberate sacrifice of major neurovascular structures can often be avoided, provided that there is meticulous attention to dissection, a margin of normal tissue can be obtained, and neurovascular structures are not surrounded by tumor.[118,172] If negative margins cannot be achieved with wide excision, amputation should be very strongly considered. Extensive reconstruction may be required after wide excision of soft tissue sarcomas of the hand. Talbot and colleagues developed an anatomic, site-specific reconstruction algorithm that can help in decision making during complex soft tissue reconstruction after resection of soft tissue sarcomas.[193]

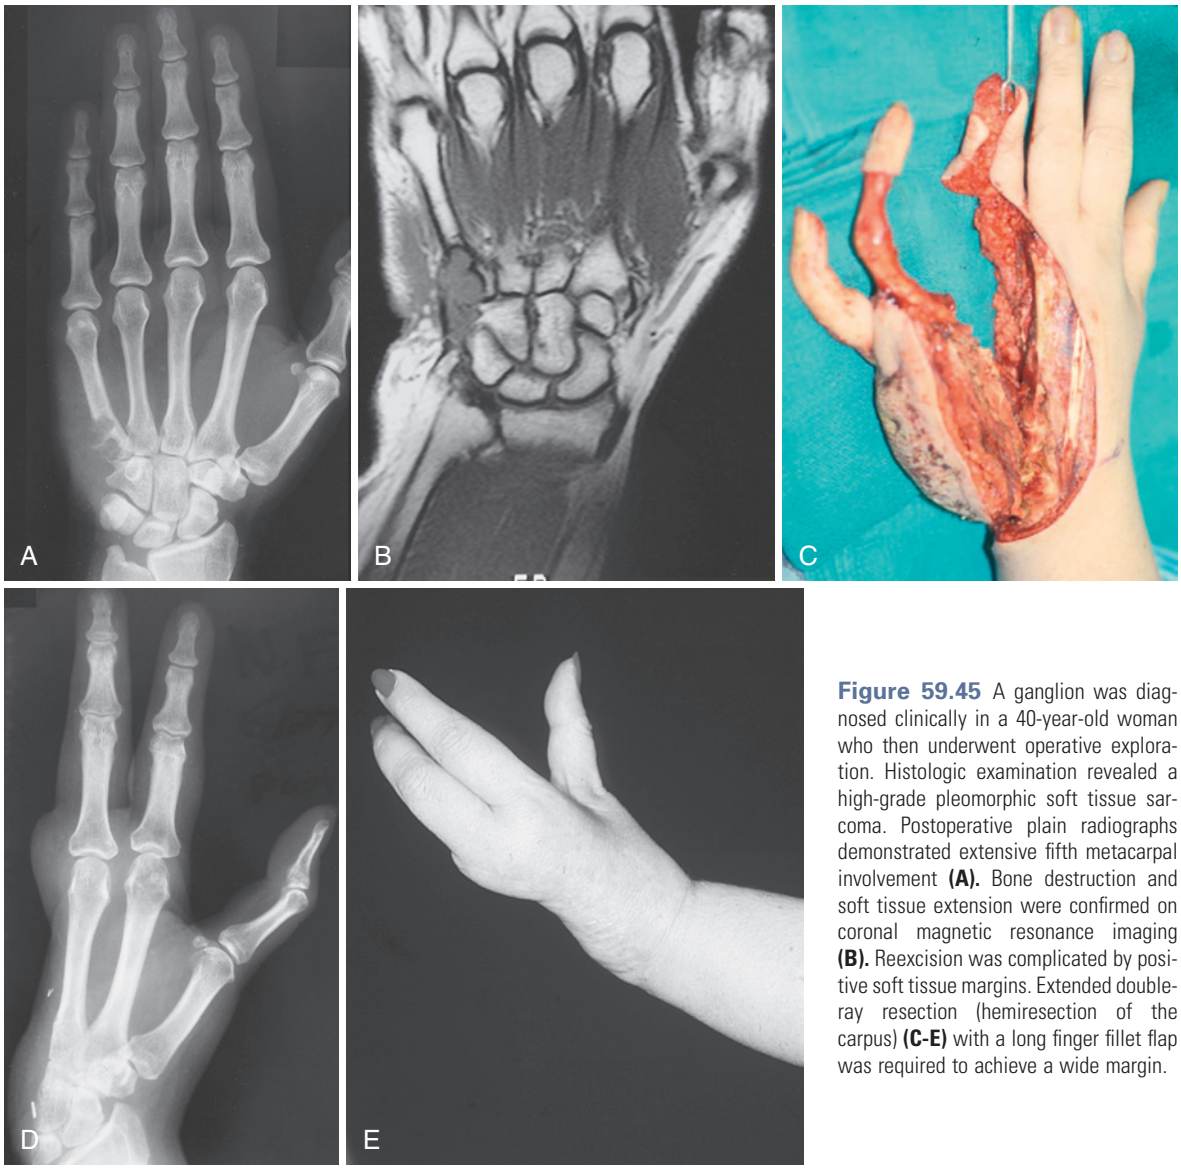

Figure 59.45 A ganglion was diagnosed clinically in a 40-year-old woman who then underwent operative exploration. Histologic examination revealed a high-grade pleomorphic soft tissue sarcoma. Postoperative plain radiographs demonstrated extensive fifth metacarpal involvement **(A).** Bone destruction and soft tissue extension were confirmed on coronal magnetic resonance imaging **(B).** Reexcision was complicated by positive soft tissue margins. Extended double-ray resection (hemiresection of the carpus) **(C-E)** with a long finger fillet flap was required to achieve a wide margin.

After wide excision of a large (>5 cm) high-grade lesion, patients require either brachytherapy* or external beam irradiation in an effort to reduce the risk for local recurrence.[25,26,28,194] Excision of large low-grade lesions should be followed by external beam irradiation. Small (>5 cm) high- or low-grade extremity lesions that can be widely excised may not require adjuvant radiation therapy, although this issue has not been conclusively answered for the hand.[4,28,118,194] Digit, single-ray, or multiple-ray amputation may often be the best solution for patients with soft tissue sarcoma involving the fingers or web space. Wide margins cannot be readily obtained in the digit, and the functional result of amputation may be superior to that of digit salvage and reconstruction. Large lesions or lesions involving the contents of the carpal tunnel may not be amenable to a hand-sparing operation and are frequently best treated with below-elbow amputation.

The role of chemotherapy in the treatment of soft tissue sarcomas in the extremities is still under investigation. Chemotherapy can have a small but real overall survival benefit and may increase the disease-free interval in well-selected patients with extremity lesions.[73] Certain patients with large high-grade lesions may benefit from preoperative chemotherapy in an effort to reduce the size of a lesion to make an unresectable lesion resectable. Patients with large high-grade lesions may be at high risk for metastasis and should be considered for investigational protocols in conjunction with a medical oncologist. Patients initially seen with metastasis can also be candidates for chemotherapy and resection of lung nodules.[74]

*_Brachytherapy_ refers to the use of radioactive implants to deliver radiation over short periods. Small, flexible catheters are implanted at the time of surgery, and beginning about 5 days after surgery, radioactive implants are loaded into the catheters. These implants are left in place for 3 to 4 days during which time high doses of radiation can be delivered directly to the tissue at risk with predictable minimal scatter. Another advantage is that this method dramatically shortens the duration of radiation treatment when compared with external beam therapy (5 weeks). Brachytherapy is more effective for high-grade tumors than for low-grade ones and should not be considered for the latter.

Patients referred after primary excision with positive margins should be strongly considered for reexcision or amputation because the risk for local recurrence in this situation is high.[28,119,194] Patients with metastasis should be treated aggressively locally in the extremity and in the chest, as well as systemically, because survival is possible.[74]

CRITICAL POINTS *Treatment of Forearm and Hand Soft Tissue Sarcomas*

Indications

- Attempted curative treatment of a patient with a soft tissue sarcoma
- Patient able to tolerate limb salvage and reconstruction

Preoperative Evaluation

- Have the pathologic diagnosis confirmed by an experienced pathologist before surgery.
- Complete the staging workup and appropriate consultation before surgery.
- Make a preoperative plan detailing positioning, resection steps, and reconstruction options.

Technical Points

- Mark limb salvage incisions so that they incorporate the previous biopsy tract and any previously contaminated tissue.
- Prioritize tourniquet time to critical portions of the procedure—usually dissection of neurovascular structures.
- Create flaps while leaving the biopsy tract en bloc with the major tumor mass.
- Dissect or sacrifice major nerves and vessels first.
- Leave a cuff of normal, uninvolved, nonreactive tissue covering the major tumor mass.
- Use the nondominant hand to palpate the tumor mass and ensure dissection at least one fingerbreadth from the tumor whenever possible.
- Avoid any contamination from the tumor.
- Take advantage of fascial or compartment boundaries by dissecting on the opposite side of the fascia from the tumor.
- Sacrifice functional tissues, nerves, tendons, vessels, and bone as needed to achieve negative margins.
- Confirm negative margins of resection by assessment of frozen sections.
- Consider a separate reconstruction team, especially with free tissue transfer.
- Use separate isolated fields and clean instruments and clothing for remote tissue harvest for reconstruction.
- Achieve excellent hemostasis before closure.

Postoperative Care

- Confirm the pathologic diagnosis on permanent analysis.

Epithelioid Sarcoma

Epithelioid sarcoma has been reported to be the most common soft tissue sarcoma occurring in the forearm and hand.[22,59,162,165,185] This tumor is notorious for its innocuous appearance, frequent misdiagnosis, propensity for local recurrence, and regional lymph node metastasis. Epithelioid sarcoma is commonly manifested as a painless nodule on the volar surface of the digits or palm that may ulcerate. Misdiagnosis has included infection, Dupuytren nodules, and other types of sarcomas. The extent of local disease is often not evident on clinical or radiographic examination. This tumor is characterized by a tendency to spread proximally along the course of tendons, lymphatics, and fascial planes without respecting fascial boundaries.[162] A high risk for lymph node involvement has been reported, with several authors recommending lymph node dissection.[162,165,185]

Epithelioid sarcoma must be treated aggressively with a true wide excision, radical resection, or amputation. Epitrochlear and axillary lymph node sampling should be strongly considered, even in the absence of clinically or radiographically detectable disease because excision of involved nodes has the potential to be lifesaving. The role of sentinel lymph node biopsy, as opposed to prophylactic lymphadenectomy, is under investigation.[106] Forequarter amputation has resulted in cure of patients with proximally recurrent disease or axillary lymph node involvement.[28] Marginal excision, even when combined with external beam irradiation, has resulted in unacceptably high rates of local recurrence and regional spread and is not a reasonable option for the treatment of epithelioid sarcoma.[185] External beam irradiation or brachytherapy should be done after wide excision of larger lesions. Chemotherapy should be considered for patients with lymph node involvement, metastasis, or recurrence.

Synovial Sarcoma

Synovial sarcoma is a high-grade malignant soft tissue sarcoma that usually arises in proximity to joints, tendons, or bursae.[47,151,171] This tumor most commonly occurs in the region of the carpus and is rarely seen in the fingers. A painless mass over the dorsum of the hand or in the palm, often present for many years, is the most frequent finding and can lead to the false impression that the lesion is benign. Rare intraneural lesions may be heralded by intense radiating pain not usually seen with schwannoma or neurofibroma. Synovial sarcoma can grow very slowly initially, and the patient may give a history of no apparent growth. Any soft tissue mass that is unexplained and not readily diagnosed by physical examination or imaging should be sampled to establish an accurate diagnosis.

Soft tissue calcifications may be seen in 20 to 30% of patients on plain radiographs.[47] The lesion metastasizes to regional lymph nodes in as many as 25% of patients in whom metastasis develops. Although the size of synovial sarcoma has been thought to be an important prognostic factor in general case series,[151] small size may not necessarily be associated with a better prognosis for lesions arising in the hand.[28,47] Studies suggest a benefit from the use of intensive or high-dose chemotherapy, particularly in patients with resectable metastatic disease.[171,184] This tumor is treated as previously discussed for soft tissue sarcomas.

Liposarcoma

Liposarcoma is one of the most common types of soft tissue sarcoma, but it is only rarely seen in the hand.[28,194] Histologic subtypes of liposarcoma include well-differentiated, myxoid, round cell, dedifferentiated, and pleomorphic liposarcoma. Differentiation of liposarcoma into its various subtypes is useful because histologic appearance and tumor grade correlate with clinical behavior, risk for metastasis, and prognosis.[58] Clinically, these lesions can resemble lipomas, but more often they are painful and grow more rapidly. Findings on MRI also may be similar to those for lipoma with the notable exception of greater heterogeneity or lack of suppression on fat suppression sequences (Figure 59.46).

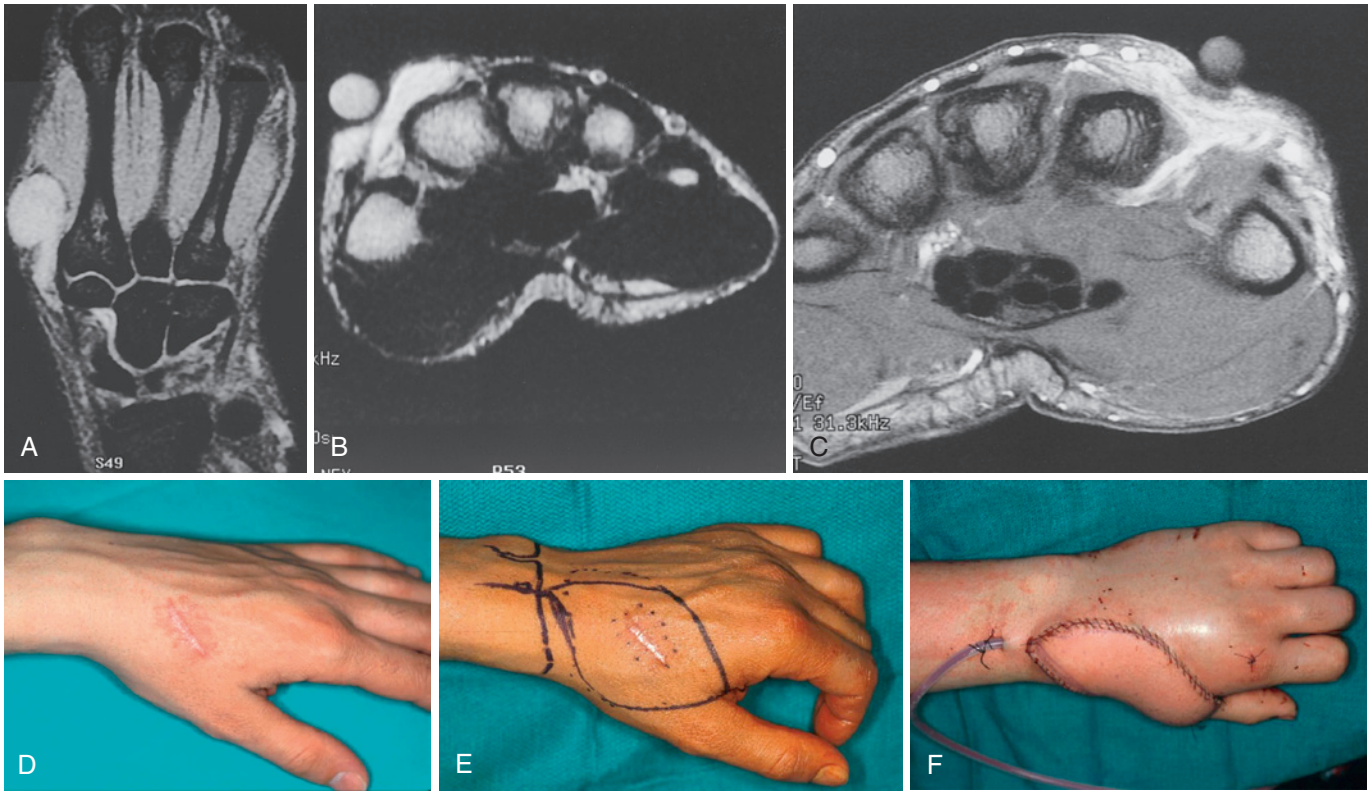

FIGURE 59.46 Preoperative coronal **(A)** and axial **(B)** magnetic resonance imaging (MRI) demonstrating a soft tissue mass with signal characteristics similar to those of subcutaneous fat. After marginal excision for a presumed benign lesion, it was not possible to differentiate residual myxoid liposarcoma, postoperative change, and normal fat on an axial MRI image **(C).** The initial marginal excision biopsy was done through an oblique incision **(D).** The margins were positive. Wide excision **(E)** was done and a lateral arm free flap used for closure **(F).** Reexcision that included a portion of the index metacarpal achieved negative margins.

Any lesion diagnosed preoperatively as lipoma based on the history, physical examination, and radiographic studies should be approached as though it were potentially malignant. Any biopsy or excision should not compromise a subsequent limb salvage operation or amputation. Frozen section diagnosis of fat-containing tumors is difficult, and suspicious lesions are best treated after a malignant diagnosis can be confirmed on permanent sections.

Appropriate treatment of liposarcoma is wide excision and adjuvant radiation therapy for large lesions. Amputation may be necessary if wide margins cannot be achieved, particularly for high-grade lesions. Chemotherapy may be considered for very large high-grade lesions or for patients initially seen with metastasis or in whom metastasis develops.

Fibrosarcoma

Approximately 30% of soft tissue fibrosarcomas occur in the upper extremity, although hand involvement is extremely rare.[70,114] There can be considerable difficulty in making the diagnosis of fibrosarcoma, particularly in children younger than 5 in whom the aggressive histologic appearance of benign fibrous lesions is similar to that of fibrosarcoma. The clinical course of these lesions is different from that of fibrosarcoma in that they are not known to metastasize. Treatment of high-grade lesions in adults includes systemic staging, wide excision, and consideration of irradiation and chemotherapy, as previously outlined for soft tissue sarcomas.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is an uncommon low-grade malignant soft tissue tumor that may be encountered in the forearm and rarely in the hand (Figure 59.47).[160,174,] This lesion arises in the dermis and most often appears as a painless violet-red plaque or nodule that may have been present for several years. Long-standing lesions may ulcerate or extend deep to subcutaneous tissues to involve muscle, tendon, and fascia. DFSP has a striking propensity for horizontal spread in the dermis and subcutaneous tissues, and there is a notoriously high risk for local recurrence, even after wide excision.

Patients with DFSP must have their disease carefully staged locally before planned excision. MRI is extremely useful in assessing the local extent of disease (see Figure 59.47). Several reports have suggested a 3-cm margin of resection and inclusion of the deep fascia to minimize the risk for local recurrence.[160,174] Retrospective microscopic analysis of resection margins has shown that 75% of lesions can be effectively excised with a 1-cm margin, 80% with a 1.5-cm margin, 85% with a 2-cm margin, and 100% with a 2.5-cm margin.[160] Historically, the risk for local recurrence of DFSP has been 50%. If appropriate wide excision is performed for either primary or recurrent lesions, the incidence of local recurrence is reduced to approximately 12%.[174] The risk for metastasis of this low-grade lesion is less than 5%.[174]

External beam irradiation has been of benefit for improving local control in patients with positive margins, although

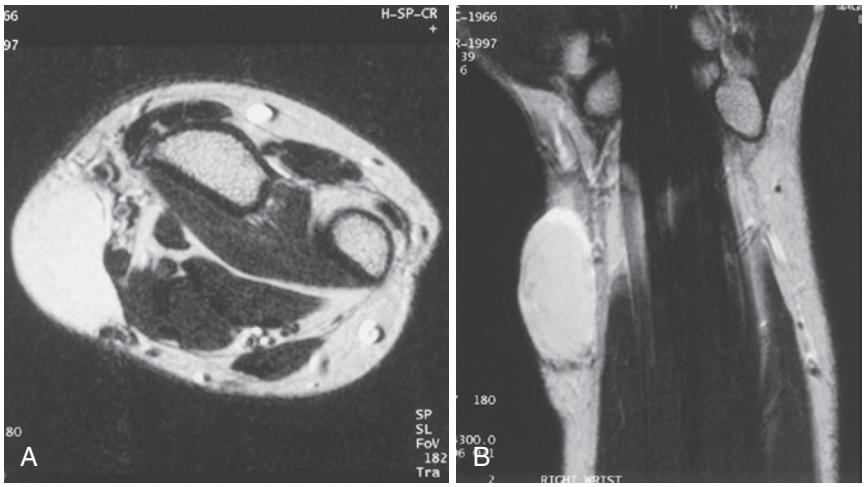

FIGURE 59.47 Axial **(A)** and coronal **(B)** magnetic resonance imaging of dermatofibrosarcoma protuberans abutting the radial artery.

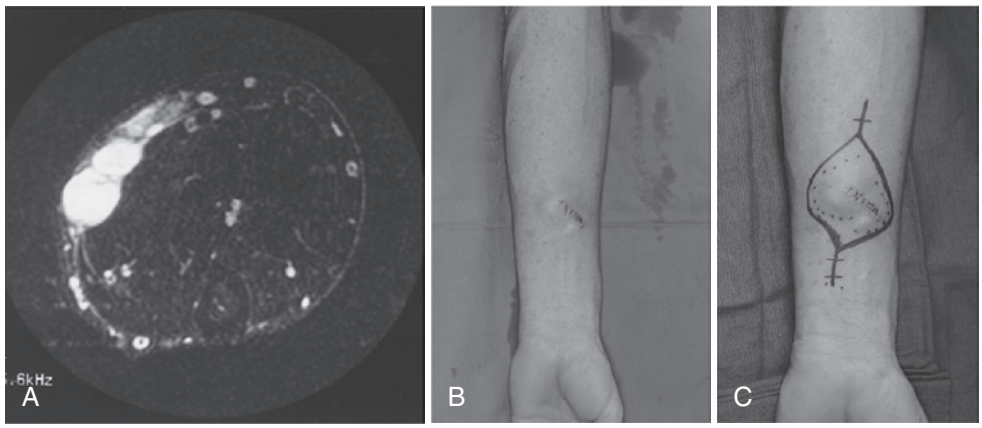

FIGURE 59.48 **A,** Magnetic resonance imaging of malignant fibrous histiocytoma of the forearm. **B,** An oblique incision was used for incisional biopsy. (A straight longitudinal incision would have been better because it is more easily incorporated into a limb-sparing incision at the time of definitive resection.) **C,** The planned wide excision included generous skin margins.

reexcision is generally recommended for those with positive margins. Soft tissue coverage is frequently required after the generous excision of skin needed to achieve appropriate margins. Reports of Mohs micrographic surgery noted excellent short-term local control and may allow surgery with narrower margins.[128,160] Neoadjuvant imatinib may be beneficial in locally advanced or recurrent dermatofibrosarcoma protuberans.[197]

Malignant Fibrous Histiocytoma

There are very few reports of malignant fibrous histiocytoma occurring in the hand, although 19% of lesions arise in the upper extremity, many of which are located in the forearm.[58,92,202] It may arise in the soft tissues or as a primary bone tumor. Bone lesions are lytic on plain radiographs and may arise from a preexisting lesion such as Paget's disease or a bone infarct. Multifocal soft tissue lesions in the hand have been reported. These lesions are best treated by wide excision or amputation (Figure 59.48). Adjuvant radiation therapy is necessary to maximize local control after wide excision of large lesions. There may be a role for chemotherapy in treating very large soft tissue lesions and those arising in bone.

Malignant Peripheral Nerve Sheath Tumor (Neurofibrosarcoma/Malignant Schwannoma)

Malignant peripheral nerve sheath tumor (MPNST) is the accepted term for malignant soft tissue tumors of neural origin, including neurofibrosarcoma, neurosarcoma, and malignant schwannoma.[45,67] Approximately 30% of MPNSTs occur in the upper extremity, with 50% of cases arising in the setting of neurofibromatosis (von Recklinghausen disease). This lesion may be seen as a secondary sarcoma after primary radiation therapy for a different sarcoma or lymphoma.[24,67] MPNST is known for its propensity to grow along peripheral nerves and has an exceptionally high rate of local recurrence, even after amputation. This tumor does not appear to be radiosensitive, nor has chemotherapy been shown to be of benefit.[45,200] Wide excision or amputation has been the recommended treatment. Forequarter amputation may be necessary to achieve local control of brachial plexus lesions. Poor prognostic factors include proximal location of the primary lesion, large tumor size, and neurofibromatosis. The 5-year survival rate for patients with MPNST is approximately 40%, with the poorest prognosis for patients with neurofibromatosis.[67,200]

Rhabdomyosarcoma

Rhabdomyosarcoma is a malignant round cell tumor most frequently seen in childhood, but it is uncommon in the hand.[42,87,127,138] Extremity rhabdomyosarcoma has been associated with a poor prognosis, although upper extremity lesions and distal lesions fare better than lower extremity or more proximal lesions. Alveolar rhabdomyosarcoma is the most common histologic variant seen in the hand and in the past has been thought to confer a worse prognosis. More intensive chemotherapy regimens appear to improve the prognosis for patients with this histologic subtype of rhabdomyosarcoma.[42]

Patient survival in the past 25 years has dramatically improved with the use of effective multiagent chemotherapy and radiation therapy. The extent of disease at initial evaluation and the surgeon's ability to completely remove the lesion with negative margins affect the prognosis.[42,138] Limb-sparing surgery through a wide margin has been recommended for obtaining local control in the setting of multiagent chemotherapy. Marginal surgery or gross total excision has been advocated rather than amputation because of the ability to improve local control with irradiation for patients who do not have wide margins. Extremity rhabdomyosarcoma appears to have a high risk for regional lymph node metastasis, and pathologic evaluation of lymph nodes has been advocated to improve staging and to direct systemic treatment.[68]

Leiomyosarcoma

Leiomyosarcoma is most commonly seen in the viscera and only rarely in the hand.[28,46] This lesion appears to arise in areas of smooth muscle and has been seen in the veins of the hand. There is a report of an apparent benign angiomyoma in the hand recurring as leiomyosarcoma. Some reports have noted a particularly high rate of local recurrence when surgery is not followed by radiation therapy in extremity lesions. Leiomyosarcoma is best treated by wide excision and consideration of adjuvant treatment, as previously outlined for the treatment of soft tissue sarcomas in general.

Clear Cell Sarcoma

Clear cell sarcoma, or malignant melanoma of soft parts, is an uncommon soft tissue sarcoma with a propensity to occur in close association with tendons and aponeuroses.[28,57] It has been confused with metastatic acral lentiginous melanoma. This lesion has been noted to have both a high risk for local recurrence and a potential for regional lymph node metastasis as high as 53%. Regional lymph nodes should be carefully assessed both clinically and radiographically during staging. Strong consideration should be given to regional sentinel lymph node biopsy in patients with clear cell sarcoma. These lesions are best treated as previously outlined for soft tissue sarcomas.

BENIGN BONE TUMORS

Enchondroma

Enchondromas are benign cartilaginous lesions that are the most common primary bone tumors arising from the hand's bones.[15,18,43,62,86,93,126,192] Approximately 35% of all enchondromas develop in the hand, and enchondromas account for as many as 90% of bone tumors seen in the hand.[15,93] Monostotic lesions most commonly occur in the fourth decade, with the majority of lesions developing between the ages of 10 and 40.[93,192] The proximal phalanx is the most common site of involvement, followed by the metacarpal and middle phalanx. The carpus is rarely involved, although enchondromas have been reported in the scaphoid, lunate, and capitate.

Patients with monostotic lesions are most commonly evaluated initially because of either localized swelling, which may be painless, or pathologic fracture associated with minor trauma. Enchondroma can also be diagnosed as an incidental finding on plain radiographs. They typically demonstrate a well-defined lytic lesion, which may be lobulated (Figure 59.49). Matrix calcification may be seen. Soft tissue extension is not typical and is suggestive of a more aggressive neoplasm. The diagnosis of enchondroma in the overwhelming majority of cases can be

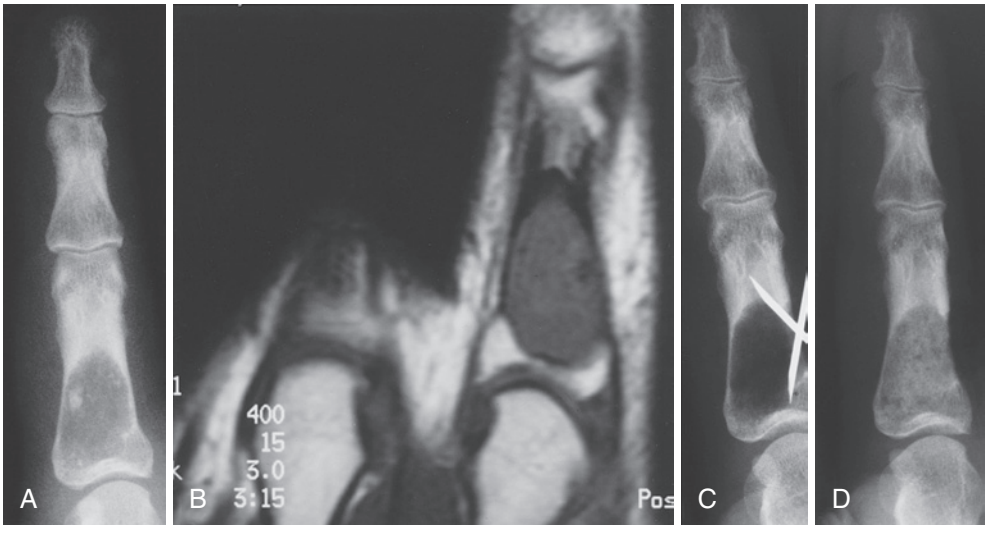

FIGURE 59.49 Enchondroma. A well-demarcated lytic lesion with stippled calcification was seen on radiographs of the proximal phalanx of the index finger **(A).** Magnetic resonance imaging confirmed the intraosseous nature of the lesion **(B).** An open biopsy from ulnar lateral approach confirmed the clinical impression of enchondroma. Intraoperative radiographs after curettage documented complete removal of the lesion **(C)** and complete filling of the cavity with bone graft **(D).**

made with plain radiographs without the need for axial images obtained with CT or MRI.

Small asymptomatic lesions with a typical radiographic appearance can simply be observed. Large or symptomatic enchondromas or lesions that do not demonstrate a characteristic radiographic appearance should be treated by biopsy and curettage. Pathologic fractures can be treated acutely, but the evaluating pathologist should be given the clinical history because the presence of osteoid seen during fracture healing may add confusion to the pathologic diagnosis. Alternatively, the lesion can be treated after the pathologic fracture has healed. There are data to suggest that clinical outcome can be improved if treatment is done after healing of the pathologic fracture.[2]

Enchondromas can be approached dorsally or laterally. The initial biopsy should be done through a limited exposure and the diagnosis confirmed on frozen section before proceeding with wider exposure. Several reports have emphasized the need for thorough curettage, with recurrence being attributed to inadequate curettage. Intraoperative radiographs are useful to be certain of complete removal of all tumor (see Figure 59.49, C). Iliac crest or distal radius bone graft has been most commonly used to fill the defect left after curettage,[15] although fresh frozen or freeze-dried irradiated allograft has been used with similar excellent results reported.[15]

More recently, several authors have reported excellent results with simple curettage without filling the defect with any material.[84,86] Injectable calcium phosphate bone cement has been used to fill the defect in one small series.[205] Although data are limited, whether the cavity is filled with any material does not appear to affect the risk for local recurrence. The latter methods eliminate the morbidity of graft harvest and are an alternative to iliac crest bone graft. There is a small but real risk of disease transmission with allograft. It is not clear whether there is an increased risk for fracture if the cavity is not grafted or whether certain lesions are best excluded from this form of treatment. The incidence of local recurrence after curettage is 4.5 to 7%. Early mobilization can be encouraged in an effort to minimize joint stiffness, provided that there is sufficient residual bone stock and stability. Filling the curetted cavity with methylmethacrylate cement has been advocated to ensure immediate stability and facilitate early motion. Malignant degeneration of monostotic enchondroma to chondrosarcoma, although rare, has been adequately described.[43]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

I prefer to expose phalangeal lesions from a lateral approach rather than dorsally to minimize scarring and contamination of the extensor mechanism. My current preference is to fill the curetted cavity with freeze-dried irradiated allograft mixed with the patient's bone marrow. I consider curettage alone in those patients who wish to avoid bone graft. Only rarely do I use local bone graft from the radius or ulna in treating any bone tumor in the hand because of the risk of contamination of the donor field with tumor cells.

Multiple Enchondromatosis (Ollier Disease)

Multiple enchondromatosis, or Ollier disease, is an uncommon, nonhereditary skeletal disorder characterized by the presence of multiple enchondromas or cartilaginous masses in the metaphysis and diaphysis of long bones or short tubular bones of the hands and feet.[93] The disease is usually unilateral or predominant on one side. The enchondromas in Ollier disease can be large and produce significant cosmetic and functional hand deformity, as well as brachydactyly (Figure 59.50). Benign lesions are typically not painful. Growth of the lesion after skeletal maturity, radiographic progression, or the onset of pain should raise the question of malignant transformation. The risk for malignant transformation to chondrosarcoma or osteosarcoma in patients with Ollier disease is approximately 30%.[62,93,126] Histologic confirmation of chondrosarcoma in these patients is difficult and requires correlation with clinical findings and radiographs.[126] Patients with Ollier disease require periodic surveillance with physical and radiographic examination because of the risk of malignancy. Progressive nonmalignant deformity has been treated by diaphysectomy and fibula strut grafting.[62]

CRITICAL POINTS *Treatment of Enchondroma of the Hand Bones*

Indications

- Same as for biopsy
- Lesions at risk for pathologic fracture
- Lesions in which pathologic fracture has previously occurred

Technical Points

- Review the case with a pathologist in advance and confirm availability of that person at time of surgery.
- Draw a limb salvage incision or amputation flaps in the event of a final diagnosis of chondrosarcoma.
- Place the biopsy incision in line with the limb salvage incision or within the amputation field.
- Use radial or ulnar lateral incisions whenever possible.
- Minimize dissection or retraction of the extensor mechanism to minimize postoperative adhesions.
- Consider using Kerrison rongeurs to allow the creation of precise bone windows.
- Confirm the diagnosis of enchondroma on frozen section analysis.
- Place needle markers in the bone cavity and obtain radiographs to confirm adequate curettage.
- Fill the cavity with autograft or allograft, as indicated.

Postoperative Care

- Confirm the diagnosis on permanent analysis.
- Initiate early active or active-assisted range-of-motion exercises under supervision.
- Apply a splint for 6 weeks or as indicated.
- Monitor for local recurrence (4-7% risk).

Maffucci Syndrome

Maffucci syndrome is an extremely rare disease that affects the hands in the majority of cases.[93,121] The radiographic findings in bone are identical to those seen in Ollier disease (see Figure 59.50), but these patients also have multiple hemangiomas, which may be apparent radiographically because of the presence of phleboliths. Patients with this syndrome are also at high risk for the development of both bone and soft tissue sarcomas.[93,121]

Periosteal Chondroma

Periosteal chondroma is an uncommon benign cartilaginous lesion that can occur in the phalanges and be confused

FIGURE 59.50 Multiple enchondromas (Ollier disease).

FIGURE 59.51 **A,** Periosteal chondroma of the proximal phalanx. **B,** Two years after marginal en bloc excision without grafting, normal bone contour has been restored.

radiographically with enchondroma and histologically with chondrosarcoma.[21,120] Periosteal chondroma is most commonly seen in males in the second or third decade. The second most common location for this lesion is the metaphyseal–diaphyseal junction of the phalanges of the hand.[120] Radiographs typically reveal a subperiosteal lytic lesion with erosion of the underlying cortex, buttressing at the proximal and distal extent, and occasionally an overlying rim of sclerosis (Figure 59.51). Histologic examination demonstrates an aggressive-appearing cartilaginous lesion that may be confused with chondrosarcoma. This lesion has a benign clinical course but can recur locally if the overlying periosteum is not excised en bloc with the tumor. Marginal excision is usually curative, with local recurrence rates being less than 4%.[120]

It is important to attempt to make the diagnosis of periosteal chondroma preoperatively based on plain radiographs to treat the lesion appropriately and avoid the unnecessary amputation that has been reported. Periosteal chondroma most often has a characteristic radiographic appearance: external cortical erosion by a lytic unilobular lesion with a faint overlying calcified rim. The differential diagnosis of this lesion includes enchondroma, juxtacortical chondrosarcoma, periosteal osteogenic sarcoma, and subperiosteal aneurysmal bone cyst.

Osteochondroma

Osteochondroma is one of the most common bone lesions seen in the general skeleton, but it is not frequently seen in the hand, except in patients with multiple hereditary exostoses.[35,144] These lesions are osseous growths with a hyaline cartilage cap thought to originate from the physis or regions of tendon insertion.[93] Osteochondromas in the hand are generally seen at the distal aspect of the proximal phalanx during the second or third decade of life.[144] The prominence caused by an osteochondroma can result in cosmetic deformity and impaired function by producing a mechanical block to motion. Angular growth disturbance or rotational abnormalities may be seen, particularly with lesions arising distally in the phalanges. Osteochondromas with a characteristic radiographic appearance that are asymptomatic and do not impair function may be observed. Lesions that produce progressive deformity, pain, or impairment of function should be excised. There is a known risk for malignant transformation of osteochondroma to chondrosarcoma in the general skeleton, but malignant transformation of an osteochondroma in the hand has not been reported.

Bizarre Parosteal Osteochondromatous Proliferation

Osteochondromas are distinct entities and are not related to so-called bizarre parosteal osteochondromatous proliferations.[149] The latter is a benign, large proliferation of bone and cartilage that appears to arise from the cortical surface and lacks continuity with the medullary cavity. It has an aggressive radiographic and histologic appearance and may be confused with parosteal osteogenic sarcoma.[149] Although there is a high risk for local recurrence after marginal excision, wide or radical excision is not necessary because of its benign clinical course.

Subungual Exostosis (Subungual Osteochondroma)

Subungual exostoses are frequently misdiagnosed and may be confused with osteochondromas. This lesion has a cap of fibrocartilage, as opposed to the hyaline cartilage seen with an osteochondroma. Nail removal with excision of the exostosis has been successful in correcting the deformity, without reported recurrence.[35]

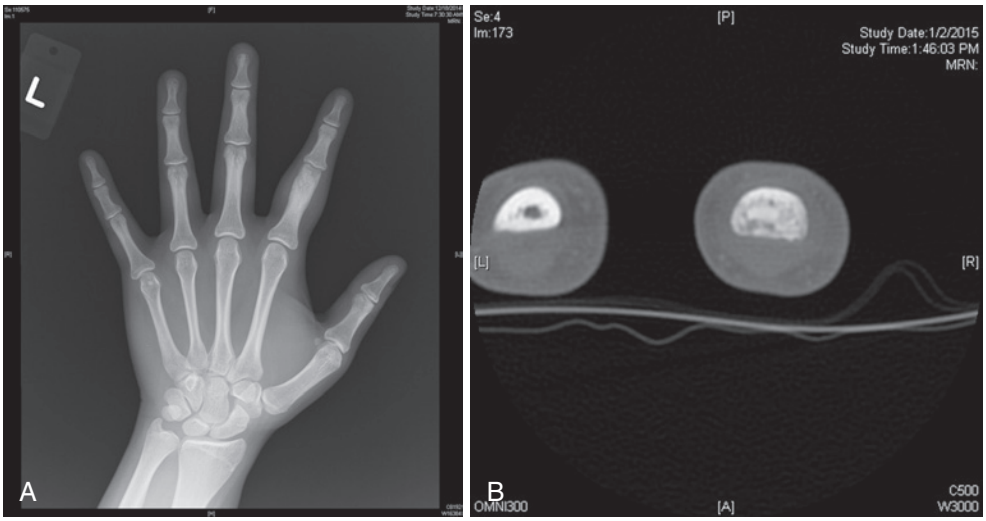

FIGURE 59.52 Osteoid osteoma. **A, B,** A 19-year-old woman was evaluated for a painful proximal phalanx that was dramatically relieved with aspirin. Note the classic sclerotic cortical area with a radiolucent nidus. Complete relief of pain followed local resection of the tumor nidus.

Chondromyxoid Fibroma

Chondromyxoid fibroma is a benign cartilaginous lesion.[78,176,188] Patients may give a long history of mild pain or swelling. Plain radiographs most often reveal a lytic lesion in the metaphyseal region of the bone. In large bones, the lesion is usually eccentric, but in the hand, it is more commonly central. Cortical expansion and the presence of a sclerotic rim are frequent. Pseudotrabeculation may be seen, and matrix calcification is rare in comparison to enchondroma. The lesion is most common before the age of 30, with a male-to-female ratio of 2:1. Curettage and bone grafting have been successful in controlling hand lesions. Recurrence rates of 7 to 25% have been reported with this method of treatment in large case series.[78,176] Local recurrence after curettage and bone grafting for lesions in the hand is uncommon. The most important issue in treating this lesion is making an accurate diagnosis. Chondromyxoid fibroma has been confused with chondrosarcoma in the past because of its aggressive histologic appearance, and amputation has been performed unnecessarily.

Osteoid Osteoma

Osteoid osteoma is a benign bone lesion that has been well described in the hand and distal end of the radius.[7,16,72] Five percent to 15% of osteoid osteomas occur in the hand and wrist,[7,16] most commonly in the proximal phalanx and carpus; involvement of the middle phalanx is rare. Lesions arising in the distal phalanx may be atypical in their findings, with frequent pulp swelling and nail deformity. Radiographs usually demonstrate a lytic lesion rather than the classic appearance of reactive sclerosis surrounding a central lucent nidus.

Patients are typically seen initially in the late second or early third decade of life with a deep, dull ache that is constant and frequently relieved with nonsteroidal antiinflammatory drugs (NSAIDs). Painless osteoid osteomas in the hand do occur, and in these instances the primary complaint is swelling. Osteoid osteoma of the capitate has been reported to cause symptoms of carpal tunnel syndrome, and lesions of the radial styloid have been manifested as de Quervain tenosynovitis.[72] Physical examination usually demonstrates well-delineated tenderness and swelling. The classic radiographic appearance is reactive sclerosis surrounding a central lucency less than 1 cm in diameter (Figure 59.52), although lesions initially seen in an early stage may not show these findings. Diagnosis of hand lesions is frequently delayed, with a mean time to diagnosis of longer than 15 months in two large case series.[7,16] Radionuclide bone scan, tomography, and CT may improve diagnostic accuracy and assist in better defining and localizing the lesion before planned surgical treatment.[16]

Treatment of osteoid osteoma in the hand or carpus has consisted of surgical excision with either curettage of the nidus or en bloc excision. Persistence of the lesion has been reported if the nidus is not completely excised.[7,16] Successful use of percutaneous CT-guided laser photocoagulation has been reported.[206] Radiofrequency ablation may be considered for carefully selected lesions that are not subcutaneous or near major nerves. Successful treatment with prolonged use of NSAIDs has been described for lesions occurring in long bones with a mean symptom duration of 33 months.[113]

There is no large report of this type of treatment for lesions occurring in the hand. Prolonged use of NSAIDs may be an alternative to surgical treatment if the clinical and radiographic findings are strongly supportive of a diagnosis of osteoid osteoma and excision or biopsy of the lesion might produce excessive morbidity. This also may offer an alternative for the treatment of recurrent or residual lesions in which the diagnosis of osteoid osteoma had clearly been established previously.

Osteoblastoma

Osteoblastoma is a rare benign tumor that is usually larger than 2 cm in diameter and is characterized by osteoid and woven bone production.[81,146] The tumor is most frequently found in the posterior elements of the spine. Its histology is similar to that described for osteoid osteoma, but it is important that the tumor be distinguished from osteosarcoma. Differentiation between osteoblastoma and osteoid osteoma is usually based on

location and size. Osteoblastoma is more commonly centered in the medullary portion of bones, whereas osteoid osteomas tend to be cortical, medullary, or subperiosteal in location. Local recurrence may be seen in 20 to 30% of cases after curettage and bone grafting in general case series. Under circumstances in which the lesion has recurred or has become locally destructive, cure may require marginal or wide excision with subsequent reconstruction.

Unicameral Bone Cyst

Unicameral bone cysts are benign, cystic lesions of uncertain etiology that are extremely rare in the bones of the hand and forearm.[30,163,175] Most information on natural history and treatment has been gained from the care of proximal humeral and femoral lesions. Unicameral bone cysts are usually asymptomatic until there has been a pathologic fracture. Radiographs demonstrate a lytic metaphyseal lesion with well-defined borders and septa or minor trabeculations (Figure 59.53). The radiographic differential diagnosis of lesions occurring in the forearm and hand can include enchondroma, aneurysmal bone cyst, and telangiectatic osteogenic sarcoma.

Treatment of unicameral bone cysts has included observation, curettage and bone grafting, drilling, corticosteroid injection, and en bloc excision. Cyst aspiration and corticosteroid injection have become more popular for the treatment of these lesions because of the lower risk for complications and healing rates similar to those attained with curettage and bone grafting.[30,175] Intraosseous injection may need to be repeated several times to achieve partial or complete healing.[175] There is no known risk for malignant degeneration of unicameral bone cysts. Indications for treatment, when a diagnosis has been established, are based on the potential for mechanical failure (fracture) and deformity.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

Unicameral bone cysts are sufficiently rare in the hand to warrant biopsy in all suspected cases because accurate radiographic diagnosis of this hand or forearm entity may not be predictable. Although "classic" lesions in the distal radius may be treated by corticosteroid injection, my preference is to treat them with open biopsy, curettage, and bone allograft after frozen section diagnosis. This technique offers the advantage of an accurate pathologic diagnosis and potentially less anesthetics for the patient than may be required with repeated corticosteroid injection.

Aneurysmal Bone Cyst

Aneurysmal bone cysts account for approximately 5% of benign bone tumors, but only 3 to 5% of all aneurysmal bone cysts occur in the hand.[69,137] Hand lesions most commonly occur in the second decade of life, with males and females being equally affected. Metacarpal involvement is more common than phalangeal involvement, and carpal lesions are rare. Its radiographic appearance may be similar to GCT of bone, although more frequently there is an expansile deformity and a thin rim of bone that surrounds the entire lytic lesion (Figures 59.54 and 59.55).[139] Soft tissue extension is uncommon. Although this lesion can be aggressive locally, it is not known to metastasize. The risk for local recurrence may be as high as 60% after curettage and bone grafting of lesions in long bones.[137]

Frassica and coworkers reported the successful use of curettage in six of seven patients, but only three were treated

FIGURE 59.53 Solitary (unicameral) bone cyst in an 18-year-old man with a pathologic fracture through the bone cyst. Biopsy revealed a cavity with fluid present. Treatment consisted of curettage and bone grafting, and the prognosis was excellent.

FIGURE 59.54 Lytic expansile lesion with a surrounding rim of sclerosis typical of an aneurysmal bone cyst.

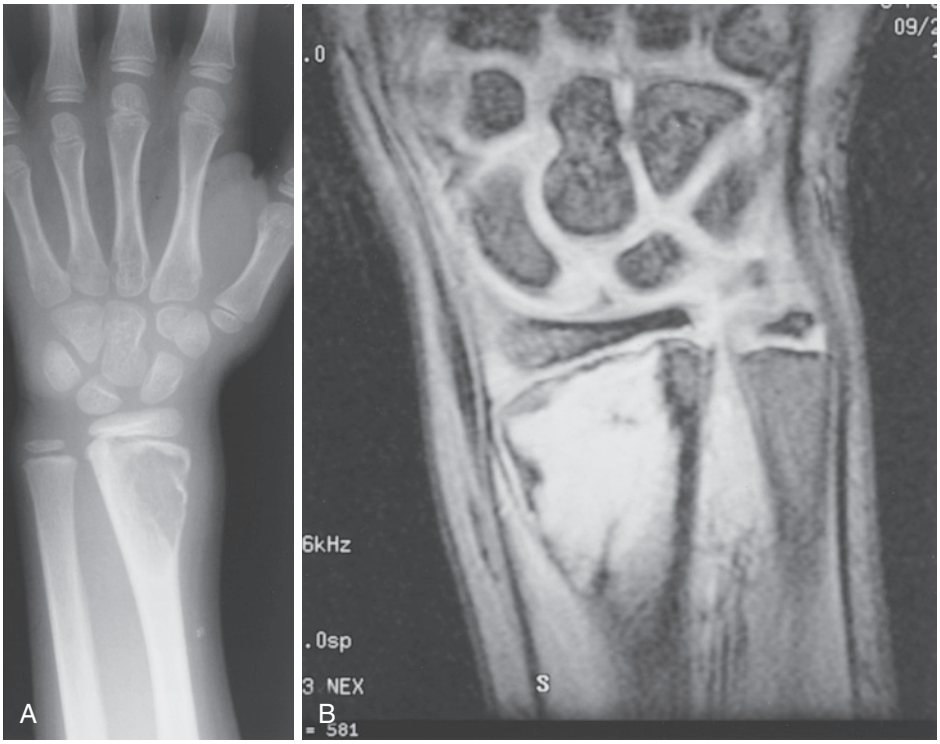

FIGURE 59.55 Aneurysmal bone cyst. **A,** A lytic lesion of the distal radius on a plain radiograph. **B,** Magnetic resonance imaging suggested a fluid-filled lesion. The radiographic interpretation was a unicameral bone cyst, but biopsy revealed an aneurysmal bone cyst. The lesion recurred 2 months after curettage and bone grafting.

effectively at the first operation.[69,139] Marcove and colleagues reported successful local control of 86% of lesions treated by curettage, cryosurgery,[†] and cementation or bone grafting.[137] Cryosurgery has been used successfully to treat recurrent aneurysmal bone cyst in the proximal phalanx. Wide excision has been successful in treating metacarpal lesions, and large distal phalangeal lesions have been treated effectively with amputation.[69]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

When performing all incisional biopsies on lytic lesions of the hand bones, I am equipped and prepared to perform cryosurgery immediately after frozen section diagnosis. Most aneurysmal bone cysts can be treated with curettage and bone graft with the knowledge that the majority may require a second curettage and bone graft following recurrence. Cryosurgery, when used as an adjuvant to curettage, has significantly reduced the risk for local recurrence in long bones and has been used successfully for the hand. Recurrent lesions can be treated with a second session of curettage and cryosurgery, provided that there is sufficient bone stock remaining in the affected bone. Wide excision followed by reconstruction is an alternative for large recurrent proximal phalanx or metacarpal lesions. Metacarpal lesions are readily reconstructed with diaphyseal fibula bone graft.

[†]The principle of cryosurgery is to cyclically rapidly freeze the neoplasm or any remaining microscopic disease after curettage, followed by slow warming to room temperature. This produces intracellular crystal formation and cell lysis on rewarming and effectively extends the zone of curettage in a controlled but not precise manner. The technique causes nonselective tissue necrosis based on the temperature produced in the tissues. Rapid freezing is typically accomplished by direct pour or spray of liquid nitrogen into the tumor cavity after the soft tissues have been isolated and protected. A metal or synthetic cryoprobe that circulates liquid nitrogen is an alternative to the direct pour or spray technique.

Giant Cell Tumor of Bone

Although GCT of bone accounts for approximately 5% of benign bone tumors, only 2% of them occur in the hand.[12,13,93] These tumors are considered benign lesions based on their histology, but they may behave in a locally aggressive fashion, metastasize, and ultimately result in death.[12,13,133] Lesions that arise in the bones of the hands have a higher risk for local recurrence after intralesional treatment, have a greater propensity to metastasize than such lesions seen elsewhere in the body, and must be approached with great caution.[12,13,80,152] Local recurrence rates of greater than 80% may be seen after intralesional treatment with curettage, even with the use of phenol as an adjuvant.[12,13] There are several well-documented cases of pulmonary metastases from benign GCTs of bone that developed in the hand.[12,13,133]

GCT of bone generally arises early in the fourth decade of life. The most common locations in the hand are the metacarpals and phalanges, although GCT has been reported in all carpal bones.[12,13,115] A propensity for multicentricity has been reported.[13] Patients have pain and swelling in the affected region or after a pathologic fracture. Radiographs typically demonstrate a lytic lesion with no matrix and indistinct borders, which helps differentiate this lesion from aneurysmal bone cyst (Figure 59.56). Cortical expansion, destruction, and soft tissue extension are common. The epiphyseal and eccentric locations

FIGURE 59.56 Giant cell tumor of bone showing the typical cortical expansion.

typically seen elsewhere in the body are less common in hand lesions because they frequently involve a major portion of the bone at initial evaluation.

Incisional biopsy should be done through a well-planned approach that can later be incorporated into a salvage operation or amputation. Soft tissues must be protected during the biopsy because GCT has a propensity to seed soft tissues, which could result in subsequent soft tissue local recurrence.[12] Proximal carpal lesions have been treated by either curettage or proximal row carpectomy.[12,115] Wide excision has been recommended for distal carpal row lesions.[115] Isolated curettage followed by bone grafting of metacarpal and phalangeal lesions is associated with an unacceptably high risk for local recurrence.[12,13] There are reports of success with the use of curettage, cryosurgery, and bone grafting or cementation for both metacarpal and phalangeal lesions.[136,203]

Metacarpal lesions have been treated successfully by ray amputation or wide excision and reconstruction.[11,13,31] Phalangeal lesions have been treated successfully by amputation or wide excision and reconstruction with toe phalanx transfers.[12,196] External beam irradiation has been effective in the treatment of benign GCT of bone, but radiotherapy is associated with a risk for malignant transformation as high as 8.7%.[168] Malignant GCT of bone that occurs after external beam irradiation is fatal in most cases. Conventional chemotherapy has not been shown to be effective for benign GCT of bone.[133] Denosumab (Prolia) has recently been shown to have a beneficial effect for patients with lung metastases and unresectable primary tumors. Its role in the treatment of primary and metastatic GCT of bone is currently being investigated and defined.[117]

The third most common site of occurrence of GCT in the body is the distal end of the radius.[93] A review of 225 patients with long bone lesions treated by curettage, burring, application of phenol, and packing of the cavity with methylmethacrylate noted a 25% risk for local recurrence.[152] However, when cases arising in the distal radius are selectively reviewed, the risk for recurrence is 50%. In the Memorial Sloan-Kettering Cancer Center series, which included radiographically advanced lesions, the risk for local recurrence was reduced to 22% when curettage was combined with cryosurgery.[178] The most predictable method of local control has been wide excision of the distal radius.[147,178,199] Patients with distal radius lesions appear to be at an increased risk for metastasis.[133] Reconstruction after wide excision has been done with intercalary bone grafting for arthrodesis, articular fibula autograft, articular distal radius allograft, and creation of a one-bone forearm.[147,178,199]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

GCT of bone should be approached as a low-grade malignancy when it occurs in the hand and wrist. The disease should be staged after diagnosis with chest radiographs and a bone scan to rule out pulmonary metastasis and multicentric lesions. Phalangeal or metacarpal lesions that perforate the cortex or extend into soft tissues are best treated by amputation or wide en bloc excision and reconstruction. Distal carpal row lesions are best treated by wide excision and limited carpal fusion for reconstruction. Proximal carpal row lesions can be treated by proximal carpal row carpectomy. I would consider performing curettage and cryosurgery for lesions that do not perforate the involved bone and have sufficient remaining bone stock to allow bone grafting. Cryosurgery is associated with significant risks for soft tissue necrosis, wound infection, pathologic fracture, and neurapraxia and should be used only by those experienced with it.[136,140] Isolated curettage and bone grafting or curettage, application of phenol, and bone grafting cannot be advocated for the treatment of GCT of the bones of the hand.

I prefer to treat distal radius lesions that have not perforated the cortex (Campanacci grade I or II lesions) with curettage, burring, cryosurgery, and cementation as long as there is sufficient remaining native bone stock (Figure 59.57). Patients with a single plane-of-palmer perforation may be candidates for intralesional treatment with curettage, cryosurgery, and cementation.[102] Patients with a pathologic fracture or large or multiplane cortical perforation are most predictably treated by wide excision of the distal radius. Reconstruction with an intercalary fibula graft and rigid internal fixation gives the most predictable result.

MALIGNANT BONE TUMORS

Chondrosarcoma

Chondrosarcoma is the most common primary malignant bone tumor that occurs in the hand.[37,43,44,70,75,85,99,103,158,170] This tumor can arise primarily or can develop from a preexistent benign lesion such as an enchondroma or osteochondroma. The lesion usually occurs in patients older than 60 years. The proximal phalanges and metacarpals are the most commonly affected. Only rarely has chondrosarcoma been reported in the distal phalanges or carpus.[70] This lesion often appears as a slowly growing, firm, and painful mass. Radiographs typically reveal a tumor matrix with stippled calcifications, areas of lysis, and poorly defined borders. Extreme cortical expansion,

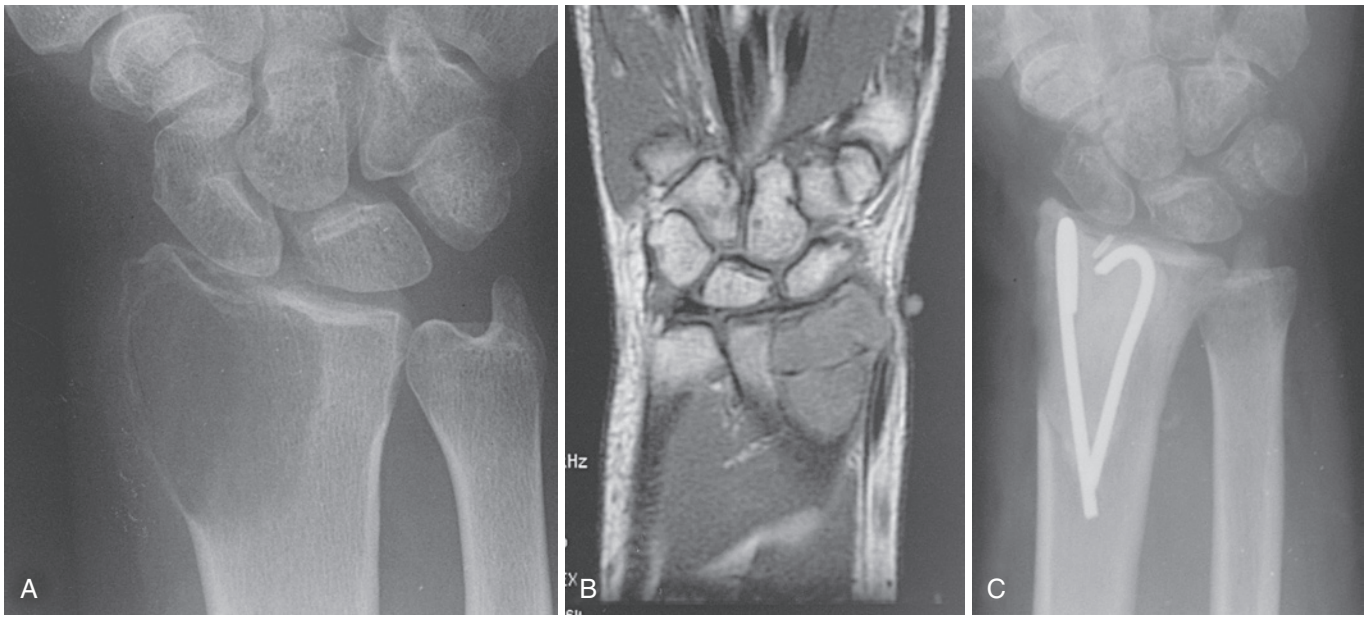

FIGURE 59.57 **A,** An expansile lytic lesion of the distal radius without a reactive sclerotic rim. **B,** Magnetic resonance imaging further delineates the lesion. Open biopsy revealed a giant cell tumor of bone. **C,** A radiograph was taken after curettage, burring, cryosurgery, and cementation with internal Steinmann pin struts.

CRITICAL POINTS *Giant Cell Tumor of Bone*

Preoperative Evaluation
- GCT should be considered a low-grade malignancy.
- Patients should be staged with CT of the chest and a total body bone scan.
- Use MRI to determine the extent of soft tissue contamination.

Indications for Wide Excision or Amputation
- Soft tissue contamination precluding the use of curettage with adjuvant therapy.
- Amputation for the majority of nondistal radius lesions.
- Wide excision for distal radius lesions with perforation of more than one cortex.

Technical Points
- The same as for biopsy or wide excision.

Postoperative Care
- Surveillance for local recurrence or metastasis for 10 years.

perforation, or extension into the surrounding soft tissues helps differentiate this lesion from enchondroma (Figure 59.58, *A, B*).

Even though there are well-documented instances of metastasis and mortality, the majority of chondrosarcomas are low-grade, slow-growing lesions that do not metastasize. The prognosis for patients with chondrosarcoma in general is related to the histologic grade of the lesion, although it is not clear that this principle applies to lesions arising in the hand.[93] The risk of metastasis for lesions occurring in the hand is approximately 10%, and it usually occurs after local recurrence following intralesional treatment.[99]

A well-planned incisional biopsy should be performed for suspicious lesions. It is imperative that the surgeon consult with the pathologist before the biopsy and that the biopsy specimen be reviewed in the presence of the plain radiographs. Interpretation plus diagnosis of cartilaginous lesions in the hand, in particular low-grade chondrosarcoma, is extremely difficult.[44] In general, peripheral cartilaginous lesions (i.e., those in the hand) tend to show greater degrees of cellularity and atypia on histologic examination, although the clinical course is that of a benign lesion. Radiographic findings of an inactive or, alternatively, an aggressive lesion can influence the pathologic diagnosis of cartilaginous lesions, and this has great implications for appropriate treatment. Malignant transformation in the setting of Ollier disease is particularly difficult to diagnose.

Patients suspected of having chondrosarcoma must have their disease staged locally and systemically. Chondrosarcoma most commonly metastasizes to the lungs, and patients should be evaluated with CT of the chest. Currently, chondrosarcoma of the hand bones is best treated surgically with wide en bloc excision or digit or ray amputation. There is investigational interest in intralesional procedures because of the limited metastatic potential of hand lesions.[23] The potential indications for this less aggressive approach remain to be defined. Chemotherapy is not known to be effective for the vast majority of chondrosarcomas. There may be a role for chemotherapy in the treatment of dedifferentiated chondrosarcoma or mesenchymal chondrosarcoma.[71] There is no role for radiation in the treatment of chondrosarcoma arising in the bones of the hand. Patients must be monitored for both local and systemic recurrence because metastasis may become apparent several years after treatment of the primary lesion.

Osteogenic Sarcoma

Osteogenic sarcoma is the most common primary bone tumor seen in children and adolescents, but it only rarely occurs as a primary hand lesion.[33,36,65,70,143,142,154] When it does involve the hand, it may be in older patients in the fourth, fifth, and sixth decades, often arising from a preexisting lesion.[10,33,36,154] Low-grade lesions may be more commonly seen in the hand.

FIGURE 59.58 **A, B,** Chondrosarcoma of the fourth (ring) finger proximal phalanx. Note the poorly defined borders and extension into soft tissues on magnetic resonance imaging.

Survival of patients with osteogenic sarcoma has improved dramatically with the use of systemic chemotherapy, and all patients with high-grade malignant lesions should receive adjuvant chemotherapy.[82,142,143]

Patients with osteogenic sarcoma have a rapidly enlarging firm and painful mass. Plain radiographs may reveal an expansile, sclerotic lesion with malignant new bone formation or with a more lytic or mixed pattern with destruction and a soft tissue mass (Figure 59.59). Parosteal osteogenic sarcoma may appear as a surface lesion with soft tissue involvement. This lesion most commonly occurs in the proximal phalanges and metacarpals.

A well-planned incisional biopsy should be performed while considering the need for subsequent amputation or a limb salvage procedure. After confirmation of the diagnosis, the lesion should be treated by wide en bloc excision or digital or ray amputation. Before modern chemotherapy, hand lesions were thought to have a better prognosis than those occurring elsewhere in the body.[33,36] It is not clear to what extent adjuvant chemotherapy affects the prognosis of patients with hand lesions,[154] but currently adjuvant chemotherapy is considered to be part of a comprehensive treatment plan.[82,142] There is no significant difference in survival with the use of chemotherapy before excision (neoadjuvant) or after excision (adjuvant), although neoadjuvant therapy may improve the quality of resection margins and reduce the risk for local recurrence.[142] There is no role for external beam irradiation in attempted curative treatment of these lesions. Long-term survival after aggressive treatment of local recurrence may be better for lesions occurring in the hand than in general case series, in which the prognosis is extremely poor.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

After confirmation of the diagnosis and local and systemic staging, I prefer to immediately initiate neoadjuvant chemotherapy. Although there may be no significant survival benefit with the use of neoadjuvant as opposed to adjuvant chemotherapy, an effective adjuvant in most cases decreases the size of the tumor and reduces surrounding soft tissue edema. This may facilitate wide en bloc excision or improve the quality of margins at amputation. A good response to chemotherapy appears to reduce the risk for local recurrence after wide excision. Analysis of the resection or amputation specimen allows quantitation of response to chemotherapy, which has prognostic significance and can affect postoperative adjuvant treatment plans.[142] After local treatment, chemotherapy should be resumed promptly because a delay in the resumption of it beyond 23 days adversely affects survival.[142] Prolonged local and systemic surveillance for recurrence or metastasis is mandatory.

Ewing's Sarcoma

Ewing's sarcoma is one of the common primary childhood sarcomas of bone but only rarely arises in the hand.[29,48,60,70,98,108,111,116,156,167] This tumor most frequently occurs in the first or second decade of life, with the youngest recorded case occurring in the distal phalanx of a 5-month-old infant. Survival has improved considerably with the use of adjuvant chemotherapy. Local treatment of Ewing's sarcoma in the hand must be done in the context of well-planned and coordinated systemic treatment. [76,98,111,156]

The clinical manifestation of Ewing's sarcoma in the hand is very similar to that seen with infection. Pain, swelling, and erythema are common. A significant soft tissue mass is frequently seen. Signs of systemic illness may be present and include fever and an elevated white blood cell count and sedimentation rate. There are several reports of misdiagnosis and prolonged treatment of presumed infection.[135] The tumor most commonly arises in the metacarpals or phalanges, with extensive soft tissue involvement. There is no well-documented case of this tumor arising in the carpus, and middle phalangeal involvement is rare. Radiographs typically reveal a large lytic, destructive, expansile lesion with associated soft tissue involvement. A mixed lytic and sclerotic appearance may be seen.[167] MRI is particularly useful in delineating the extent of bone and soft tissue involvement that may not be apparent on plain radiographs (Figure 59.60).

Incisional biopsy is indicated for patients with lytic destructive lesions of the bones of the hand. In addition, biopsy must always be strongly considered before the initiation of treatment for presumed deep infection because this is the most common

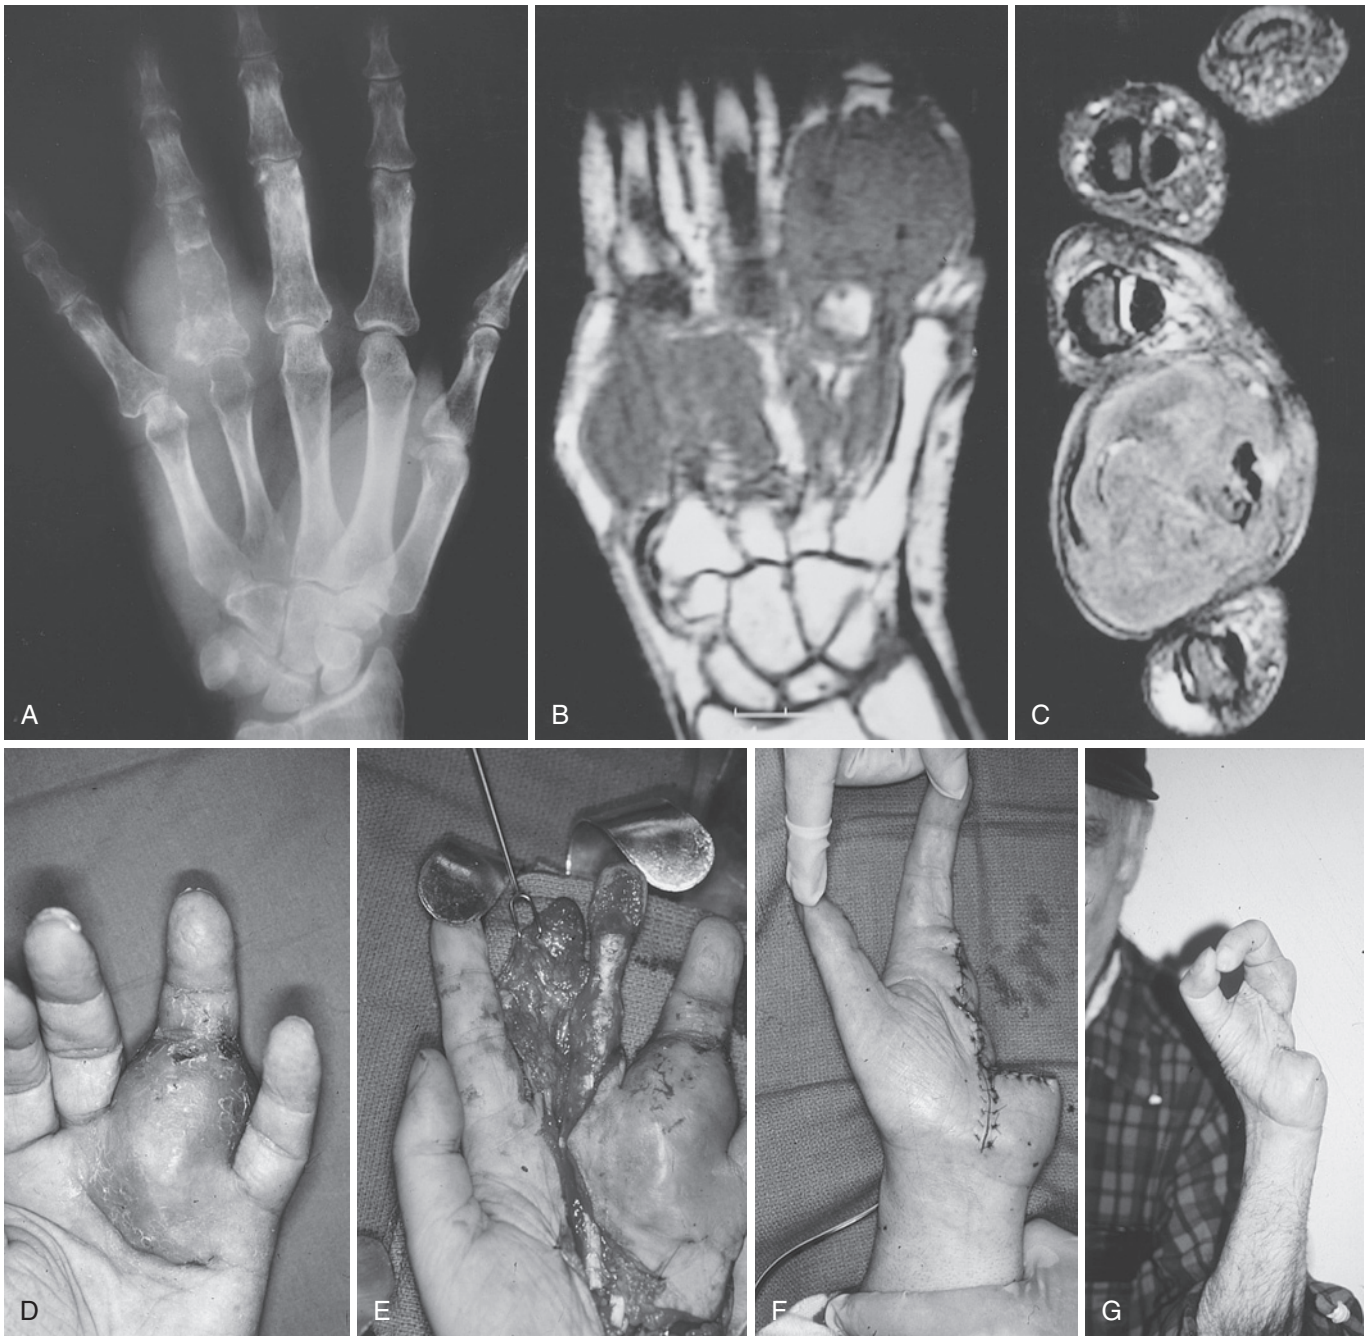

FIGURE 59.59 Osteogenic sarcoma. **A,** Lytic destructive lesion with soft tissue extension in the proximal phalanx of the ring finger. **B, C,** Magnetic resonance imaging demonstrates extensive soft tissue involvement, including the metacarpal head region. This elderly man was unable to tolerate chemotherapy and was treated by triple-ray amputation (long, ring, and small fingers). This very large tumor **(D)** was approached palmarly and dorsally, and closure was facilitated with a fillet flap of the long finger **(E). F,** Appearance after closure. **G,** Useful function.

error in diagnosis. The biopsy must be carefully planned and executed in an effort to avoid additional soft tissue contamination, which may compromise subsequent ablative or limb salvage procedures. The pathologist who will be evaluating the specimen should be consulted in advance, and arrangements should be made to perform cytogenetic analysis because this will improve the accuracy of diagnosis and assist in the diagnosis of particularly difficult cases.

There is considerable controversy regarding the timing and method to be used for obtaining local control of tumors in the hand. The radiation oncology literature supports the use of external beam irradiation to obtain local control in the context of systemic treatment with chemotherapy.[98,111] The hand surgery literature supports the use of ablative surgery with or without the use of external beam irradiation, as well as in the setting of systemic treatment with chemotherapy.[48,60,191] Similar rates of

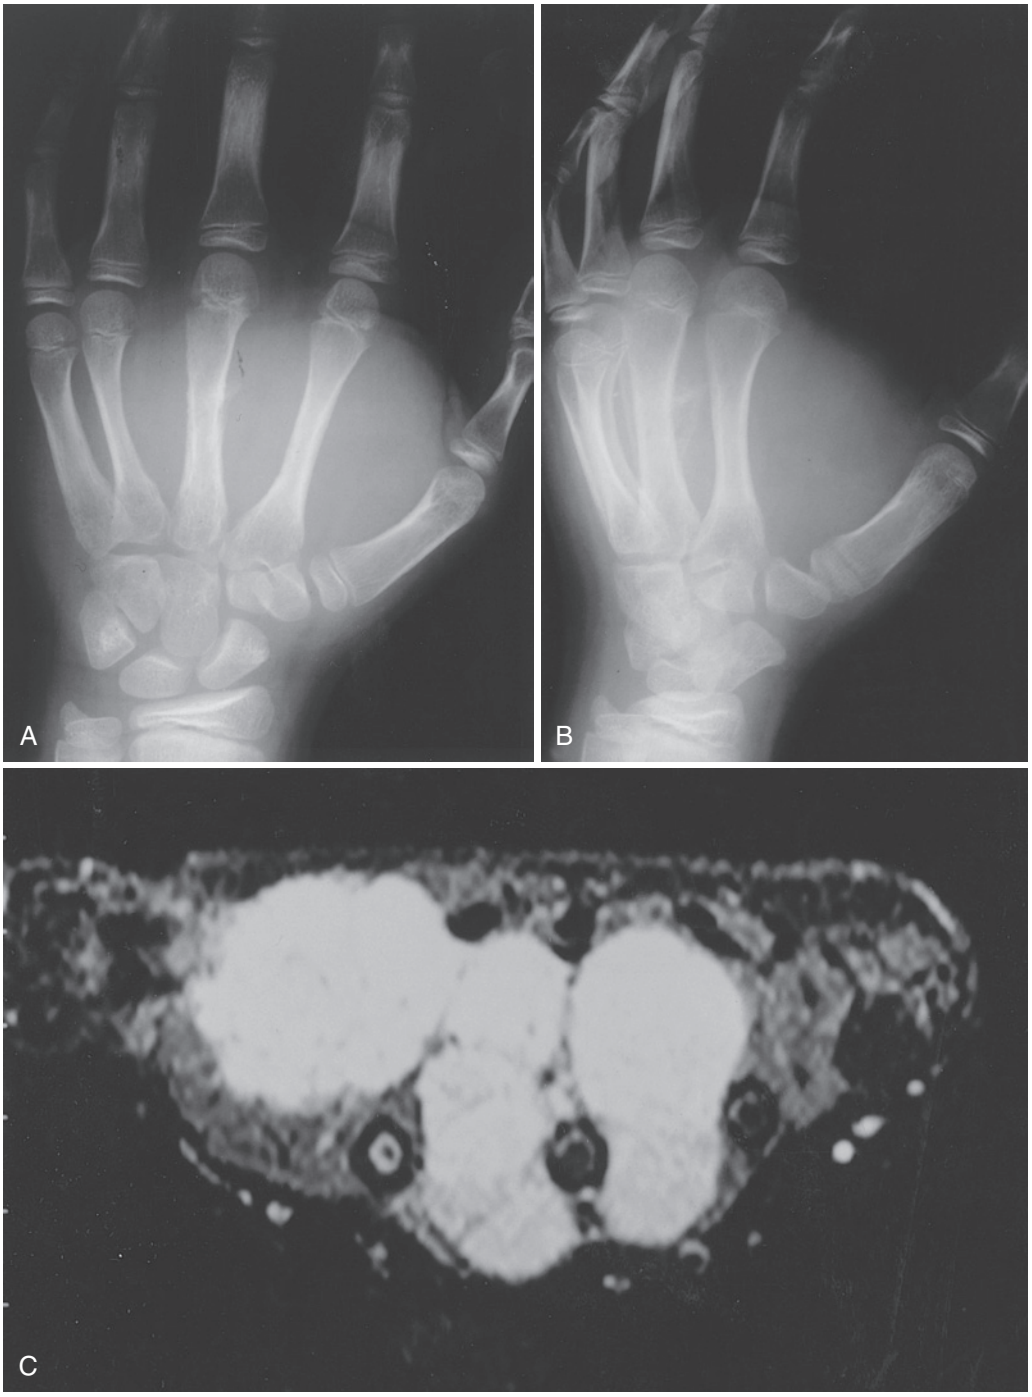

FIGURE 59.60 Ewing's sarcoma. **A, B,** Diaphyseal sclerosis and periosteal new bone formation of the third metacarpal on radiography. **C,** Magnetic resonance imaging demonstrating a large soft tissue mass surrounding the third metacarpal with extensive palmar and radial involvement.

local control with the use of either curative external beam irradiation or surgery have been reported.[159] It is imperative that local control be obtained at the time of primary treatment because local recurrence has been found to be uniformly fatal in some series.[76] Although survival of patients with Ewing's sarcoma occurring in the hand or foot appears to be better than that for patients with more central primary lesions, when cases occurring specifically in the hand are selectively assessed, the rate of survival is similar to that for lesions elsewhere in the body, with the exception of tumors arising in the pelvis.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT

I prefer the immediate initiation of systemic chemotherapy before definitive local treatment. Ewing's sarcoma is a highly lethal malignancy, and there may be a survival benefit with immediate initiation of systemic treatment without the delay

that can occur after normal postoperative healing or a postoperative complication. In addition, the use of an effective preoperative adjuvant in most cases decreases the size of the tumor and facilitates subsequent surgery. Analysis of the resected specimen provides information regarding the effect of chemotherapy and has implications for additional adjuvant treatment, the possible need for postoperative external beam irradiation, and prognosis. I favor the use of wide en bloc excision or amputation through a wide margin to obtain local control for lesions that occur in the hand. If a wide margin of normal tissue has not been obtained after analysis of the excised specimen, external beam irradiation should be added to the treatment protocol after the completion of chemotherapy.[157] Although external beam radiation may be effective in achieving local control, it could be associated with soft tissue contracture, neuropathy, pathologic fracture, growth inhibition, and radiation-induced malignancy.[122] Wide excision with adequate margins eliminates the need for radiation and avoids the associated morbidity.

Although rates of local control appear to be similar when external beam irradiation is used as primary treatment of Ewing's sarcoma in the hand, the available data are limited. Autopsy studies have documented residual disease at the primary site of malignancy in up to 20% of patients who subsequently died of pulmonary metastases when the primary tumor was treated by external beam irradiation, even in the absence of local clinical recurrence. Local control must be obtained at the time of initial treatment because local recurrence unquestionably adversely affects patient survival.

Metastatic Tumors

Metastasis to the bones of the hand is uncommon.[6,27,88,109] Acrometastases develop in <0.3% of patients with cancer. Metastasis to the hand usually occurs as a rare, preterminal event and is often part of widespread dissemination of the primary malignancy. For as many as 50% of patients with acrometastasis, the lesion can mimic a benign condition or can be the first manifestation of malignancy or metastatic disease.[88]

Although the distal phalanx has previously been noted to be the most common site of metastasis to the hand, the other phalanges and metacarpals can be equally affected. Involvement of the carpal bones is rare. A predilection for involvement of the dominant hand has been noted.[173] Bronchogenic carcinoma of the lung has been reported as the primary malignancy in as many as 50% of cases and is the most common metastatic lesion occurring in men (Figure 59.61).[88] Other reported primary malignancies include renal, esophageal, breast, colon, prostate,

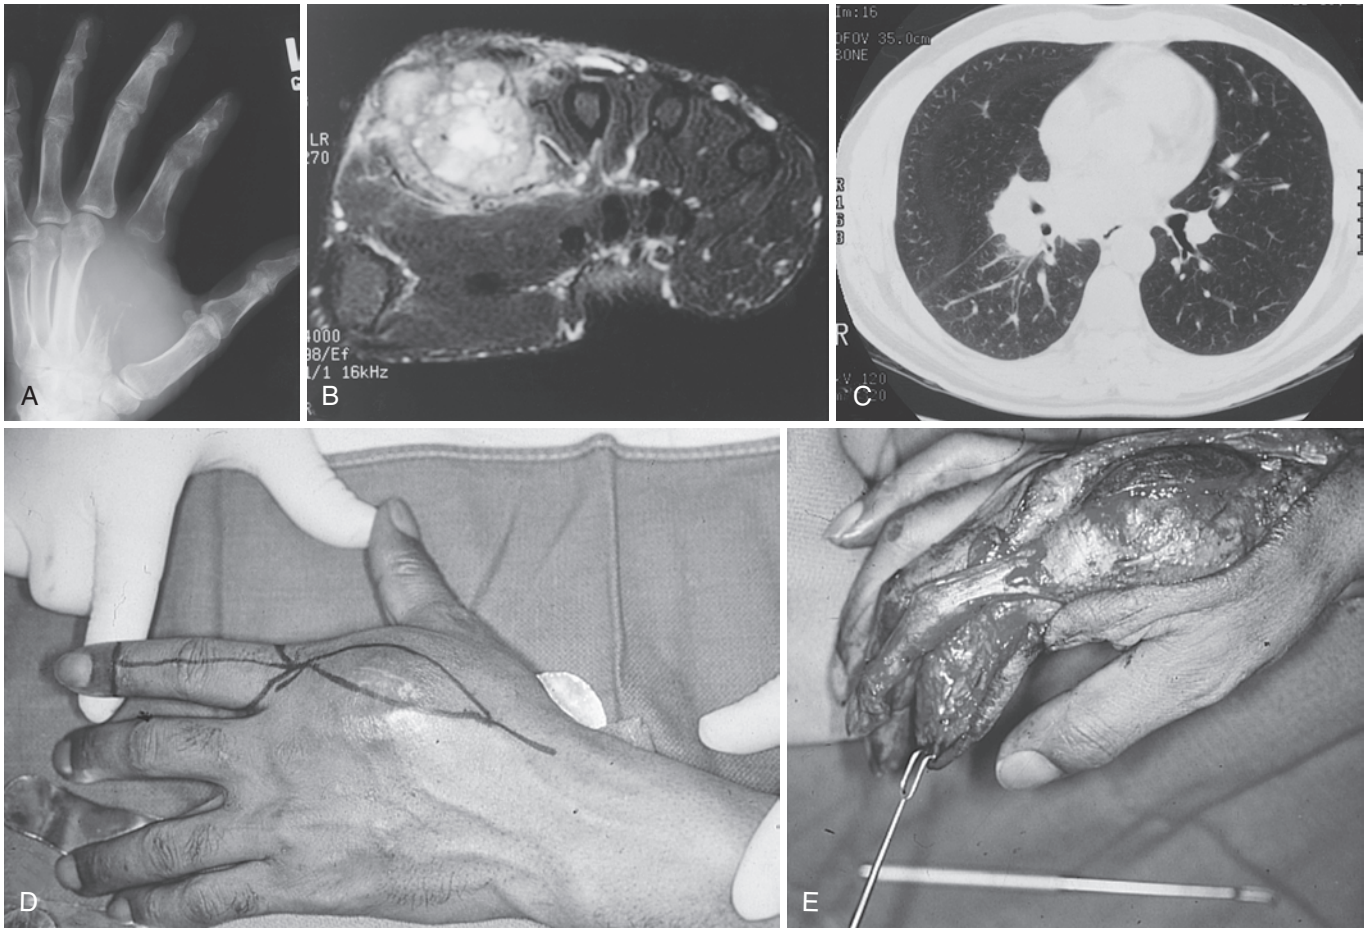

FIGURE 59.61 Metastatic tumor. **A,** In this 46-year-old man with a history of noninvasive bladder cancer and smoking, radiographs demonstrated a destructive lytic permeative lesion of the index metacarpal. **B,** Magnetic resonance imaging documented the extent of soft tissue involvement. **C,** Computed tomography of the chest revealed bilateral masses. An index ray amputation with fillet flap closure was done **(D, E)** after confirmation of the diagnosis of metastatic lung cancer.

thyroid, and bone cancer. In one study the mean time to the development of hand metastases was 16 months after diagnosis of the primary malignancy.[88]

Clinical findings include the typical signs of inflammation—pain, swelling, and erythema—which can lead to an initial clinical diagnosis of infection. Misdiagnosis is common and has included osteomyelitis, felon, gout, rheumatoid arthritis, reflex sympathetic dystrophy, and traumatic fracture.[27,88] Radiographs usually reveal a lytic destructive lesion, although metastatic prostate carcinoma can produce a sclerotic lesion. Extension into adjacent joints is uncommon. Lytic destructive lesions in the bones of the hand should be sampled and cultured without delay in the absence of a known primary malignancy.

Treatment of documented metastases should be directed toward relief of pain and preservation of function. Amputation and ray resection are effective in providing palliation and local control of disease. Although amputation has been done for lesions occurring in the carpus, curettage and packing with methylmethacrylate may offer an alternative method of providing local control of small lesions without the associated morbidity of an amputation in a patient who is terminally ill. External beam irradiation can be used for patients with multiple or inoperable lesions, although pain relief is less predictable.[27] Systemic staging should be done after diagnosis of the metastasis and consideration given to systemic treatment in consultation with an oncologist. The median survival for patients with metastases to the hand is approximately 6 months and is related to the primary malignancy. Early diagnosis may improve morbidity, particularly when the metastasis is the primary symptom of an undiagnosed malignancy.

Treatment of isolated metastasis of renal cell carcinoma to the hand deserves special consideration. Long-term survival and a prolonged disease-free interval have been reported after the resection of isolated metastatic renal cell carcinoma to the extremities.[5,195] A long interval between manifestation of the primary lesion and detection of isolated metastasis, as well as distal extremity metastasis, has been correlated with longer survival. Isolated metastatic renal cell carcinoma to the hand should be approached like that of a primary bone sarcoma.

Vascular Disorders of the Hand

William C. Pederson

Acknowledgment: This chapter was previously written by Dr. Andrew Koman and his associates. The author acknowledges Dr. Koman's scientific approach to the subject and his lifelong body of research into ischemia of the hand. The reader is referred to the chapter in the previous edition if a more scientific background on ischemia of the hand is desired.

Vascular disorders of the hand are relatively uncommon but can pose significant problems for patients suffering from them. Ischemic pain, ulceration, and decreasing hand function because of the foregoing are just some of the problems they face. Proper management of patients can improve their quality of life dramatically and on occasion prevent loss of tissue and potentially even the limb.

ANATOMY

Arterial blood is supplied to the hand through the brachial artery that branches in the proximal forearm primarily into the radial and ulnar arteries. These two major vessels continue down the forearm and supply the major portion of the blood that flows into the hand. The anterior and posterior interosseous vessels can provide flow via collateral circulation in chronic vascular problems; however, these two vessels are much smaller and generally cannot provide adequate oxygenated blood in the case of acute injury to both the radial and ulnar vessels. More recent work has determined that the volar forearm's median artery can provide significant blood flow to the hand, particularly in the case of injury or harvest of the radial artery.[42,47]

Blood supply to the hand was first clearly elucidated by Coleman and Anson in their classic paper,[14] in which they found that most hands have both a "superficial" and a "deep" arch that supplies the fingers. They found that 78% of the hands studied had a "complete" superficial arch, which theoretically allowed normal flow to all the fingers passing through the arch if flow by means of the radial or ulnar arteries was compromised. The ulnar artery flows into the hand on the palmar surface; its terminal portion becomes the superficial arch, while the radial artery courses around the radial volar wrist into the anatomic snuffbox, then it enters the palm via the first webspace. The terminal branches of the radial artery turn into the princeps pollicis and the deep palmar arch (Figure 60.1).

Much has been made of the presence or absence of a complete arch over the years; however, a great deal of clinical experience has shown that acute interruption of flow in either the radial or ulnar artery is extremely unlikely to result in significant ischemia of the hand or fingers.[70] In terms of which vessel provides the dominant circulation to the hand, the results of studies have been variable, with most finding that the ulnar artery is dominant[2,4,19] and others finding that it is the radial.[76] I would think that this point is actually moot because injury to one of the two vessels alone rarely causes any ischemia of the hand.

While the arterial supply to the hand enters primarily on the palmar surface, most of the venous drainage begins on the dorsal fingers and continues on the hand's dorsal surface. The primary arteries of the hand are each followed by two small venae comitantes, the configuration of which actually continues out to the fingers into the digital arteries. The primary drainage of the hand is, however, via the dorsal system, which eventually drains into the cephalic and basilic veins on the forearm and upper arm. Problems with venous drainage of the hand are extremely unusual—with the exception of possible venous thrombosis after replantation—due to the many venous channels available.

ETIOLOGY OF ISCHEMIA

Hand ischemia can result from iatrogenic injury, trauma, or vascular disease. Fortunately, iatrogenic injury is unusual; however, the potential to negatively affect flow to the hand is present in many procedures.[10] An Allen's test should be performed routinely prior to any intervention involving the radial artery (Figure 60.2). Radial artery puncture is a commonly used procedure for harvesting blood to measure gases, and indwelling catheters in the radial artery are commonplace for the monitoring of unstable patients during and after surgery. Although isolated radial artery puncture is exceedingly unlikely to cause ischemia in the hand, indwelling catheters are known to cause permanent ischemic complications in approximately 0.09% of patients.[9]

In the group of patients who develop ischemic problems, studies have shown that surgical intervention is not universally successful, probably due to the severity of vascular disease in the radial artery and the effects of distal embolization from the site of injury[25,79] (Figure 60.3). Depending on the patients' underlying problems, it may be best to manage them with anticoagulation, regional nerve blocks, and possibly intraarterial thrombolytics. The increasing trend toward management of vascular problems with endovascular techniques has led to renewed interest in peripheral artery access, with the radial artery offering a relatively easy way into the arterial system.[74] While early reports minimize the complications of this approach, it remains to be seen whether increasing application of this technique will lead to more ischemic problems in the hand.

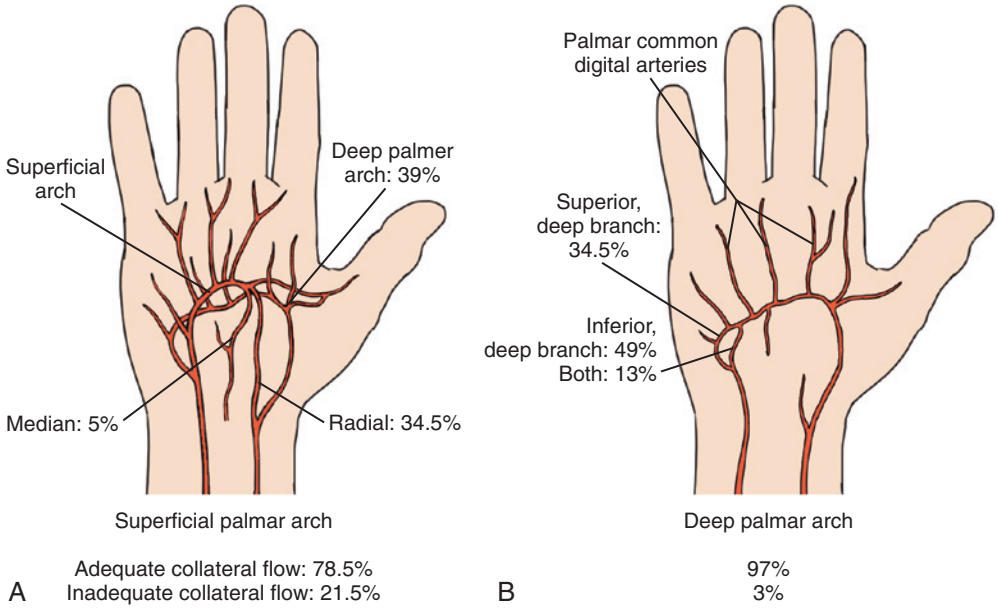

FIGURE 60.1 **A, B,** The superficial palmar arch is "completed" by branches from the deep palmar arch, radial artery, or median artery in 78.5% of patients; the remaining 21.5% are "incomplete." The deep palmar arch is "completed" by the superior branch of the ulnar artery, the inferior branch of the ulnar artery, or both in 98.5% of patients. (Modified from Koman LA, Urbaniak JR: Ulnar artery thrombosis. In Brunelli G, editor: *Textbook of microsurgery*, Milan, Italy, 1988, Masson, 75–83, with permission.)

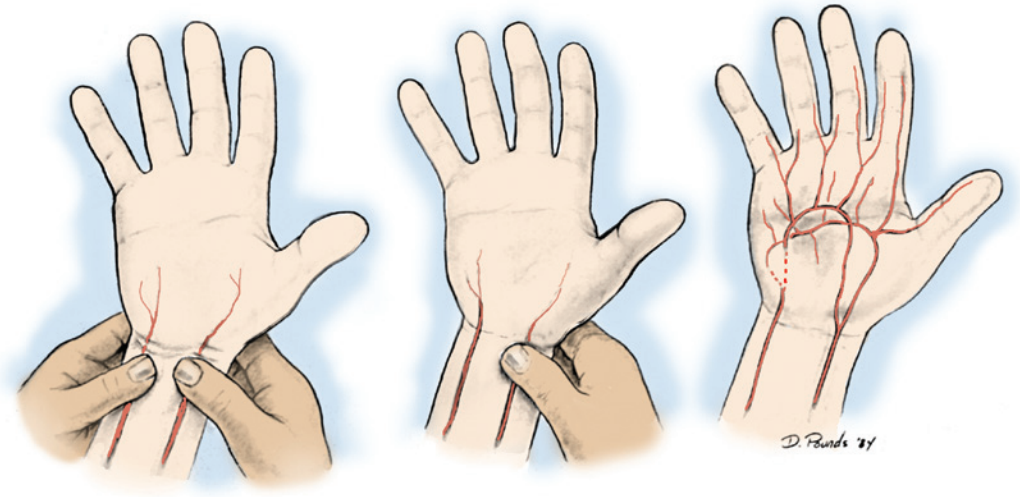

FIGURE 60.2 The Allen test is represented schematically. Blood is exsanguinated from the hand, and both the radial and ulnar arteries are compressed (*left*). After release of the ulnar artery (*middle*), no blood flows through the occluded artery, and the palm remains pale. With release of the radial artery (*right*), the entire hand will fill rapidly through the radial artery if the arch is complete. The order of the testing maneuvers can be reversed to evaluate the radial artery in a similar fashion. The test is best described as: demonstrating flow or no flow through a specific artery. (From Koman LA: Diagnostic study of vascular lesions. *Hand Clin* 1:217–231, 1985, with permission.)

Currently, the radial artery is often harvested for cardiac revascularization and radial forearm flap reconstruction, which also can lead to hand ischemia. The standard to use to avoid problems is the preoperative Allen's test, as noted earlier. Despite the routine use of it, ischemic episodes have been reported after radial artery harvest. This problem can be managed successfully, however, by performing a bypass with the autologous vein to replace the harvested radial artery.

Another iatrogenic cause of ischemia is vascular access in the upper extremity for hemodialysis. This happens in a range of 2 to 5% after a vascular access procedure[56] and can be due to distal embolization or a "steal" phenomenon; in this case, the majority of the arterial flow is diverted across the fistula, leading to ischemia in the distal hand. Often the fistula will have to be banded or even ligated to decrease the shunting of blood from the hand; however, vascular surgeons are usually unwilling to ligate these because of the difficulties of long-term access in dialysis patients. Another option is the so-called "distal revascularization interval ligation," or DRIL, procedure.

In this operation, a vein graft is sewn into the artery above the site of the fistula and the bypass is anastomosed to the distal artery at a level beyond it. The native artery is then ligated just

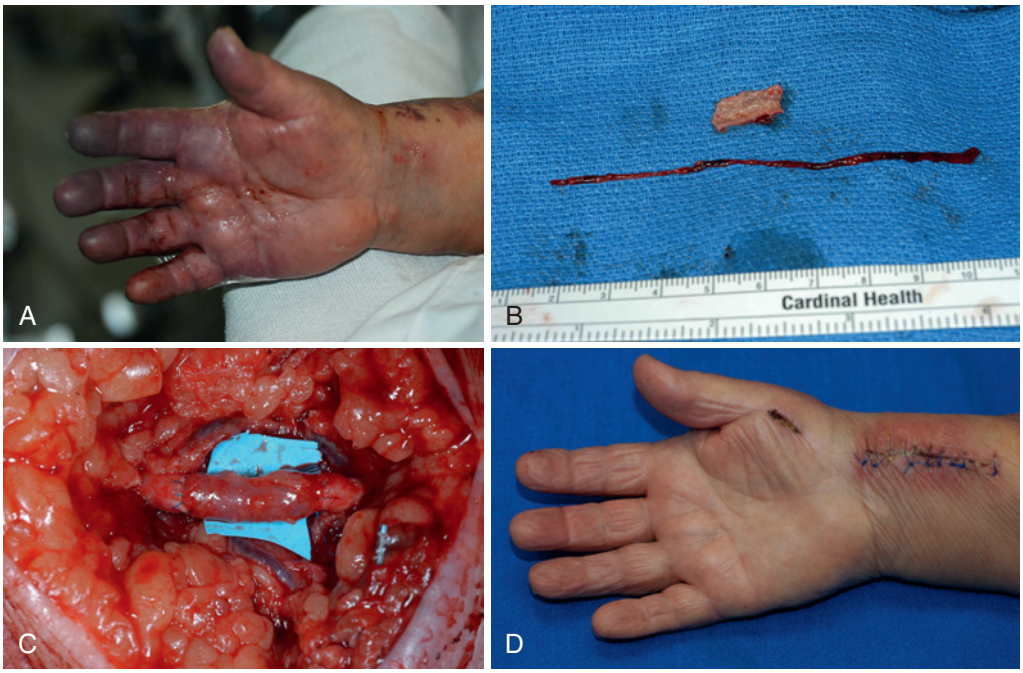

FIGURE 60.3 **A,** View of 82-year-old female's hand 36 hours after attempted radial arterial line placement during surgery. There was no Doppler signal in the distal–radial artery or in the snuffbox. **B,** View of damaged portion of arterial wall removed and thrombus extracted with Fogarty® balloon catheter. Radial artery was heavily calcified. **C,** Radial artery after repair with "Longmire" vein segment patch graft. **D,** View of hand at 2 weeks after repair.

distal to the fistula. This theoretically leads to the hand getting the majority of flow rather than the shunt and is effective in many patients.[71] Diabetic patients on dialysis present other difficulties in that they often develop worsening arteriosclerosis of the upper extremity's vessels and ongoing ischemia; this will be discussed further later.

The other cause of ischemia of the hand is trauma, which can be either an open or a closed injury to forearm and hand vessels. The classic case of a closed injury to the hand's arterial supply is in supracondylar fractures in children.[13] In these patients, displacement of the fracture leads to injury and spasm of the brachial artery, which if not recognized can lead to a compartment syndrome and ultimately a Volkmann ischemic contracture of the flexor muscles. Another fairly common type of closed vascular injury unique to the hand is ulnar artery thrombosis, or "hypothenar hammer syndrome." This injury occurs with closed trauma to the palm of the hand, often when it is used as a hammer or when the hypothenar area suffers a blow.[48] Open injuries, whether by firearms or by lacerations, are particularly common in the forearm and hand. As noted earlier, injury to a single vessel rarely causes acute ischemia but undiagnosed injuries can lead to aneurysm formation and potential distal embolization.

The final cause of ischemia in the hand is intrinsic vascular disease, which can be either arteriosclerotic or vasospastic. They can be seen in combination, which is known as "vasoocclusive" disease. Although Buerger disease has historically been a major cause of arteriosclerotic disease in the upper extremity,[15] in today's world the most common cause is a combination of diabetes and renal insufficiency. This combination of disease processes leads to accelerated occlusive vascular disease in the upper and lower extremities,[35] and it is not uncommon to see patients with bilateral lower-limb amputations appear with critical ischemia of the hand. Likewise, patients with collagen vascular disease (i.e., scleroderma primarily) suffer from vasculitis and vasospastic disease, which can lead to vasoocclusive disease.[61] The patients can present difficult management issues, and surgical intervention, while helpful, often does not provide a long-term solution.

EVALUATION

As with any problem, patients first need to provide a thorough history and undergo a physical examination. Obtaining a medical history, with particular attention to documented diabetes and/or collagen vascular disease, is very important. Obviously, a habit of smoking will have an impact as well. Medical management of the diseases with pharmacologic agents may mitigate some of the symptoms, particularly in those patients with Raynaud disease. The physical exam should pay close attention to the appearance of the hands and the color of the fingers, looking for evidence of ischemia and/or gangrene or ulceration. Likewise, the warmth of the fingers is important and sensation also plays a role, with the potential for sympathetic overactivity in the presence of nerve compression.[29]

The pulses at the elbow and wrist should be felt, and I feel that Doppler ultrasound plays a very important role in the examination of the patient with a vascular disorder. An Allen's test can be done, as described before; however, performing a similar exam with the pencil Doppler may yield much more information. The arch is located with the Doppler, and the radial and ulnar arteries are compressed sequentially at the

FIGURE 60.4 Computed tomographic angiography of palm showing level of detail that can be obtained.

FIGURE 60.5 Arteriogram of patient with recent onset of ischemic symptoms of thumb and index finger. This was read as a normal variant with a large median artery when in fact the patient had suffered thrombosis of the radial artery in the anatomic snuffbox and embolization to the thumb and index finger.

wrist. The Doppler can be moved over the arch as necessary to follow the signal, listening for a change in character or flow. This technique can almost always diagnose the site of arterial occlusion if performed carefully. Likewise, an arterial signal should be heard with the Doppler placed on the pulp of the finger; if it is not, there is a significant problem with flow to that finger.

It should be noted, however, that the presence of an audible Doppler arterial signal in one of the wrist's vessels *is not* an indication of adequate nutritional flow to the hand. By using this simple technique in the office the surgeon usually can diagnose where the occlusion is; however, this information is not adequate for planning a surgical procedure. For this I prefer using computerized tomographic angiography (CTA) or arteriography—the latter if fine detail of the hand's vessels is needed (Figure 60.4).

Others prefer a magnetic resonance angiography (MRA), but I have found that the detail in many of these images is inadequate in terms of knowing exactly where and how significant the problem is. The gold standard, however, remains digital subtraction angiography (DSA). Surgeons must view the vascular studies themselves because the radiologist or vascular specialist may or may not see the lesion.[81] A familiarity with the upper extremity's normal and variant anatomy is essential; however, surgeons who are dealing with vascular problems must evaluate every vascular study, both to review the anatomy and to identify the problem (Figure 60.5).

There are a number of other types of studies that can be done to aid in the diagnosis of vascular problems in the hand. Color-flow ultrasonography can show realtime flow and be used to evaluate an anastomosis, but it is of primary use in the venous system. A commonly performed test to evaluate vasospasm is cold-stress testing, which gives a measure of the vascular system's ability to recover from exposure to cold. In this test digital temperature is measured at baseline and the hand is then placed in cold water (5–8°C) for 5 minutes. Thermistor probes (or laser Doppler) are used to measure the time required for digital rewarming to baseline. A prolonged rewarming response is often seen in women and can be diagnostic of Raynaud's. Likewise, smokers often have a delayed rewarming response.

The digital–brachial index, which is the ratio of the blood pressure as measured in the brachial artery and the finger, can be measured with small blood pressure cuffs. This is similar to the ankle–brachial index, and in the upper extremity any value below 0.7 is felt to designate a significant occlusive problem somewhere in the forearm or hand. Blood flow in the capillary bed can be measured by laser Doppler flowmetry, which can give a quantitative measurement of blood flow at skin level. This can be a useful tool to evaluate the results of treatments, particularly for vasospastic problems; however, this equipment is quite expensive and not available to most practitioners.

Similarly, nailfold capillaroscopy shows morphology and flow at the capillary level but is not of practical use for most surgeons. Many of these sophisticated tests are difficult for the practicing surgeon to perform and do not add much, in my opinion, to decision making in terms of patient management. They, however, can be useful in determining the quality of the outcomes of management. The chapter on vascular problems in prior editions of this textbook (i.e., Chapter 66) has a more thorough and excellent discussion of these modalities and the reader is referred to the earlier edition for more information on this subject.[44]

MANAGEMENT

Management of vascular injury or insufficiency in the hand may involve techniques ranging from ligation of the injured vessel to periarterial sympathectomy to complex vein or arterial grafting. Which technique is employed depends on the level of the lesion as well as the cause of the problem. The various techniques used to treat the major causes of ischemia of the hand are discussed in the following subsections.

Open Arterial Trauma

Arterial trauma is reasonably common in the upper extremity and can be due to laceration or closed injury, as noted earlier. Reviews have noted that the majority of these injuries are open (i.e., in the 79% range) and that most were the result of lacerations.[23] The options for management differ somewhat and are discussed here. Open arterial trauma generally requires exploration because there is a wound that needs to be managed, and likewise, injuries to other structures almost always will require repair.

In general, preoperative workup of patients with an open vascular injury is limited to physical examination because a high index of suspicion should be present based on the history and location of the injury. Arterial studies are generally not indicated in open injuries with the exception of gunshot wounds with an otherwise normal examination of motor and sensory systems. It should be noted, however, that clinical studies have demonstrated that up to 50% of vessels with a proximal injury will have a palpable pulse at the wrist.[27] If the limb is well perfused, delay in management of the injury (i.e., beyond 6 h) if the bleeding is controlled and the patient is hemodynamically stable has not been shown to be detrimental.[62] It also has been shown in the military's experience during recent conflicts that temporary arterial shunting is a valuable adjunct in the management of arterial injuries. In such patients, shunts were left in as long as 11 hours and in some cases until definitive repair could be performed. The results between patients who had immediate vascular repair and those shunted showed no significant differences in outcomes.[6]

At the time of exploration, the wound will need to be extended in order to allow exploration and repair of the injured

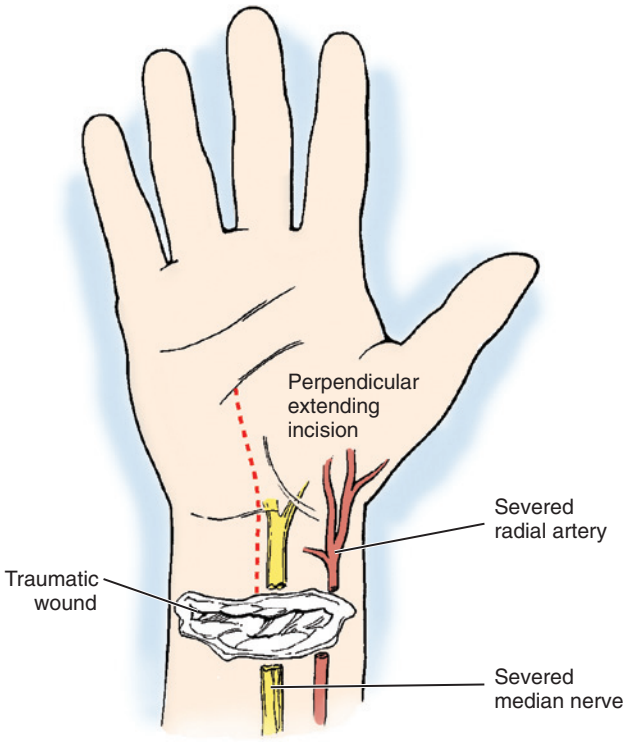

FIGURE 60.6 Schematic representation of treatment of a traumatic wound involving transection of the radial artery and median nerve. During arterial reconstruction, transverse wounds may be extended by perpendicular longitudinal incisions to facilitate exposure and protect repaired structures when wound closure is not possible. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

structures (Figure 60.6). If the hand is well perfused, a decision needs to be made as to whether repair of the injured vessel is important to the circulation in the hand. The brachial artery can suffer injury from fractures about the elbow, particularly in children with closed supracondylar humeral fractures.[7,73] Such injuries can lead to significant ischemia of forearm muscles and the hand. Studies have demonstrated that single-vessel (i.e., radial or ulnar artery) injuries in the forearm lead to little long-term sequelae even if the injured vessel is simply ligated.[26]

The flow in the remaining vessel has been shown to increase with injury or ligation of the other, and patency rates of repaired single vessels have been shown to be surprisingly low (i.e., in the 50% range), even with proper technique.[28] Arterial injuries combined with median nerve injuries have been shown to lead to increased long-term problems, probably more related to nerve injury than arterial injury. In younger patients and in those with possible vascular compromise from other factors, repair of the radial or ulnar arteries in the forearm almost certainly should be undertaken.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Arterial Vascular Repair

Sharp injuries with complete transection will lead to vessel ends pulling apart, depending on local branches and the surrounding tissue. Cutting injuries usually can be pulled together after careful trimming of the ends of the divided vessel. While forearm vessels can be sewn by most competent hand surgeons

with loupes, studies have shown that a better anastomosis can be performed with a microscope.[68] If there is some tension, a large double clamp (e.g., an Acland or Ikuta[36] microvascular) can be used to take the tension off the repair. A repair should be done in standard microsurgical fashion, and I prefer 8-0 nylon for forearm vessels, and in some cases use 7-0 polypropylene if the vessel is larger. I always use 6-0 or 7-0 polypropylene for the brachial artery and most proximal vessels. If there is a partial injury, which is sharp, it often can be repaired primarily; however, in some instances damage to the vessel of partial injuries (e.g., gunshot wounds) may well require resection of the injured segment and vein grafting.

When a vein graft is necessary, it is probably best (and easiest) to harvest it from the injured arm (Figure 60.7). Although saphenous is an acceptable choice, I have found that it is rather thick-walled and not always the perfect size match for the radial and ulnar arteries in the forearm. There are several maneuvers that can be performed if the vein graft and artery have a circumference mismatch (Figure 60.8). If a vein graft is going to be done, one must resect an adequate segment of the injured artery to be sure that the anastomosis can be performed out of the zone of injury to decrease the rate of thrombosis. Usually, this is fairly obvious, but any portion of the vessel that has suffered bruising, or has signs of intimal separation when viewed under the microscope, should be resected.

An artery with thrombus in it is not be an absolute indication to resect the vessel, as long as the arterial wall does not appear to have suffered damage. After the end is resected, it is probably wise to irrigate the proximal and distal vessels with heparinized saline (generally diluted to 100 units of heparin per milliliter of saline) to decrease the risk of thrombus formation during the time that the clamp is on the artery. Once this is done, I prefer to perform the proximal anastomosis first. When complete, removing the clamp allows the vein graft to fill with blood and both unwind and return to its normal length. After the proximal clamp is removed, the vein is allowed to bleed briefly from the end and is then reclamped. The proper length can then be better estimated than when the vein is empty.

The distal end is trimmed to the proper length if necessary and the distal anastomosis is then performed (Figure 60.9). Once the anastomosis is completed, distal pulses must be checked. A Doppler can be used, but I feel that a palpable pulse is a much better sign of adequate distal flow. The surgeon should be aware that a clot can propagate distally and embolize into the distal artery or even the hand. Familiarity with the techniques of thrombectomy is essential for those performing vascular repairs (see Figure 60.3). Tension on the repair is checked by ranging the wrist and elbow, as disruption of one

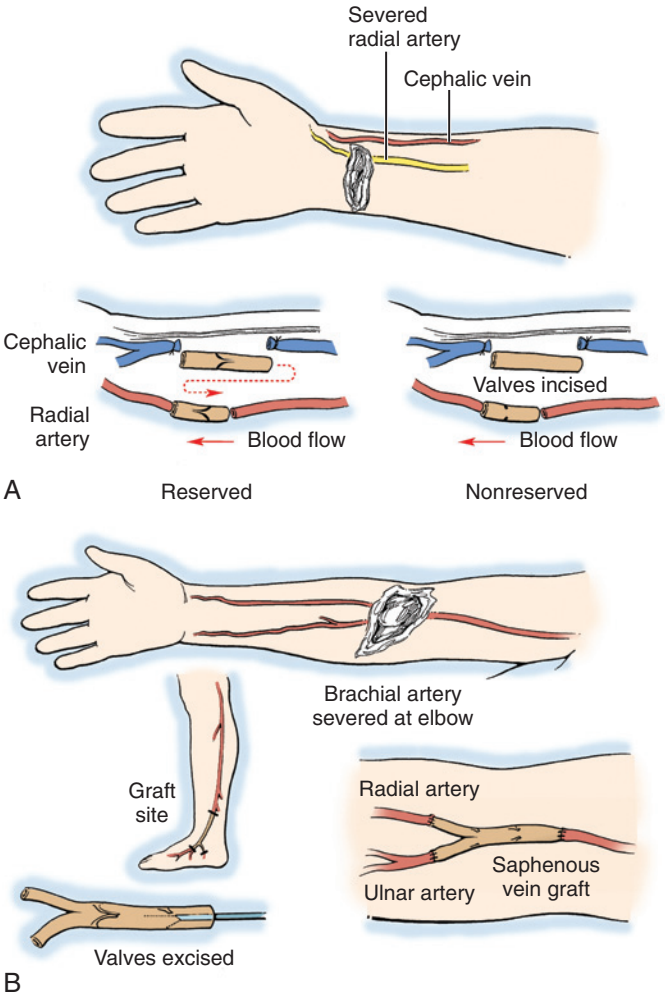

FIGURE 60.7 **A,** Interposition vein grafting may be used to repair damaged arterial segments that would be under tension with an end-to-end repair. Reversed interposition grafts may be obtained from local veins (e.g., cephalic) after reversal. Alternatively, nonreversed veins may be used if the valves are incised (*lower right*). **B,** Severe injuries that involve the brachial artery or the radial and ulnar arteries can be managed by branched vein grafts. Either reversed interposition or nonreversed (with valves incised) interposition vein grafts may be used. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

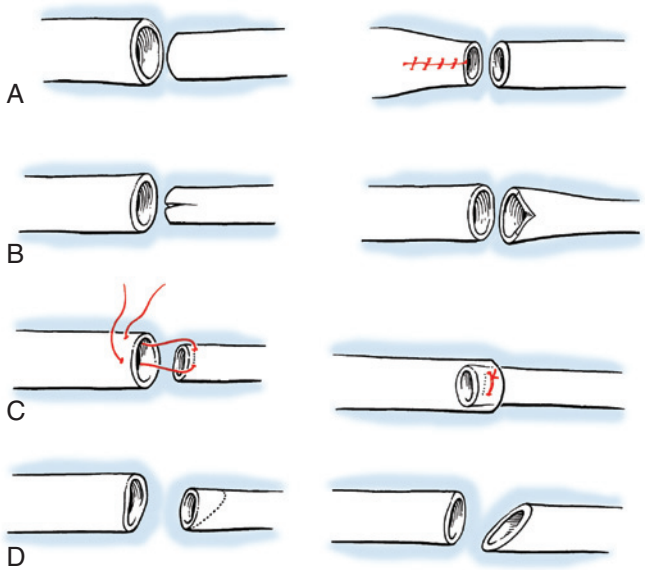

FIGURE 60.8 Mechanisms to overcome size discrepancies during arterial repair. **A,** The larger vessel may have a "V"-shaped portion excised and then be closed. **B,** Conversely, the smaller vessel may be split longitudinally and then expanded to fit the larger vessel. **C,** If the smaller vessel provides proximal inflow, it may be intussuscepted into the larger vessel via a sleeve-type technique. **D,** Small discrepancies can be managed by making a 30-degree angled or beveled cut of the smaller vessel followed by gentle dilation. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

of the anastomosis with movement of the hand or arm can be catastrophic.

Arterial repairs and arterial vein grafts cannot be left exposed in a wound nor should they be covered just with skin grafts or an allograft. Viable tissue must be placed over repairs to avoid desiccation and disruption of the repair; at times this may necessitate some type of flap. If the wound is large, as in avulsion-type injuries, selection of a vein for grafting may need to incorporate a branch to allow for placement of a free flap over it with arterial anastomosis to the branch of the graft (Figure 60.10).

CRITICAL POINTS ***Vein Grafting of an Arterial Injury***

- Resect wounded artery beyond zone of injury (bruising and/or intimal separation).
- Select appropriate length of forearm vein (i.e., basilic or cephalic), alternatively saphenous.
- Irrigate proximal and distal arteries with heparinized saline.
- Reverse vein graft and repair to proximal artery first, with 7-0 polypropylene or 8-0 nylon.
- Allow vein graft to fill with blood and clamp distally; allows vein to unwind and distend.
- Trim appropriately and perform distal repair.

Postoperative Care After Vein Graft Repair. I generally splint the elbow and/or wrist after vascular repair or vein grafting in the forearm. If the graft is loose, this is probably not necessary; however, based on the contributing trauma and severity of injury, immobilization is probably prudent. Care must be taken to ensure that the splint does not impinge or put pressure on the graft. Systemic anticoagulation has not been shown to be beneficial and in fact can cause bleeding, so this should be avoided—the patient will have received some systemic heparin from the irrigation of the proximal and distal artery that is probably adequate.

Oral aspirin may have some benefit and should be given in a low dose (i.e., 81 mg) daily for 6 weeks. I allow the patient to begin careful movement after about 3 weeks; however, this depends on which other structures (i.e., bone, tendon, nerve) have been injured and the therapy requirements for them if they have been repaired. Patency rates are generally high in upper extremity vascular repairs done with an autogenous vein.[20,23,54]

Complications. The primary complication of arterial repair and/or forearm grafting is thrombosis of the repair or graft. This is unlikely to occur unless the surgeon has failed to resect the damaged vessel or has performed a poor vascular repair. Blowout of a repaired artery or vein graft is not unheard of, however, and can be a catastrophic event and life threatening (see Figure 60.18). There must be coverage of the repaired artery or vein graft with well-vascularized soft tissue. If there is wound breakdown, this must be managed aggressively to prevent infection around the repair or graft as well. "Watchful waiting" is not advisable if there are problems with a repaired vessel.

Closed Arterial Trauma

Although blunt trauma can cause arterial injury anywhere in the upper extremity, the most commonly seen closed trauma is ulnar artery thrombosis in the palm. As noted previously, this is also called hypothenar hammer syndrome; it is seen in patients who suffer trauma to the palm or those who use the ulnar side of the palm as a hammer. Due to its relatively superficial position, the ulnar artery and nerve are easily injured with blunt trauma to the palm (Figure 60.11).

Injuries to the ulnar artery in the Guyon canal can lead to thickening of the vessel wall (with chronic low-grade trauma),

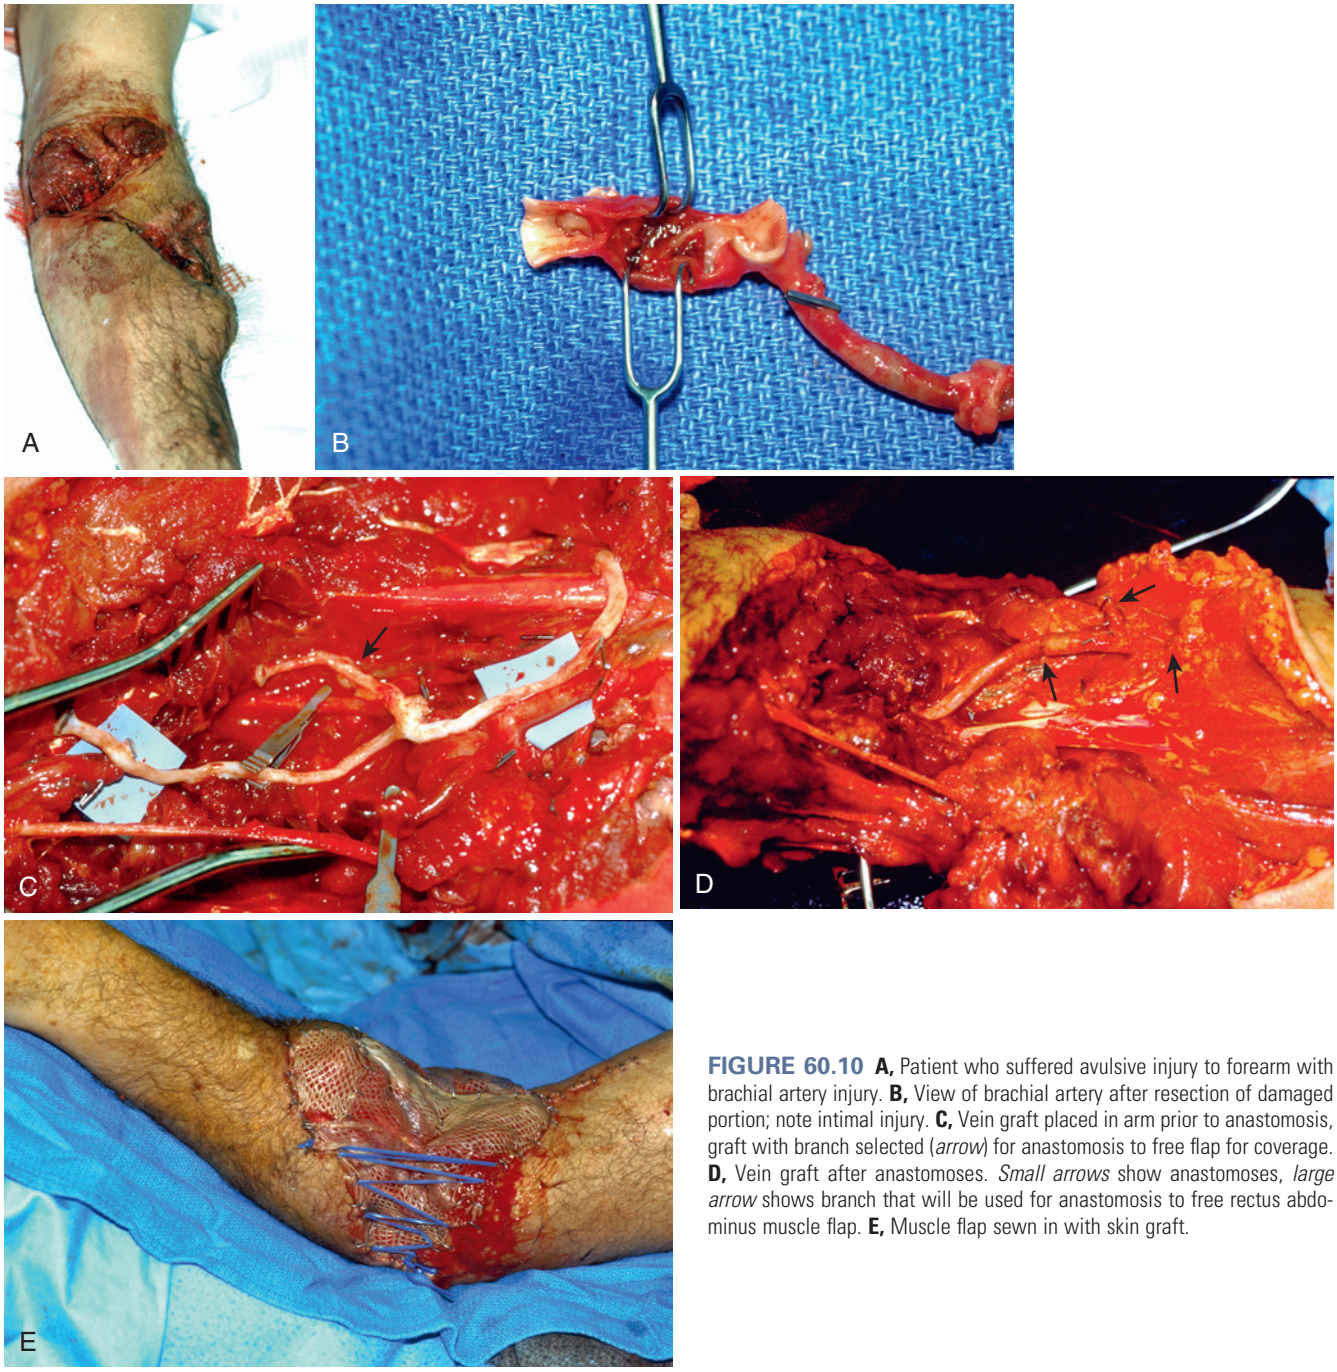

FIGURE 60.10 **A,** Patient who suffered avulsive injury to forearm with brachial artery injury. **B,** View of brachial artery after resection of damaged portion; note intimal injury. **C,** Vein graft placed in arm prior to anastomosis, graft with branch selected (*arrow*) for anastomosis to free flap for coverage. **D,** Vein graft after anastomoses. *Small arrows* show anastomoses, *large arrow* shows branch that will be used for anastomosis to free rectus abdominus muscle flap. **E,** Muscle flap sewn in with skin graft.

disruption of the intima and thrombosis, or even aneurysm formation (Figure 60.12). Regardless of the eventual pathology, these injuries can lead to distal ischemic symptoms, primarily as a result of embolization of thrombus from the site of injury. The incidence of ulnar artery thrombosis is probably underreported; I believe that many individuals may suffer from this and are not particularly symptomatic or fail to seek medical advice due to ongoing excellent perfusion of the hand through the radial artery.

Patients with ulnar artery thrombosis present with ischemic symptoms in the ulnar digits, and in my experience with more than 100 patients with this, the ring finger is involved in nearly half of the patients, with the middle and little fingers involved in closer to one-third (Figure 60.13). The thumb is rarely ischemic in patients with ulnar artery thrombosis. While it has been taught that distal ischemia is due to vasospasm, exploration of a number of these fingers in the past has proven that this is the result of embolization of thrombus (Figure 60.14). These patients frequently complain of paresthesias in the distribution of the ulnar nerve as well because the ulnar nerve can suffer contusion at the time of ulnar artery injury.

Diagnosis usually can be made based on history and physical exam. The patient relates an incident of trauma to the palm with symptoms of digital ischemia of the ring and little finger

following, and there may be ulnar nerve paresthesias as noted earlier. These symptoms may resolve but also may be intermittent after the injury (i.e., due to ongoing embolization of a clot to the distal digits). By the time the patient sees a hand surgeon, the initial symptoms may have resolved to some degree but he or she usually complains of cold intolerance and intermittent color change in the fingers. The office exam obviously should include feeling the pulse at the wrist; however, the ulnar pulse may well be present proximal to the wrist crease. There actually may be a palpable mass in the ulnar palm due to either a large amount of clot in the artery or potentially aneurysmal change as a result of the injury.

I perform a "dynamic" exam with a pencil Doppler as described before. Typically, occlusion of the radial artery at the wrist causes loss of signal over the palmar arch. With this history and exam, arterial studies should be the next step. CT arteriogram is usually sufficient to diagnose ulnar artery thrombosis if the CTA's quality is high; however, if there is any question, a standard arteriogram should be obtained. This is helpful in terms of knowing how far one may need to graft in order to bypass the area of occlusion. Likewise, some patients may develop an aneurysm due to severe intimal injury, which may change treatment options to some degree.

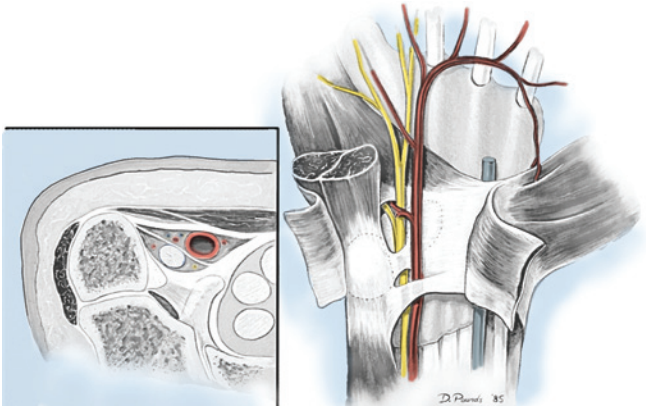

FIGURE 60.11 Schematic drawing of the ulnar artery within the Guyon canal. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

The pattern of thrombosis is fairly typical and can be seen clearly on an arteriogram of the involved hand. While the original injury is in the palm, over time the thrombus usually propagates back to the dorsal branch of the ulnar artery; it occurs roughly 2 to 3 cm proximal to the volar wrist crease. Likewise, the vessel clots distally to the palmar arch, where the common digital artery to the fourth webspace branches. At both of these points there is still outflow (i.e., from the dorsal–ulnar artery proximal and the palmar arch distally); thus, the initial injury leads to propagation of the clot to these branches (Figure 60.15).

If the patient is seen soon after injury, the area of thrombosis may be smaller as a clot has not had time to propagate proximally and distally. Arteriography also may show a "corkscrew" pattern that implies a damaged artery and in fact may show an aneurysm (Figure 60.16). Some patients can damage the artery enough to lead to development of a large aneurysm that may be palpable. Interestingly, these do not always thrombose but can certainly cause recurrent distal embolization of a clot.

Once the patient is evaluated and thrombosis of the ulnar artery is confirmed, the decision as to how to manage him or her must be made. Patients with minimal symptoms, good flow through the radial artery, and an otherwise normal palmar arch, can be managed medically. If the patient is a smoker, cessation of this activity is nearly mandatory to decrease symptoms. Similarly, calcium channel blockers (CCBs) can be used to decrease symptoms of vasospasm brought on by the clot.[33,83] If the patient is seen early on after the thrombosis, thrombolytic therapy with tissue plasminogen activator can be tried, but success has not been universal in reported cases.[16,80] Management of ulnar artery thrombosis by endovascular techniques also has been reported[1]; however, there is no convincing evidence that it is applicable to arteries at the distal forearm level. Patients with aneurysms of the ulnar artery and those who continue to have symptoms will require surgical intervention.

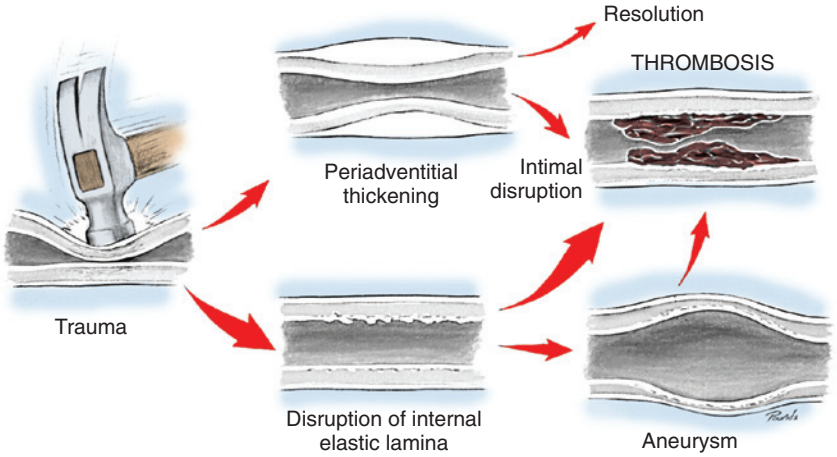

FIGURE 60.12 Mechanisms of occlusion and aneurysm formation in the ulnar artery may include acute or repeated trauma, which may cause direct intimal damage or periadventitial scarring. Periadventitial thickening may constrict the vessel and obstruct flow. Flow may be restored by surgical intervention. Without intervention, additional injury with intimal damage and exposed media may result in thrombosis or aneurysmal dilation, or both. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

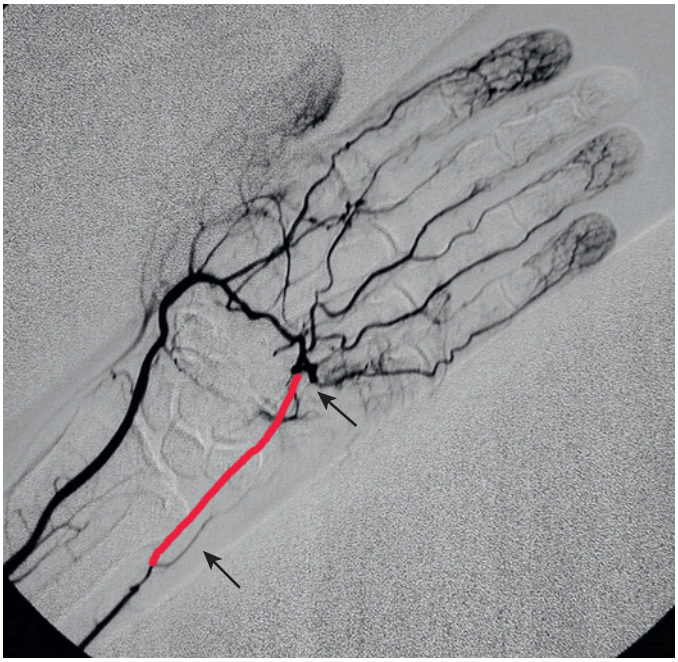

FIGURE 60.15 Arteriogram of patient with ulnar artery thrombosis. *Red line* shows usual course of ulnar artery, *bottom arrow* points to dorsal branch, and *top arrow* points to palmar arch at branching of common digital artery to fourth webspace.

The approach to the ulnar artery via the Guyon canal is standard. A Bruner-type incision is made in the palm over the course of the ulnar artery to the level of the distal palmar crease to allow it to be carried across the palm if necessary. Usually this incision needs to be carried proximally about 3 cm up the distal forearm for access to the ulnar artery at the level of the dorsal branch. While the thrombosed segment of artery can be simply ligated and excised, which accomplishes a "Leriche" sympathectomy, Koman and others have demonstrated that a bypass offers significant improvement over excision.[12,41]

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Ulnar Artery Bypass

On occasion, the area of thrombosis is small, the involved artery can be resected, and the ulnar artery repaired primarily, but this is unusual. In most cases, a vein graft is required from the distal forearm to the palmar arch where the common digital artery to the fourth webspace branches off. I prefer to utilize the basilic vein in the mid-forearm to graft the ulnar artery in such cases. This vein offers several advantages over the saphenous in that it is locally available, the wall is not as thick as the saphenous, and the donor site rarely has healing problems. There has been some discussion about the use of arterial grafts for the management of ulnar artery thrombosis, the argument being that an arterial graft may withstand future trauma better than a vein graft and the size match of available arteries—that is, primarily the deep inferior epigastric and descending lateral femoral circumflex.[72,75] Although I have had limited experience with this technique, it would appear to have some merit. The benefits of arterial grafts over standard vein grafts have yet to be proven convincingly, however.[49]

The thrombosed or aneurysmal segment of the ulnar artery is resected back proximally until there is no further thrombus and the intima and medial layers of the vessel wall do not separate when the vessel is cut. The vein is reversed and the technique is as described earlier for traumatic injuries. The distal anastomosis can almost always be performed at the level of the "Y" between the common digital artery to the fourth webspace and the superficial palmar arch (Figure 60.17). Postoperative care is the same as for any venous interposition graft, with attention being paid to avoid kinking of the graft with motion or any pressure on the graft from a splint. I generally do not anticoagulate patients undergoing vein grafting of an ulnar artery thrombosis but give them an 81-mg aspirin daily for at least 6 weeks postoperatively. As noted before, cessation of smoking is essential if ongoing symptoms are to be prevented.

The results of vein grafting of a traumatic ulnar artery thrombosis are generally good,[12,18,33] and my experience has been that there is around a 90% patency rate at 2 years. Even patients who suffer another thrombosis of the ulnar artery do not always become symptomatic again, probably because of the sympathectomy effect of resection of the thrombosed ulnar artery.[33]

Complications. The complications of ulnar artery bypass are the same as those noted after arterial repair or grafting in the forearm. The bypass can thrombose, which can be due to ongoing trauma to the palm, and there is evidence that thrombosis rates of vein grafts increase over time. The rare complication of blowout of the vein graft can be significant but usually is the result of wound-healing problems (Figure 60.18).

The radial artery also can suffer from thrombosis in the hand, and this usually occurs in the anatomic snuffbox over the area of the trapezium (Tq) and under the extensor pollicis longus (EPL).[11,51] The symptoms of this disorder are primarily ischemia of the index finger and occasionally the thumb. The patient also may complain of dull pain in the thenar muscles, which may be a type of claudication from ischemia of the muscles. The etiology of this is unclear, but it would appear to be from trauma to the artery from the overlying EPL tendon. This problem is more common in women than in men, in my experience, and is not usually seen in those with collagen vascular disease. These patients also suffer from embolization of clot into the distal index finger, and ulnar-sided fingers are basically never involved.

Arteriography may in fact show thrombus in the radial artery in the anatomic snuffbox (Figure 60.19). This problem seems to resolve in some patients without the need for further intervention; however, if the radial artery is found to be completely occluded on arteriogram and the patient is suffering from critical ischemia of the finger, treatment with excision of the clotted segment and vein grafting is probably warranted. The cephalic vein is in the field when the radial artery is exposed,

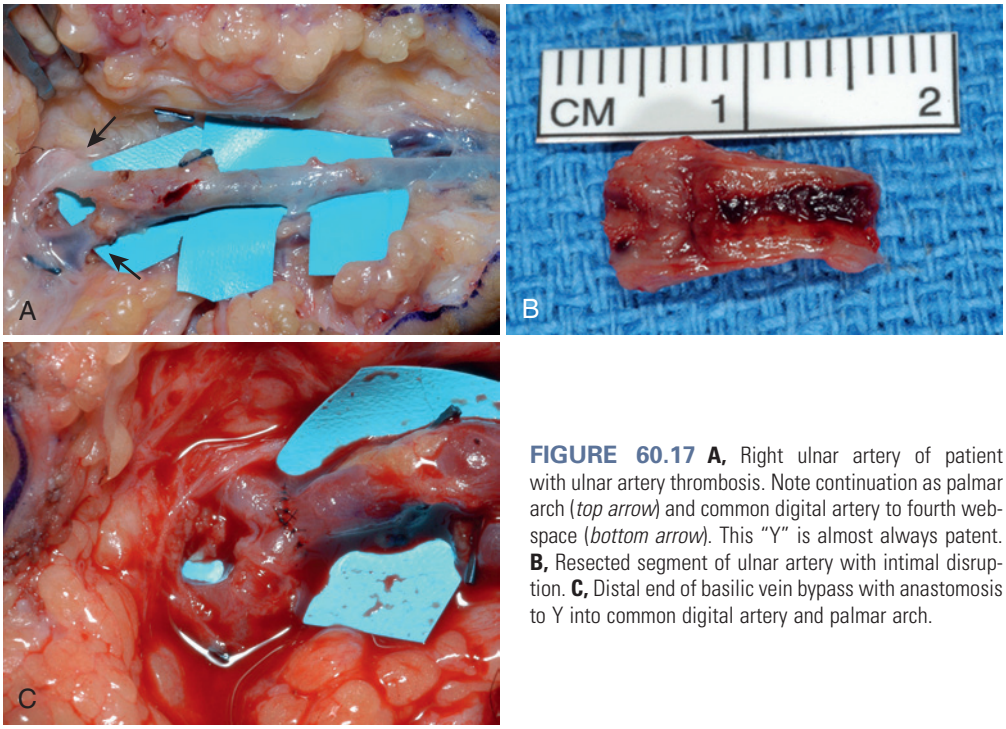

FIGURE 60.17 A, Right ulnar artery of patient with ulnar artery thrombosis. Note continuation as palmar arch (*top arrow*) and common digital artery to fourth web-space (*bottom arrow*). This "Y" is almost always patent. **B,** Resected segment of ulnar artery with intimal disruption. **C,** Distal end of basilic vein bypass with anastomosis to Y into common digital artery and palmar arch.

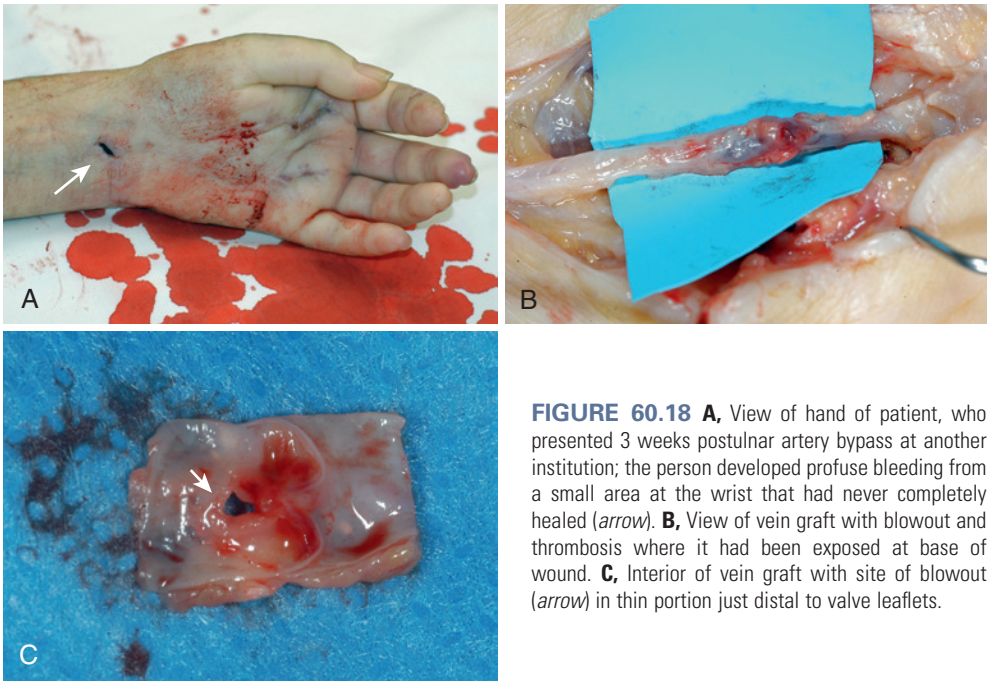

FIGURE 60.18 A, View of hand of patient, who presented 3 weeks postulnar artery bypass at another institution; the person developed profuse bleeding from a small area at the wrist that had never completely healed (*arrow*). **B,** View of vein graft with blowout and thrombosis where it had been exposed at base of wound. **C,** Interior of vein graft with site of blowout (*arrow*) in thin portion just distal to valve leaflets.

and this can be used for the graft. The issue of the EPL tendon pressing on the graft must be addressed, and while the graft may be brought superficial to it, I will usually make a small sling out of a portion of the extensor carpi radialis longus (ECRL) tendon from the base of the second metacarpal to pull the EPL away from the graft (Figure 60.20). Alternatively, the EPL can be freed from its fascial sling at the Lister tubercle and allowed to slide away from the artery proximally.

Vascular Disease

Arterial occlusive disease was not seen frequently in the distal upper extremity 30 to 40 years ago except in patients with Buerger disease. This is a fairly common problem now and is primarily related to the combination of diabetes, renal disease, and often organ transplantation. The need for access for hemodialysis compounds this problem by potentially altering the circulation distal to the site of the arteriovenous fistula. Patients

with collagen vascular disease often suffer from vasospastic disease (see later), but they can also have vascular occlusion from the effects of vasculitis. Today, Buerger disease is an uncommon cause of ischemia of the hand, but it would appear that other disease states leading to critical ischemia of the hand are on the rise. Many patients have already suffered loss of one or both of their lower extremities, and loss of the hand can be devastating from the mobility standpoint. Therefore, I feel that an aggressive approach is warranted for these patients to try and avoid loss of the hand.

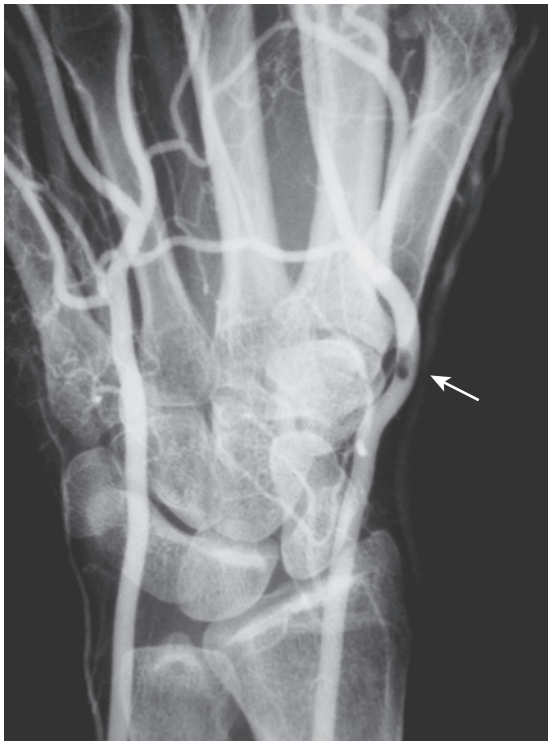

FIGURE 60.19 Arteriogram of patient with symptoms of ischemia of index finger. Note clot (*arrow*) in radial artery in snuffbox under extensor pollicis longus tendon.

Preoperative Evaluation

Patients presenting with ischemia of the hand in the face of vascular disease need a thorough workup. The presence or absence of pulses at the wrist is important, but if absent, they should be sought out with a pencil Doppler. In the absence of a palpable pulse, the presence of a pulse with use of the Doppler is not a sign of adequate nutritive flow to the hand, however. As noted previously, I also use a "dynamic" Doppler to listen to the arch and sequentially occlude the wrist's radial and ulnar arteries. The flow to the fingers should be evaluated for the presence or absence of a signal in the pulp as well. Ischemic, gangrenous, or ulcerated fingers should be noted. Likewise, any previous surgery to the hand and arm should be noted, particularly prior or currently functional vascular access procedures.

The Doppler signal at the wrist should be evaluated with the fistula open and with it occluded with digital pressure to note any improvement in flow with the fistula occluded. Generally, arteriography remains the gold standard for most patients with critical ischemia of the hand because proper evaluation requires good visualization of the forearm vessels, palmar arch, and digital vessels that is difficult to achieve with MRA or CTA. Many patients present from the vascular surgeon with results of an arteriography, but I feel very strongly that the surgeon planning vascular intervention in the hand must view the actual studies.

After exam, all patients who have not had arterial studies should undergo arteriography. Many patients with critical

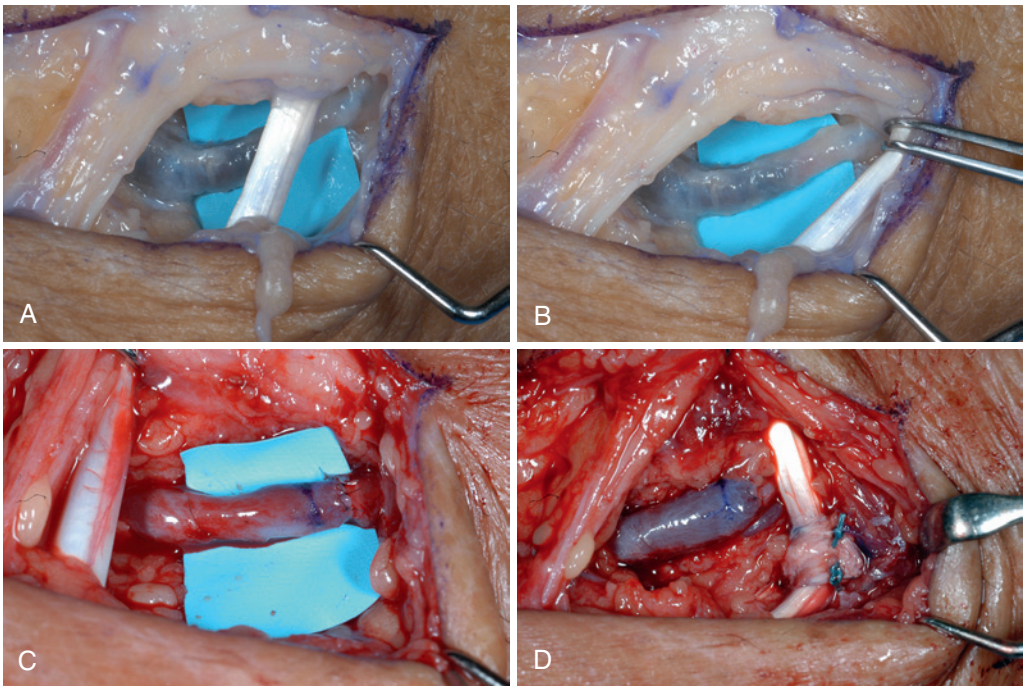

FIGURE 60.20 **A,** View of right radial artery going under extensor pollicis longus (EPL) tendon after thrombosis. Hand is to the right and forearm to the left. **B,** Note thrombus after EPL is moved off of artery. **C,** Repair after excision of thrombosed segment and vein grafting with cephalic vein. **D,** EPL has been pulled off vein graft with a sling made from a portion of extensor carpi radialis longus to the base of second metacarpal.

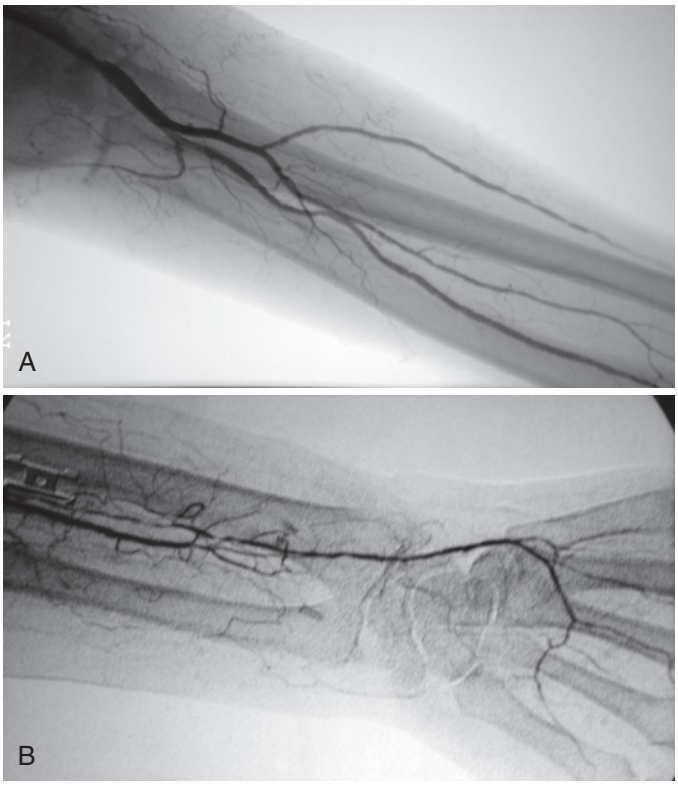

FIGURE 60.21 **A,** Arteriogram of proximal forearm of patient with hand ischemia. Note multiple levels of partial occlusion. **B,** Distal arteriogram of another patient with critical ischemia. While the patient does have flow into the hand through the radial artery, it is fed completely by collaterals. Arteriography is essential to see this level of detail and to know that there is an open distal arch available for potential bypass grafting.

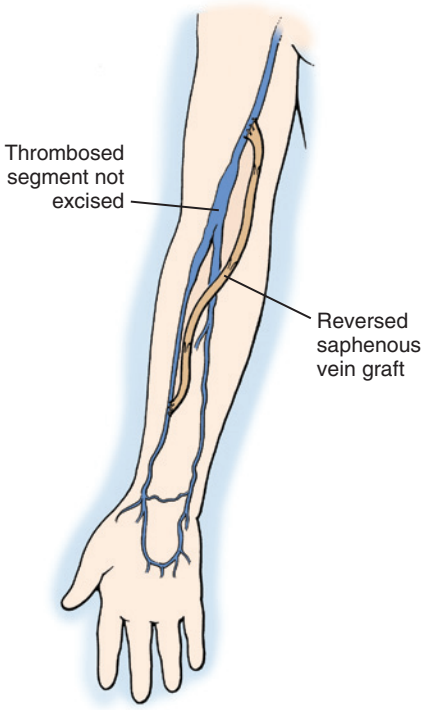

FIGURE 60.22 Technique of local bypass using reversed saphenous vein to go around the occluded segment. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

ischemia due to complications of diabetes and renal disease will have multiple levels of partial occlusion that can be seen in the forearm vessels on arteriography, and these types of lesion do not lend themselves to a local approach (Figure 60.21). Patients with collagen vascular disease usually have an occlusion limited to the vessels in the distal forearm and/or hand, but the digital vessels may be involved as well. The arteriogram should be used to decide the best approach to improve flow to patients' hand. In the case of ulnar or radial artery thrombosis in the distal forearm and hand, excision of the occluded segment to accomplish a Leriche sympathectomy with bypass grafting usually is indicated. The approach is similar to that discussed earlier for ulnar and radial artery thrombosis.

Patients with multisegment disease require a more aggressive approach. Bypass can be performed in the forearm of occluded areas using saphenous vein grafting very successfully (Figure 60.22). For most patients, however, I feel that going from the proximal brachial artery above all sites of occlusion to an open ulnar or radial artery at the wrist level usually is the most successful option. Patients often have lower-extremity vascular disease and the saphenous may not be available as a result of prior harvesting (e.g., for extremity or cardiac surgery) or because of loss of the lower limb. I have also found that healing of the saphenous donor site in the lower and upper leg can be very problematic in this patient group. The saphenous is quite thick and can present difficulties in anastomosis to the hand's smaller vessels. For all of these reasons, I prefer to do an in situ bypass technique in the hand, generally using the cephalic vein to go from the brachial to the radial artery in the snuffbox if the arch is open (see Figure 60.21, *B*).

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: In Situ Bypass of the Forearm

I prefer to use the cephalic vein for in situ bypass whenever possible because the radial artery in the snuffbox usually is patent in patients with significant vascular disease.[63-65] The radial artery bifurcates deep in the snuffbox into the princeps pollicis and deep palmar arch; anastomosis usually is done just proximal to this bifurcation. Even with severe calcific arterial disease, there is a segment of the artery just before the bifurcation that is soft enough to sew with a 7-0 or 8-0 suture. Due to the nature of these patients, the cephalic vein may not be patent or partially thrombosed; thus, it is wise to examine this vein prior to undertaking surgical intervention.

In case the cephalic is unusable, the basilic is an option but will not reach the radial artery, so the distal anastomosis must be done to the ulnar arch. In cases in which both of the vessels cannot be used, the reversed saphenous vein remains an option. At times, the only way to be certain about the patency and/or adequacy of these veins is by exploring them, and it must be explained preoperatively to the patient and family that another incision on the leg may be necessary.

An incision is made from over the snuffbox to the antecubital fossa over the brachial artery, largely following the course of the cephalic vein, which is carefully exposed and all branches are sought out. The bigger branches are preserved to allow passage of the valvulotome, while the smaller branches are ligated with little vascular clips. Enough vein is dissected out

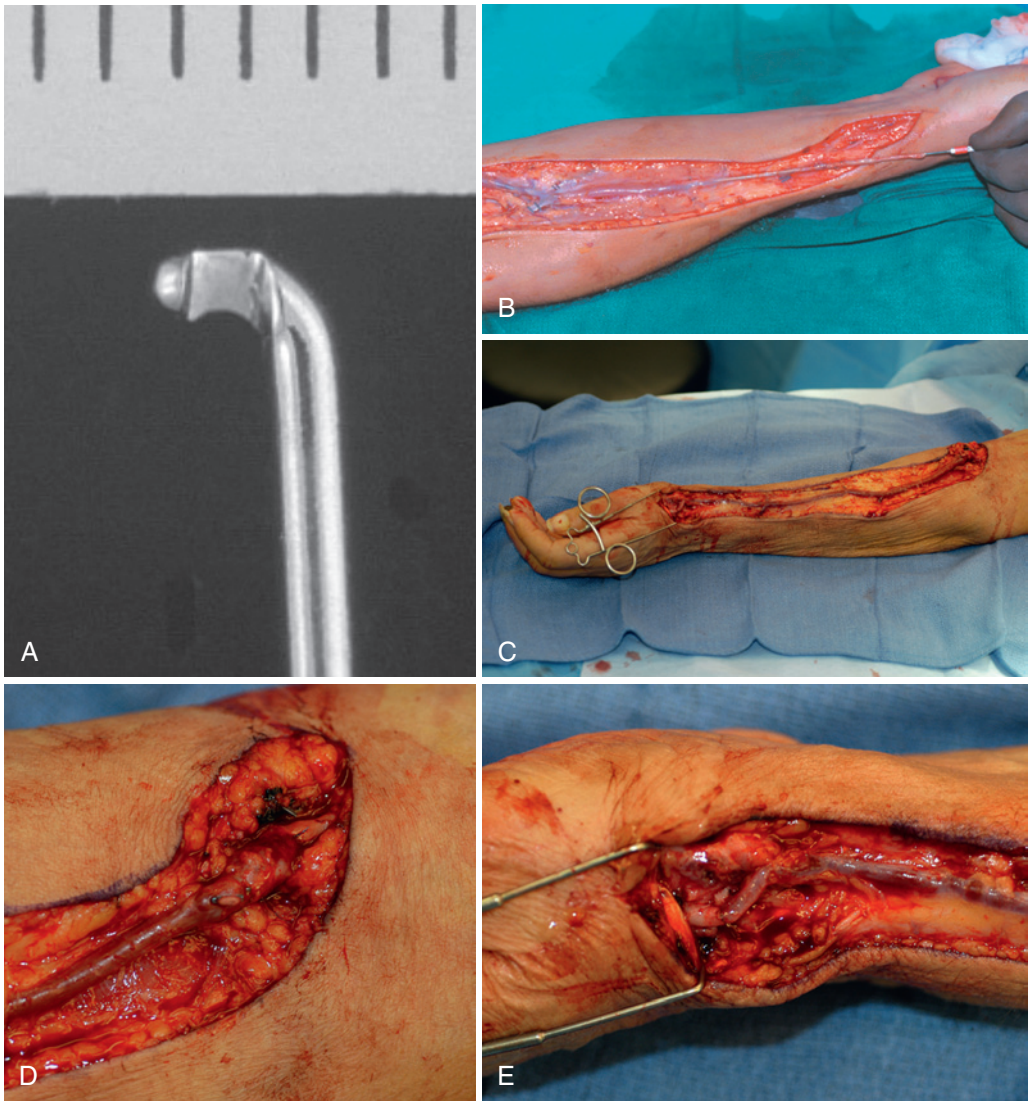

FIGURE 60.23 **A,** Leather-Mills valvulotome: This is the end of the reverse-cutting device that renders the venous valves incompetent. **B,** Valvulotome being passed from distal end of cephalic vein to proximal, and then withdrawn carefully to remove valves. **C,** After completion of brachial–radial bypass with in situ cephalic vein. **D,** Proximal end-to-side anastomosis to brachial artery in antecubital fossa. **E,** Distal end-to-end anastomosis to radial artery in anatomic snuffbox. (From Pederson WC: Revascularization options for terminal distal ischemia. *Hand Clin* 31(1), 2015, Elsevier Scientific, with permission)

proximally and distally to have adequate length for the graft to reach the brachial and radial arteries proximally and distally, respectively. The brachial artery is dissected free in the antecubital fossa, and blue vascular loops are placed on branches to provide proximal and distal control.

Similarly, the radial artery is dissected out from the snuffbox to the site of the bifurcation and an appropriate place for anastomosis is selected (e,g., primarily an area with minimal calcification if this can be located). The larger branches of the cephalic are controlled with small vascular clamps or bulldogs; once the sites for anastomosis are selected proximally and distally, the vein is divided at appropriate sites to allow enough for proximal and distal anastomoses. The vein is then irrigated and the valves are removed carefully with the Leather-Mills valvulotome. This instrument comes in forward-cutting (i.e., antegrade placement) and reverse-cutting (i.e., retrograde placement) styles. I prefer the retrograde reverse-cutting model because it seems to be safer and more able to be controlled (Figure 60.23).

The vein is filled with heparinized saline and the valvulotome is run down the vein distally as far as it will go. It is then withdrawn slowly and resistance is felt as it encounters a valve in the vein. Great care must be taken as the instrument comes to a branch in the vessel, as it can cause a large tear at the site of branching if it catches on it. The valves in the vein are bileaflet; thus, the instrument must be turned 180 degrees and brought back through the area of the valve to cut both leaflets. Once the valves are cut, the vein is irrigated proximally to distally with heparinized saline to make sure all of them have been rendered incompetent. If there is any obstruction to flow, the remaining valve or area of occlusion must be sought out and corrected or the bypass will not stay patent. The valvulotome is passed again carefully and intact valve leaflets located until proximal irrigation goes freely through the graft.

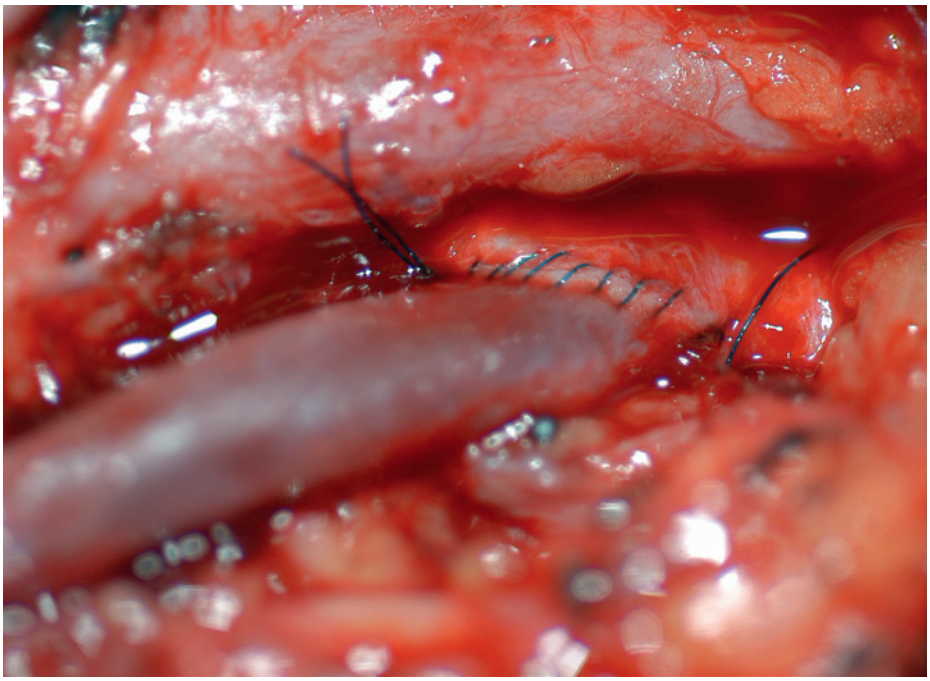

FIGURE 60.24 View of half of end-to-side anastomosis running to brachial artery with 6-0 polypropylene suture.

Likewise, any remaining branches should be checked for and ligated. Once a widely patent graft is ensured, the proximal anastomosis is performed. I prefer to occlude the brachial artery with DeBakey vascular clamps proximally and distally. An arteriotomy in the exposed portion of the brachial artery of the appropriate size is performed with a number 11 scalpel blade. It is preferable to open this up a bit from a simple longitudinal cut to an oblique opening with microscissors or Potts-Smith vascular scissors. Once this is done the artery is irrigated proximally and distally with about 10 cc of heparinized saline to prevent thrombus formation while the artery is clamped. The proximal vein is trimmed appropriately and the anastomosis is usually performed with 6-0 or 7-0 vascular polypropylene. I prefer to use two running sutures with this material on the medial and lateral sides of the arteriotomy (Figure 60.24). Once this is complete, the clamps are removed and the adequacy of flow through the graft is assessed. If there is brisk flow, the distal vein is allowed to "unwind" to remove any twists; this is then secured with a small vascular clamp or bulldog.

After appropriate trimming, the distal anastomosis is performed end-to-end to the radial artery just proximal to its bifurcation in the snuffbox. If the artery is soft, this can be done in standard fashion with an 8-0 nylon microsuture; however, if the artery is heavily calcified, which unfortunately is often the case, the anastomotic technique may need to be modified and a "sleeve" anastomosis performed between the vein graft and the distal artery.[32,84] This is done by placing two 6-0 vascular sutures that are double-armed with needles in the vein graft 180 degrees apart. These sutures are then passed inside-out on the radial artery several millimeters from the site of arteriotomy. The two needles of each suture are passed and then tied on the outside of the artery; this tacks the intima down and pulls the vein inside the artery (Figure 60.25). This can be quite a successful technique in the face of a severely calcified artery.

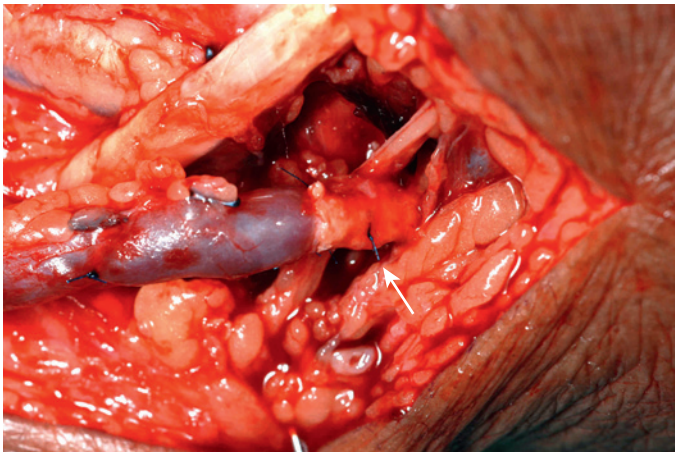

FIGURE 60.25 View of distal sleeve anastomosis between cephalic vein and calcified radial artery. Note two polypropylene sutures are tied on outside of artery (*arrow*).

Once the distal anastomosis is performed, the clamps are removed. Adequacy of flow can be checked by palpating the vein graft for a pulse and listening distally with a pencil Doppler over the arch as well. The graft is again checked for open branches that should be ligated to prevent the formation of arteriovenous fistulae. The arm and hand are arranged to make sure there is no tension or kinking of the graft, which is uncommon with this technique. The wounds are closed and the hand is placed in a soft, bulky dressing. While the hand and forearm are not splinted, use of the arm should be fairly limited for a few weeks until it heals. A more thorough description of this technique is available from other sources.[66]

Complications. The primary complication of in situ bypass is thrombosis of the graft. Fortunately, this is uncommon because,

FIGURE 60.26 View of forearm and hand of patient with long-standing renal disease who underwent in situ bypass 8 years previously for impending loss of his hand. His bypass remained patent for another 5 years when he unfortunately succumbed to his underlying metabolic problems. (From Pederson WC: Revascularization options for terminal distal ischemia. *Hand Clin* 31(1): 2015, Elsevier Scientific, with permission.)

if adequate inflow is provided through the brachial artery and all of the valves are removed, there is a high rate of flow down these grafts. If the graft thromboses, however, there can be severe consequences for the hand, as whatever little flow may have been provided via the radial or ulnar artery (i.e., whichever vessel was used for the distal anastomosis) is now gone. Most of these patients do reasonably well, and it is not uncommon for them to succumb to their basic underlying disease process before the bypass occludes (Figure 60.26).

If arteriography reveals that there is inadequate flow into the arch by way of the radial or ulnar arteries for outflow, an alternative technique for revascularization of the hand is available with arterialization of the venous system. This technique has been found to be useful for patients with no other reasonable option and critical ischemia of the hand.[40,50,65] In the case of poor to no visible outflow to the hand on vascular studies and impending gangrene, this is arguably the best option. The technique is very similar to in situ vein grafting, except that no distal anastomosis is performed and the cephalic or basilic venous system is left intact into the dorsal hand. The valves must be removed as for in situ bypass, but experience shows that the valves distal to the wrist do not need to be cut—attempting this can damage the dorsal venous system that is the basis of how the oxygenated blood reaches the fingers' capillary bed.

It appears that arterial pressure is enough to render the valves in the smaller veins of the dorsal hand incompetent. A branch at wrist level is used to pass the valvulotome, and once the valves are cut, a proximal anastomosis is performed. All branches proximal to the wrist are ligated, however, to prevent proximal arteriovenous fistulae and shunting of blood flow away from the hand. Surgeons can usually detect a Doppler signal in the veins at the metacarpophalangeal level initially, and this usually progresses out to at least the level of the proximal interphalangeal joints after a few weeks. Swelling is not uncommon during the postoperative period, but this usually resolves over a couple of months. One caveat is that this probably should not be attempted in the face of open wounds; as I have had two patients with open wounds who developed severe infections that required amputation of their hands after this procedure.

Management of Vasospastic Disorders

Maurice Raynaud first noted the syndrome of intermittent ischemia of the fingers in a young woman in Paris in the late 1850s and published these findings (along with those of 24 other patients) in his doctoral thesis in 1862. Raynaud was not quite sure what the etiology of this was at the time of his publication. Although the pathophysiology of this condition is much better understood today, treatment for it remains somewhat problematic.

Cold sensitivity is the most common early manifestation of vasospasm and affects up to 10% of the population and up to 30% of premenopausal women.[44] The sympathetic nervous system controls vascular tone in the periphery, and increased tone leads to decreased perfusion that may be physiologic in the face of hypotension or cold temperatures causing thermoregulatory changes. There has been a lot of study of the pathophysiology of this phenomenon, which is beyond the scope of this chapter.[53]

Pathologic hyperactivity of the sympathetic system leads to pathologic decreases in nutritive flow to the digits and eventually can lead to gangrene and ulceration. Koman believes that impending gangrene or ulceration is a sign of distal thrombus and/or thrombosis of one of the main vessels supplying the hand.[44] *Raynaud disease* is vasospasm seen without any underlying systemic disease process while *Raynaud syndrome* is vasospasm seen in conjunction with one of the systemic diseases manifested by vasospasm (e.g., systemic sclerosis). Merritt suggested that the two differentiations of the term be dropped and vasospasm simply be referred to as "Raynaud's," which I think is a practical approach.[52]

Patients presenting with "cold" fingers alone usually do not require any type of medical intervention unless the condition is severe. They can be treated by keeping the fingers warm and avoiding exposure to cold situations. Patients with more severe symptoms that interfere with their daily lives will need a workup and some form of treatment. An evaluation starts with taking a careful history and doing a physical exam. The history should focus on the time course of the symptoms and any other medical conditions that might contribute to the vasospasm. In particular, a history of trauma to the hand should be sought out, as patients with vascular injury (i.e., ulnar or radial artery thromboses) often present with symptoms of vasospasm limited to the involved fingers.

In the absence of previous trauma, evidence of collagen vascular disease should be sought out. I have diagnosed a number of patients over the years with collagen vascular disease who were referred with the primary symptoms of Raynaud's based on history, a physical, and lab work. A thorough evaluation of the vascular system, with pulse and dynamic Doppler exams, should be carried out. The pulp of each finger should be examined with the pencil Doppler because digital artery occlusion may be the underlying issue.

For patients with no signs of vascular occlusion, lab work to screen for inflammatory markers and collagen vascular disease should be ordered, including C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), antinuclear antibody (ANA), and anticentromere antibody (ACA) studies. In the face of positive results, the patient should be referred to a rheumatologist for further evaluation and long-term management of the systemic condition. If there is evidence of thrombosis of the radial or ulnar arteries, the patient should undergo vascular studies (e.g., usually arteriography) to determine the extent of the occlusion.

Nonsurgical Management of Vasospastic Disorders

As noted previously, if there is no impending gangrene or ulceration, many patients can be managed by cold and stress avoidance whenever possible. The use of calcium channel blockers (CCBs) (e.g., nifedipine and diltiazem primarily) have been shown to be beneficial—that is, decreasing the frequency and severity of attacks.[34] A general impression is that CCBs lose some efficacy over time; thus, use of this treatment during the colder months and stopping it when the weather gets warmer seems to be an effective method of managing such patients.

Use of sildenafil also has been shown to have some potential benefits in increasing blood flow and decreasing the severity of Raynaud's episodes, but several patients had to stop treatment because of side effects.[24,31] Controlled studies of a large number of patients are not available for this drug unfortunately, and the drug remains very expensive for the patient because this is an "off-label" use.[8] Patients with more severe symptoms, but without impending ulcers or gangrene, present more difficult management issues. Botulinum toxin (Botox®) injected around the common digital vessels has been shown to improve symptoms in this group of patients and has healed digital ulcers for a few.[53,58,59]

Neumeister and colleagues observed up to a 300% increase in skin blood flow with laser Doppler after Botox injection.[53] It appears to have a reasonable longevity as well, with patients having relief in some studies for many months,[60] whereas some will require reinjection. For patients with occlusion of one of the major vessels, Botox is not likely to give long-term relief. The technique is to inject 10 units (2 cc of reconstituted protein) around each common digital vessel in the palm of each hand. The primary complication of this technique has been intrinsic muscle weakness in some patients, and around 40% of them will require a repeat injection.[59]

Operative Management of Vasospastic Disease

Even though Botox can help with the management of patients with moderately severe symptoms from vasospasm, its long-term efficacy is not entirely clear. Patients with impending gangrene or who already have ulcerations are usually considered candidates for periarterial sympathectomy. It should be stated very emphatically that periarterial sympathectomy is *not* indicated for patients with calcific arterial disease because these vessels are unable to respond to the removal of sympathetic nerves. Thoracoscopic sympathectomy has had some advocates in the past for the management of Raynaud's[17]; however, this has been shown to lead to a rebound hypersympathetic response and is to be avoided in these patients.[44] Periarterial sympathectomy of the arteries of the distal forearm and palm has been shown to be very effective in managing vasospasm in patients who do not do well with nonsurgical therapy.[53,69,82]

Although total flow is not increased, studies have documented that nutritional flow is improved, and there seems to be less arteriovenous shunting, which occurs during vasospasm and deprives the fingers of nutritive blood flow.[43] This procedure is indicated for patients whose ulcers do not heal with conservative treatment and can be effective for ones with occlusion of the ulnar or radial arteries. If surgery is being considered, however, it is prudent to obtain arterial imaging studies to evaluate the patency of the ulnar and radial arteries.

Ulnar artery thrombosis is quite common in patients with collagen vascular disease,[30] and knowledge of the status of the ulnar artery preoperatively can help in planning the best surgical approach. If the ulnar artery is thrombosed, it can be excised in toto to interrupt the sympathetic nerves along the vessel; this accomplishes a so-called "Leriche" sympathectomy.[46] The other option is bypass of the ulnar artery along with periarterial sympathectomy. The long-term patency of venous grafts in patients with underlying collagen vascular disease has been shown to be low, however.[38] Contraindications are relative, and large nonhealing wounds are probably a reason to avoid elective procedures in the hand.

The technique involves stripping of the adventitial tissue off of the arteries, which in turn removes the very small sympathetic connections from the nerves (Figure 60.27). This surgery can be performed with high-powered loupe magnification, but a microscope is used by most surgeons. The areas to be stripped are the radial and ulnar arteries in the distal forearm for 3 to 4 cm, the palmar arch, and common digital arteries distal to the arch (Figure 60.28). If the ulnar artery is thrombosed and excision versus bypass is to be considered, the incision can be extended from the ulnar forearm to include the course of the ulnar artery out to the superficial palmar arch.

All of these vessels are carefully stripped of surrounding perivascular tissue and veins, but care must be taken, particularly in the digital vessels, to avoid damage to the vessel wall by overvigorous stripping. It is preferable to avoid the proper digital arteries in the fingers, as my experience has been that this significantly increases morbidity from this operation in terms of wound-healing problems and stiffness. If an individual finger fails to improve (or gets worse) after forearm and palmar sympathectomy, I will consider performing a limited sympathectomy on the digital arteries over the proximal phalanx.

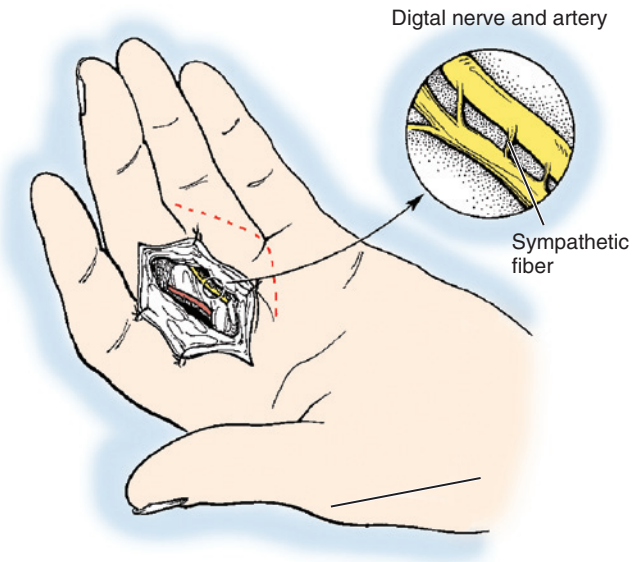

FIGURE 60.27 Digital periarterial sympathectomy (i.e., Flatt-Wilgis technique) is accomplished through a zigzag volar (Bruner) incision. The adventitia is cleaned of sympathetic fibers, and all connections with the accompanying peripheral nerve are transected. The initial dissection is performed under loupe magnification with subsequent dissection visualized with an operating microscope. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

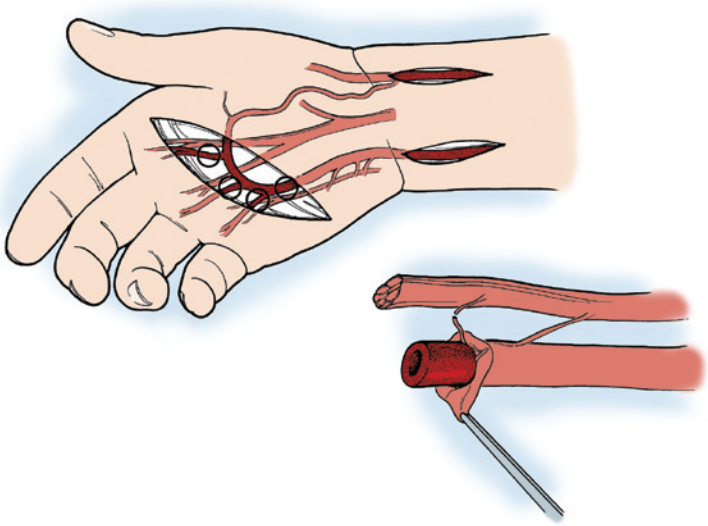

FIGURE 60.28 Schematic representation of periarterial sympathectomy of the hand. Longitudinal incisions are used to expose the radial and ulnar artery, and an oblique incision is used in the palm to expose the superficial arch and the origins of the common volar digital arteries (i.e., the Koman technique). A separate incision (not shown) can be used over the anatomic snuffbox to expose the radial artery. After initial dissection under loupe magnification, the operating microscope is used to strip the adventitial fibers from the vessels and sever connections with parallel peripheral nerves. (From Koman LA, editor: *Bowman Gray school of medicine orthopaedic manual*, Winston-Salem, NC, 1997, Wake Forest University Orthopaedic Press, with permission.)

Ulnar artery bypass can be very helpful, particularly for patients who are stable and quickly develop increasing symptoms and ulceration, which is often due to recent occlusion of the artery.[22] The primary issue is whether these patients benefit long term from bypass of the ulnar artery; it would appear that they do. Experience shows that the two-year patency of venous grafts to the ulnar artery in patients with scleroderma is around 70 to 80%, and it should be noted that those who occlude the grafts generally do not develop acute exacerbation of their symptoms. This is probably the result of the benefit of the sympathectomy effect of excising the diseased and/or occluded artery.

Postoperative Management and Anticoagulation. The use of heparin, low molecular weight heparin, or other acute antithrombotic agents in the perioperative period has been helpful; however, there are no short-term or large studies documenting efficacy. In the setting of grafts, some surgeons use a single dose of 5000 U of heparin at the release of the tourniquet. In subsequent weeks, others have reported the use of warfarin for the first 3 months following the vascular procedure.[82] These measures seem to be used on a case-by-case basis.

❖ AUTHOR'S PREFERRED METHOD OF TREATMENT: Periarterial Sympathectomy

As noted earlier, I feel that periarterial sympathectomy is indicated for patients who have ongoing or worsening symptoms despite conservative measures to manage their vasospasm. The acute development of ulcers usually signals ulnar artery thrombosis. I generally study these patients and if the involved segment of ulnar artery is limited to the very distal forearm and palm, I consider sympathectomy with excision of the ulnar artery. If there is found to be adequate flow from the ulnar artery proximal to the area of occlusion, I perform a bypass as discussed previously. If the segment of ulnar artery thrombosis/thickening goes above the dorsal arterial branch in the forearm, I generally do not perform bypass because, in my experience, long grafts that cross the wrist have a rather poor patency rate. I perform periarterial stripping of the radial and ulnar arteries in the forearm as well as the palmar arch. If the primary symptoms (e.g., ulcers) are on the radial side of the hand, the radial artery in the anatomic snuffbox can also be stripped; this seems to be helpful for some patients.

Aneurysms

Aneurysms in the vessels of the forearm and hand are uncommon and are usually from trauma resulting in a "false" aneurysm due to injury to the vessel wall. These are by far most commonly seen in the ulnar artery secondary to hypothenar hammer syndrome (see before) but can be the result of other traumatic injury as well (Figure 60.29). These patients often present with ulnar nerve symptoms based on compression of the nerve in the palm from the mass of the aneurysm.[55] One also can see aneurysms of the digital vessels as a result of injury. The management of these depends on which vessel is involved and whether ligation and/or excision of the aneurysm will cause ischemia downstream. In the ulnar artery, I feel that usually these should be excised and blood flow restored. On occasion if the aneurysm is small and the artery tortuous, the lesion can be excised and the artery repaired primarily. In most cases, however, a reversed vein graft is required (Figure 60.30). The technique for vein grafting the ulnar artery was discussed previously.

Venous Thrombosis

Deep venous thrombosis in the upper extremity is a rare condition, and it does not always lead to significant symptoms.

Near-total venous occlusion of all the veins in the limb is called "phlegmasia cerulea dolens" and is extremely rare in the hand.[5,39] When coupled with deep venous thrombosis, it can lead to compartment syndrome and potential loss of the limb, however.[3] This syndrome is almost always associated with malignancy or a severe systemic disease state. Management is difficult and often is not successful. Surgical management of the compartment syndrome coupled with anticoagulant therapy may be the only option available. I have treated one patient by exploration, which found every superficial vein in the forearm thrombosed. The vessels in the hand and antecubital fossa were open, however, and a long interposition saphenous vein graft corrected the problem and salvaged the hand.

FIGURE 60.29 Arteriogram of young woman who suffered "minor" stab wound to palm approximately 1 month ago. Now she has a mass in the palm, ulnar nerve paresthesias, and numbness.

Vascular Malformations

Vascular malformations are unusual in the hand and upper extremity. This term can cover a range of lesions from small, low-flow venous malformations to large, pulsatile arteriovenous ones. Abnormalities of the lymphatic system are often seen in conjunction with venous anomalies. True hemangiomas are very rare in the hand and usually are lesions found in children. Hemangiomas are dermal–epidermal lesions that often are involute as the child grows and do not always require treatment. Other vascular malformations may be asymptomatic until they get larger, and it is my impression that thrombosis of an otherwise small and asymptomatic venous lesion often leads to the development of pain. The diagnosis is usually best made with MRI scan of the area; this often can help make the diagnosis and outline the extent of the lesion and its potential involvement of other structures.[67]

If the lesion is asymptomatic, it usually can be left alone. Some patients are effectively treated with a fitted compression glove if the lesion tends to swell when dependent or with activity as it fills with blood. If it is large and potentially affects hand function, treatment should be considered. While sclerosis and embolization are techniques frequently used to good effect in vascular lesions of the head and neck, this approach is problematic in the hand. I have seen permanent nerve injury, as well as loss of digits, after attempted hand sclerosis/embolization has

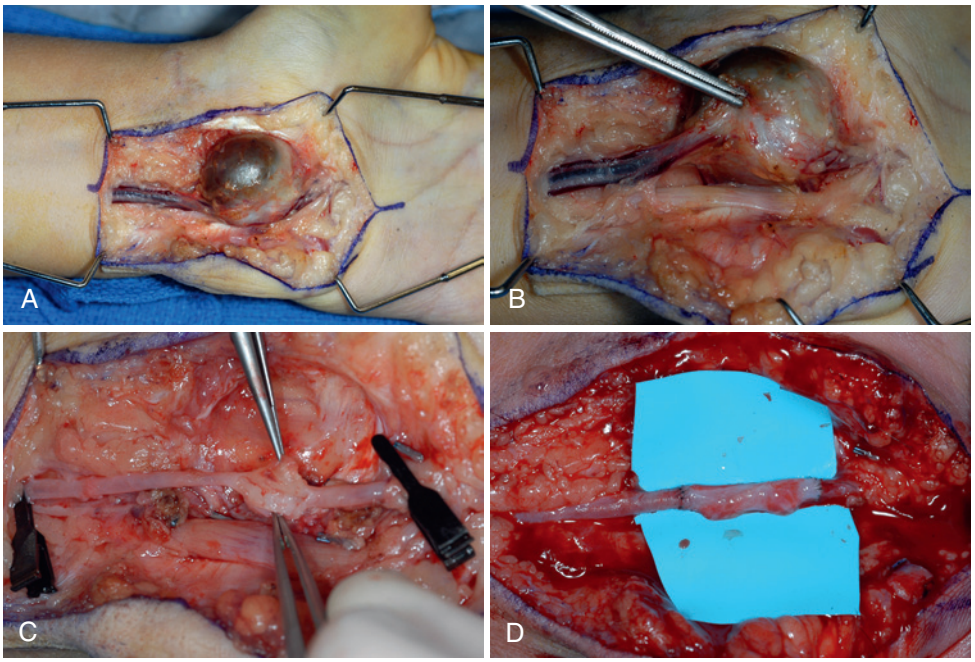

FIGURE 60.30 **A,** Intraoperative view of patient whose arteriogram is shown in Figure 60.29. **B,** Note ulnar nerve compression by aneurysm. **C,** Area of arterial injury after excision of aneurysm. **D,** Repair with reversed basilic vein graft.

happened. If the lesions are markedly symptomatic, I believe that they should be approached surgically.

Upton has vast experience with these lesions and states that the goals of treatment are to completely extirpate the lesion, preserving tendons, bone, nerve, and uninvolved muscle.[78] Vascular supply is then reconstituted as needed with microvascular repairs and vein grafting. His results and those of others have shown that an aggressive surgical approach in symptomatic lesions in all but the worst high-flow lesions leads to acceptable outcomes with low complication rates.[21,37]

Venous malformations are the most common, and excision of these is usually fairly straightforward. The difficulties in dealing with vascular lesions seen in the head and neck are obviated in the hand by the ability to use a tourniquet to limit blood loss. Venous lesions are often seen on or around nerves, and great care should be taken to limit damage to any significant nerve in the hand (Figure 60.31). Although these lesions may recur, surgical excision usually reduces pain and improves function for a significant period of time; thus, a surgical approach that can preserve vascular supply and nerve function is warranted.

High-flow arteriovenous malformations present another set of problems. These patients are often severely symptomatic in terms of pain and disability. The lesions cause proximal shunting of blood flow through large arteriovenous fistulae that leads to distal ischemia. Again, while embolization may be helpful for particularly large lesions, there is a significant risk of loss of tissue distally with this approach. They can be explored very safely and excised with a tourniquet on the upper arm, so blood loss can be minimal. Planning is essential, and I usually prefer to get arteriographic studies for these patients to accurately delineate the extent of the lesion and the involvement of the major vessels of the forearm and hand.

A surgeon should plan to excise the involved abnormal arteries and reconstruct whatever is necessary with vein grafts. Often the other, uninvolved artery will need ligation to decrease the large amount of inflow characteristic of these lesions (Figure 60.32). Ischemic digits are probably best amputated, and results can be very satisfying in terms of decreased pain and improved function for patients. Although such lesions typically recur over time and major amputation is often eventually required, the quality of life for these patients can be improved tremendously for a period of time with aggressive resection and reconstruction.[78]

Glomus Tumors

These tumors are lesions of the glomus body that involves thermoregulation of microvascular blood flow. These tumors make up 1 to 5% of all those in the hand. They can be located nearly anywhere, but in the hand the most common location is in the subungual area.[57] The lesions can be excruciatingly painful, and patients experience pain if any pressure is placed on the lesion and also may have severe cold sensitivity. Any patient with a history of fingertip and/or nailbed pain with marked tenderness of the nail should be evaluated for a glomus tumor of the nailbed. MRI scan is usually diagnostic (Figure 60.33) but sometimes imaging can be negative.[77] Any area of significant pain in the fingers or hand without an obvious cause should include a possible glomus tumor in the differential. Excision is usually curative, and in the most frequent presentation in the nailbed, tumors usually can be enucleated without long-term nail deformity (see Figure 60.33).[45]

Page numbers followed by "*f*" indicate figures, "*t*" indicate tables, "*b*" indicate boxes, and "*e*" indicate online content.

A
ABCDE acronym, for melanoma, 1977
ABCDEFG procedure (alphabet reconstruction), 1139
Abdominal wall flap, random, for burn deformities, 1944
Abduction, in restoration of thumb-index key pinch, in ulnar nerve palsy, 1058-1059
Abductor advancement, for radial collateral ligament injuries, 309
Abductor digiti minimi (ADM), 138
  transfer of
    in hypoplastic thumb reconstruction, 1292
    in median nerve palsy, 1032-1033, 1033*f*-1034*f*
Abductor pollicis longus (APL)
  imbrication of, for thumb-in-palm deformity, 1112
  transfer of, accessory slip of, 1058, 1058*f*
Abductorplasty, of flexor pollicis longus, for thumb-in-palm deformity, in spasticity, 1111-1112
Abscess
  antibiotic recommendations for, 21*t*
  nerve, in Hansen disease, 106, 109-110, 112-113, 113*f*-114*f*
  shooter's, 51-52
  subaponeurotic space, 37
    treatment for, 38
  subcutaneous space, 37
    treatment for, 38
  web space (collar-button), 37-38, 38*f*-39*f*
    case study, 38.*e*1*b*, 38.*e*1*f*
    treatment for, 38
      preferred method of, 39
Abuse, drug, infections caused by, 51-52
Acanthosis nigricans, 1959-1960
Acid burns, 1948-1949. *see also* Burns
Acid-fast stain, for infections, 65-66, 65*t*
Acquired immunodeficiency syndrome (AIDS), 119-121. *see also* Human immunodeficiency virus (HIV)
  bacillary angiomatosis in, 120-121, 120*f*
  cellular immune responses in, 119.*e*2
  classification and clinical diagnosis of, 119.*e*1-119.*e*2, 119.*e*1*t*
  clinical features of, 119.*e*2
  clinical manifestations of, 119-121
  etiology and epidemiology of, 119
Acquired immunodeficiency syndrome (AIDS) *(Continued)*
  herpes simplex virus in, 120
  indicator conditions, to hand surgery, 119.*e*1*t*
  Kaposi sarcoma in, 121
  treatment of, 121
Acral fibrokeratoma. *see* Digital fibrokeratoma
Acral lentiginous melanoma, 1978
Acral nevi, 1966
Acrosyndactyly, 1227, 1227*f*-1228*f*
  secondary to constriction ring syndrome, 1257
Actinic keratosis, 1972, 1972*f*
Actinobacillosis, 67-68
Actinomycetoma, 70-73
  clinical findings on, 71
  diagnosis of, 72
  etiology and epidemiology of, 70
  microbiology of, 70-71, 71*f*
  treatment of, 72-73
Actinomycosis, 68
Action potential, sensory nerve, in thoracic outlet syndrome, 968
Active stability, of proximal interphalangeal joint, 279
Activity modification, for epicondylitis, 865
Acupuncture, for complex regional pain syndrome, 1817
Acute compartment syndrome, 1763
  diagnosis of, 1765-1767
Acute injury
  in complex traumatic elbow dislocation
    clinical assessment of, 813-814
    imaging of, 814
    treatment of, 818-824
  in longitudinal forearm instability repair, 808
Acyclovir, for herpes simplex virus, 120
Adaptive misalignment, carpal, 463
Adaptive modalities, for complex regional pain syndrome, 1818
Adduction, of thumb, restoration of, 1056-1058
Adductor advancement, for radial collateral ligament injuries, 309
Adductor pollicis, transfer of, in median nerve palsy, 1041
Adenoid basal cell carcinoma, 1974
Adhesion formation, as complication of flexor tendon grafting, 224
Adipofascial flap, 1593
Adjuvant therapy, for heterotopic ossification, 857
Adrenergic compounds, for complex regional pain syndrome, 1813-1814, 1814*t*
Advancement flap(s), 1541-1542, 1547-1550, 1548*f*-1549*f*. *see also* Skin flap(s)
  palmar, for soft tissue defects of thumb, 1676-1677, 1677*b*
    with proximal releasing incision, 1677-1679, 1679*b*, 1679*f*
    without proximal releasing incision, 1677, 1678*f*
  V-Y, 1548-1550, 1549*f*-1551*f*
    in reconstruction of amputated fingertip
      Atasoy-Kleinert volar, 1712-1713, 1713*f*
      Kutler lateral, 1713-1714, 1714*f*
      volar advancement, 1714, 1715*f*
Aeromonas hydrophila, infection with, 1584
Aeromonas species, 48
Afterburn, 1927
Agee single-portal endoscopic technique, for carpal tunnel syndrome, 933-934
Algae infections, 116
Algorithm, management, for pain or paresthesia, 147*f*
Allen test
  for vascular disorders, 2036, 2037*f*
  for vascularity assessment, 1490
Allergic response, to regional anesthesia, 12-14
Allodynia, 1802
  definition of, 1799*t*
Allogeneic bone grafts, 1635-1636
Allograft(s). *see also* Autograft(s); Xenograft
  for mangling injuries, 1510
  of radial head, salvage using, 765
Al-Qattan's classification, of phalangeal neck fractures, 1431-1432, 1433*f*
Amelanotic melanoma, 1980
Amitriptyline, for complex regional pain syndrome, 1812*t*
Amlodipine, for complex regional pain syndrome, 1815*t*
Amniotic band syndrome, 1255-1258, 1256*f*-1257*f*, 1258*b*. *see also* Amniotic disruption sequence
Amniotic disruption sequence, 1255-1258, 1256*f*-1257*f*, 1258*b*

Amoxicillin, for anthrax, 69
Amphotericin B
  for candidiasis, 85
  for coccidioidomycosis, 85-86
  for deep sporotrichosis, 88
  for fungal infections, 79
  spectrum of activity of, 79*t*
Amplitudes, in nerve conduction studies, 929
Amputation
  below-elbow (transradial), 1737
  digital tip, 1709-1717, 1709*f*, 1720*b*
    case study of, 1737.*e*1*b*, 1737.*e*1*f*-1737.*e*3*f*
    cross-finger pedicle flap for, 1714-1716, 1715*f*
    with exposed bone, 1711-1717
    free flaps in, 1717
    island flaps in, 1717
    preferred method of treatment for, 1717, 1722-1723
    with skin or pulp loss only, 1709-1711
    Smith and Albin thenar H-flap in, 1716, 1716*f*
    thenar flap in, 1716
    V-Y flap for
      Atasoy-Kleinert volar, 1712-1713, 1713*f*
      Kutler lateral, 1713-1714, 1714*f*
      volar advancement, 1714, 1715*f*
  of fingers. *see also* Ray amputation
    toe transfer for. *see also* Toe transfer, in finger replacement
      distal digit in, 1646-1647
      multiple-digit in, 1648-1649
      proximal, 1648, 1648*f*-1649*f*
        digit in, 1647-1648
      single digit in, 1646, 1647*f*
  human bites and, 48-49
  interscapulothoracic, 1756, 1757*f*
  limb, major, 1753-1756
    case study of, 1762.*e*1*b*, 1762.*e*1*f*-1762.*e*3*f*, 1762.*e*3*b*
    indications for, 1753, 1754*f*
  lumbrical-plus finger after, 1718
  for macrodactyly, 1282
  for mangling injuries, consideration of skeletal contribution in, 1492-1493
  multiple-digit, 1735-1737, 1735*b*, 1736*f*, 1737*b*
  neuromas after, 1522
  pain management after, 1747-1749
  of perionychium, 323-324, 324*f*-325*f*
  postburn, 1942-1943
  with preservation of basal joint
    composite radial forearm flap for, 1697-1699, 1700*f*, 1699.*e*1*f*
    osteoplastic reconstruction for, 1696-1697, 1697.*e*1*f*
      Gillies "cocked-hat" flap in, 1696, 1697*f*
Amputation *(Continued)*
    two-stage
      stage 1, 1696-1697, 1698*f*
      stage 2, 1697, 1697.*e*1*f*
  pollicization for, index/long finger stump in, 1699-1703, 1702*f*-1704*f*, 1705*b*
  principles of, 1708*b*
  ray, 1719-1730, 1735*b*. *see also* Ray amputation
  replantation after, 1478-1479. *see also* Replantation
  through carpus, 1737
  through distal interphalangeal joint, 1717-1719, 1718*f*
    with disarticulation, 1717-1718
  through phalanx
    middle, 1718-1719, 1719*f*-1720*f*
    proximal, 1719, 1721*f*-1722*f*
  through proximal interphalangeal joint, 1719
  of thumb
    with destruction of basal joint, 1703-1704
    with preservation of basal joint, 1696-1699
    subtotal, 1688-1691
      dorsal rotational flap, 1691-1694
      regional and distant flaps, 1694-1696
      Z-plasty procedures, four flap, 1690-1691, 1690*b*, 1691*f*-1692*f*
    toe transfer for, 1646. *see also* Toe transfer, in thumb replacement
    "Z"-plasty procedures, 1689-1691
      simple, 1689, 1690*f*, 1689.*e*1*f*
  transhumeral, 1754-1756
  transradial, 1753-1754, 1754*f*
  upper extremity, rehabilitation after, 1757-1758
  wrist disarticulation, 1737-1738, 1739*f*
    preferred method of treatment of, 1737-1738
Amputation stump, posttraumatic neuralgia in, 1010.*e*5
Amyloid, deposition of, tendinopathy in, 1906-1907, 1906*f*
Amyoplasia, 1365
Analgesia, definition of, 1799*t*
Anastomosis. *see also* Microvascular surgery
  distal sleeve, for vascular disorders, 2051, 2051*f*
  end-to-end, for vascular disease, 2051, 2051*f*
  end-to-side, for vascular disease, 2051, 2051*f*
  vascular, in toe transfer, 1668
Anatomy, Dupuytren surgery and, 138
Anconeus flap transolecranon approach, to distal humeral fractures, 714-715, 716*f*
Anemia, Fanconi, radial deficiency associated with, 1289, 1290*t*, 1329*t*
Anemones, venomous, 1791-1792
Anesthesia, 1-16
  coronoid fracture-dislocation examination under, 819
  in elbow arthroscopy, 886, 888*f*
  for elbow contracture release, 849
  general, 1
  for humeral fracture fixation, 710-711
  regional, 1-14, 14*b*
    advantages of, 3
    complications of
      allergy as, 12-14
      neurapraxia as, 12, 12*b*
        incidence of, 12
        management of, 12, 13*f*
      sepsis as, 12-14
    contraindications to
      absolute, 1
      relative, 1-2
    disadvantages of, 3
    drugs, commonly used, 4*t*
    equipment for, 4
    historical techniques of, 5-6
      continuous peripheral nerve catheters, 5
      minimum effective dose, 5-6
    indications for, 2-3
      microvascular surgery patients, 2
      patients with rheumatoid arthritis, 3
      pediatric patients, 2
      pregnant patients, 2-3
    intravenous, 10-11
    for limiting use of, 3*b*
    preferred method of, 11-12
    specific blocks, 6-8, 6*f*
      axillary, 8, 8*f*
      infraclavicular, 7-8, 7*f*
      interscalene, 6, 7*f*
      supplementary, 8-11
        at digit, 9-10, 10*f*-11*f*
        at elbow, 8
        at wrist, 8-9, 9*f*
      supraclavicular, 6-7, 7*f*
    toxicity of, 4*b*
    ultrasound-guided, 5, 7*f*
  regional, for complex regional pain syndrome, 1811
  for stiff finger and hand, 340
Anesthetic procedure, for Dupuytren disease, 145
Anesthetic skin patch, for Hansen disease, 104
Aneurysmal bone cyst, 2024-2025, 2024*f*-2025*f*
Aneurysms, 2054, 2055*f*
Angiography. *see also* Arteriography
  prior to free flap transfer, 1577
Angiomatosis, bacillary, AIDS and, 120-121

Angular osteotomies. *see also* Osteotomy
  for forearm fracture malunion, 801-803, 802*f*
Angulation
  after metacarpal fractures, dorsal, 246, 246*f*-247*f*
  after phalangeal fractures
    apex volar, 266, 266*f*
    lateral, 266-267, 266*f*
  after volar plate arthroplasty, 290
Animal(s), venomous, 1788-1795
  caterpillars, 1788, 1789*f*
  cnidarians, 1791-1792, 1792*f*
  fish, 1792-1795, 1793*f*-1794*f*
  sea urchins, 1792, 1792*f*
  snakes, 1789-1791, 1790*f*-1791*f*
  spiders, 1788-1789, 1789*f*
Animal bites, 46-48
  antibiotic recommendations for, 21*t*
Ankylosis, complete, of neuropathic joint, as contraindication to total elbow arthroplasty, 909
Anterior compartment portals, in elbow arthroscopy, 888-890
Anterior drawer test, in midcarpal instability, 460
Anterior (transolecranon) fracture-dislocation, of elbow, 784.*e*13*b*, 784.*e*13*f*-784.*e*14*f*
Anterior transposition, of ulnar nerve, 947
Anterolateral portals, in elbow arthroscopy, 889-890, 890*f*
  distal, 890
  proximal, 889
Anterolateral thigh flap, 1597, 1598*f*
  for burn deformity, 1945
  for mangling injuries, 1513-1515, 1516*f*
Anteromedial portals, in elbow arthroscopy, 888-889
  proximal, 888-889, 889*f*
Anthrax, 56-57, 57*f*, 68-69, 69*f*
  cutaneous, 68-69, 69*f*
    treatment of, 69
Antibiotics, for common infections, 21*t*
Anticoagulation therapy, regional anesthesia and, 2
Anticonvulsants, for complex regional pain syndrome, 1813, 1813*t*
Antidepressants, for complex regional pain syndrome, 1811-1812, 1812*t*
Antifungal agent, activity of, spectrum of, 79*t*
Antiinflammatory medications, for carpal tunnel syndrome, 932-933
Antimony, injection of, for leishmaniasis infection, 117
Antisepsis, for Dupuytren disease, 145
Antituberculous drugs, 100-103, 101*t*
Antivenin, snake, 1789
AO/ASIF classification
  of distal humerus fractures, 703
  of distal radial fracture, 524, 526*f*
Apert syndrome, 1210*f*
  classification of, 1228*t*
  in syndactyly, 1227-1232, 1229*f*
    planning of, groin flaps in, 1228-1230, 1230*f*
Apex volar angulation, as complication of phalangeal fractures, 266, 266*f*
Apical ectodermal ridge (AER)
  in embryogenesis, 1208
  removal of, 1209, 1210*f*-1211*f*
Aponeurosis, of finger, 338.*e*3, 338.*e*5*f*
Arcade of Fröhse, 950-951
Arcade of Struthers, 699, 941, 941*f*
Arcing, 1947
Arm
  compartments of
    release of, 1769, 1769*f*
  mangling injuries of, treatment of, 1515-1519, 1519*f*-1520*f*
  release of, 1770-1771
Arm flap, lateral. *see* Lateral arm flap
Arsenical keratosis, 1972
Artelon implant, for carpometacarpal joint osteoarthritis, 362
Arterial injury, contaminant, 1008
Arterial repairs, in replantation, 1482
Arterial trauma
  closed, 2042-2047, 2044*f*-2046*f*
    complications of, 2046-2047, 2047*f*-2048*f*
    preferred method of treatment of, 2046-2047, 2047*f*
  open, 2040-2042, 2040*f*
    complications of, 2042
    postoperative care after, 2042
    preferred method of treatment of, 2040-2042, 2041*f*-2042*f*
    vein grafting for, 2041, 2041*f*, 2042*b*, 2043*f*
Arterialized venous flaps, 1577
Arteriography, of recipient site, in vascular bone grafting, 1615
Arteriovenous malformations, high-flow, 2056, 2057*f*
Artery(ies). *see also named artery, e.g.*, Radial artery

Carcinoma, 1959
Cardinal signs, in early diagnosis, for Hansen disease, 105-107
Carpal bone(s). *see also named bone, e.g.*, Scaphoid; Wrist
alignment of, measurement of, in wrist instability, 430, 430*f*-431*f*
distal row of
kinematics of, 423, 423*f*
ligaments of, 422-423
stabilization of, 425
fracture of, 588-652
in children, 1448*b*
incidence of, 625*t*
in mangling injuries, treatment of, 1500
other than scaphoid, 624-649
growth in, 1444
isolated, dislocation of, in complex carpal instability, 475-476, 475*f*
ossification centers of, 1444
proximal row of
kinematics of, 423
stabilization of, 425
stability of, soft tissue structures in, 1444-1445
Carpal collapse
lunotriquetral dissociation with, 451
chronic, treatment of, 456
lunotriquetral dissociation without
acute, treatment of, 455
chronic, treatment of, 455-456, 455*f*-456*f*
Carpal height ratio, measurement of, in wrist instability, 430, 431*f*
Carpal instability, 418, 433-463
analysis of, 433, 433*t*, 434*f*
chart of, 661*t*
chronicity of, 433
classification of, 434
complex, 465
axial fracture-dislocations in, 473-475, 474*f*-475*f*
Carpal instability *(Continued)*
isolated carpal bone dislocations in, 475-476, 475*f*
perilunate dislocations in
dorsal
greater-arc injuries and, 470
lesser-arc injuries and, 465-470, 465*f*-466*f*
treatment of, 465-470
palmar, 472, 474*f*
perilunate fracture-dislocations in, dorsal, 470-472
transscaphoid, 470-471
transscaphoid-transcapitate, 471-472, 472*f*
transtriquetrum, 472, 473*f*
treatment of, 472, 473*f*
radiocarpal dislocations in, 473
as contraindication for capsular release, 691
definition of, 433
diagnosis of, 428-432
arthrography in, 432
arthroscopy in, 432
cineradiography in, 432
clinical examination in, 428
computed tomography scans in, 430-431, 431*f*
magnetic resonance imaging in, 432
measurement of bone alignment in, 430, 430*f*-431*f*
radiological examination in, 428-430
additional views, 429-430, 429*f*
distraction views, 431
routine views, 428-429, 428*f*-429*f*
stress views, 431, 432*f*
ultrasonography in, 432
direction of, 433
dissociative, 434-457
lunotriquetral, 450-457
scapholunate, 434-450. *see also* Scapholunate dissociation
etiology of, 433
location of, 433
mechanics of, 661
nondissociative, 457-463, 458*f*
midcarpal, 459
radiocarpal, 458-459, 458*f*
severity of, 433
wrist arthroscopy for, 661-665
Carpal kinematics, 423-424, 423*f*, 425*f*
Carpal kinetics, 424-426
Carpal ligament(s)
injury to
distal radial fracture associated with, 575
pathomechanics of, 426-428, 427*f*
intrinsic, 421*f*-422*f*, 422-423
Carpal malalignment, defined, 529, 530*f*
Carpal misalignments, 463-464
adaptive, 463
secondary to deformity of distal radius, 463-464
Carpal misalignments *(Continued)*
secondary to deformity of lunate, 464
secondary to deformity of scaphoid, 464
secondary to STT arthritis, 464
Carpal stabilization
ligaments in, 425, 425*f*
muscles in, 425-426, 426*f*
Carpal tunnel, ganglion in, 2009
Carpal tunnel decompression, expected outcome after, 935
Carpal tunnel release, open, 934-935, 934*f*, 935*b*
Carpal tunnel syndrome, 930-935
anatomy of, 930-932, 930*f*-932*f*
management of
nonoperative, 932-933
surgical, revision of, preferred method of, 1822-1823, 1823*f*
provocative tests for, 926*t*
recurrent, 954-955
revision surgery for, 954-955
treatment of, operative, 933-935
Agee single-portal endoscopic technique in, 933-934
Chow two-portal endoscopic technique in, 933
postoperative care after, 935
preferred method of, 934-935, 934*f*, 935*b*
Carpal wedge osteotomy, for arthrogryposis, 1380-1382, 1382*b*
complications of, 1382
contraindications to, 1380-1381
indications for, 1380, 1381*f*
postoperative management and expectations after, 1382
preferred method of, 1382
preoperative planning in, 1381
technique of, 1381, 1382*f*
Carpectomy, proximal row
arthroscopic, 690
for scaphoid nonunion advanced collapse, 623
for scapholunate dissociation, 450
Carpometacarpal boss, 2007
clinical characteristics of, 2007, 2007*f*
complications in, 2007
operative technique for, 2007, 2007*f*-2008*f*
postoperative care for, 2007
Carpometacarpal (CMC) joint(s)
fusion of, in tetraplegic patient, House's one-stage key pinch reconstruction and, 1134, 1135*f*
injuries of, 175
of thumb, 312-315
dislocations of, 312-315
anatomy in, 312, 312*f*
historical review of, 312
postoperative management and expectations in, 314-315

Carpometacarpal (CMC) joint(s) *(Continued)*
preoperative evaluation of, 312-313, 313*f*
treatment of, 313-314
preferred method of, 313, 314*b*, 314*f*
osteoarthritis of, 359-369
anatomy and biomechanics of, 359-360, 360*f*
complications of, 368-369, 369*f*
critical points on, 366*b*
diagnostic imaging of, 359, 359*f*
epidemiologic findings on, 359
evaluation of, 359
expected outcomes on, 366-368, 367*t*
indications and contraindications for, 360-362
operative techniques on, 362-364
physical examination for, 359
postoperative management and expectations for, 366-369
preferred method of treatment for, 364-365, 365*f*-366*f*
treatment for, 360-364
nonoperative, 360-361
other procedures and devices for, 362
Carpometacarpal fracture-dislocations, 244-246
multiple, 245
preferred method of treatment of, 245-246, 245*f*-246*f*
of ring finger, 244
of small finger, 244-245
Carpus. *see also named bone, e.g.*, Scaphoid; Wrist
amputation through, 1737
indications for vascularized bone grafting in, 1624-1625
Cast(s). *see also* Immobilization
postoperative, in tetraplegic patient, 1138-1139
for proximal interphalangeal joint contractures, 340.*e*2
Cast index, 1449, 1453*f*
Casting, for distal radius fractures, 516.*e*1
Cat bites, infection from, 46-47
Catch-up clunk phenomenon, in midcarpal instability, 459
Caterpillars, venomous, 1788, 1789*f*
Catfish, marine and freshwater, venomous, 1792-1793, 1793*f*, 1793.*e*1*f*
Causalgia, 1797
nerve injury and, 1010.*e*3
CBSQ. *see* Cervical Brachial Symptom Questionnaire ("CBSQ")
CCH success, 133
CD4+ T-cell, in acquired immunodeficiency syndrome, 119.*e*1, 119.*e*1*t*
Cellulitis, 17
antibiotic recommendations for, 21*t*
Cement burns, treatment of, 1951
Central hand deficiencies. *see* Cleft hand
Central nervous system, in complex regional pain syndrome, ablative techniques and, 1817
Central slip, 338.*e*5
anatomic integrity of, 155-156, 157*f*
Central slip tenotomy, for swan neck deformity, 1115, 1116*b*, 1116*f*
Centralization
of extensor tendons, 413-414
in management of radial longitudinal deficiency, 1329-1331, 1332*f*
Cerclage wiring
for metacarpal shaft fractures, 239, 237.*e*1*t*
for proximal interphalangeal joint fracture-dislocation, 283-284, 284*f*
postoperative protocol for, 291
preferred method for, 291-293, 291*f*
Cerebral palsy, 1080
Cervical Brachial Symptom Questionnaire ("CBSQ"), 965*f*-967*f*
Cervical incision, transverse, in brachial plexus surgery, 1155-1156, 1155*f*
Cervical nerve(s)
brachial plexus formed from, 1146, 1391, 1392*f*. *see also* Brachial plexus *entries*
C5-C6 injury of, 1149
author's preferred treatment of, 1159
decisions and priorities of repair for, 1159
C5-C7 injury of, 1149
decisions and priorities of repair for, 1159
C5-T1 (pan-plexus) injury of, 1150
author's preferred treatment of, 1160
decisions and priorities of repair for, 1159-1160
C8-T1 injury of, 1149-1150
decisions and priorities of repair for, 1159
Cervical nerve root, impingement of, Spurling test for, 927
Cervical nerve transfer, C7, for brachial plexus injury, 1173-1176, 1175*f*-1176*f*
author's preferred technique for, 1176
complications of, 1176
outcomes of, 1176
postoperative care after, 1176
surgical anatomy in, 1175
Cervical plexus nerves, transfer of, for brachial plexus injury, 1177
Cervical ribs
anatomic variants of, 961*f*
in thoracic outlet syndrome, 963
Cervical spine
involvement of, in rheumatoid arthritis, 1833
in thoracic outlet syndrome, 960*f*
Chang Gung Memorial Hospital, toe transfers at, from 1985-2012, 1672*t*
Charcot-Marie-Tooth disease, 923
CHARGE syndrome, radial deficiency and, 1290*f*, 1290*t*
Chauffeur's fracture, 525*f*, 527
management of, 569-570, 570*f*-571*f*
Cheiralgia paresthetica, 947-948
Chemical burns, 1948-1951. *see also* Burns
agents and tissue damage by, 1952*t*
management of, 1949-1951, 1950*f*-1951*f*
Chemical sympathectomy, for complex regional pain syndrome, 1819-1820
Chemotherapy, extravasation, skin loss due to, 1570
Chevron-type slot graft, for short metacarpal lengthening, 1242-1243, 1242*f*
Children
brachial plexus palsy in, 1391-1424. *see also* Brachial plexus palsy, pediatric
flexor tendon reconstruction in, 223-224, 224*b*
indications of, 223
preferred technique of, 224
hand, wrist, and forearm fractures in, 1425-1475. *see also* Fracture(s), pediatric; Fracture(s), *under specific bone*
regional anesthesia in, 2
scaphoid fracture in, 607-608
trigger digits in, 1916
tuberculous osteomyelitis in, 98
Chloroprocaine, characteristics of, 4*t*
Choke vessels, 1540
Choline acetyltransferase activity, in brachial plexus surgery, 1158-1159
Chondral defects, wrist arthritis and, 689, 690*f*
Chondrodesis, for thumb-in-palm deformity, 1112
Chondrodysplasia
Grebe, 1214, 1215*f*
Hunter-Thompson, 1214
Chondroectodermal dysplasia, postaxial polydactyly in, 1232, 1233*f*
Chondroma, periosteal, 2021-2022, 2022*f*
Chondromyxoid fibroma, 2023
Chondrosarcoma, 2026-2027, 2028*f*
Chow two-portal endoscopic technique, for carpal tunnel syndrome, 933
Chromosome disorders, radial longitudinal deficiency associated with, 1329*t*
Chronic exertional compartment syndrome, 1767-1768
Chronic nerve compression, pathophysiology of, 921-924, 922*f*
Chronic regional pain syndrome, after distal radial fracture, 576

Cineradiography
of carpal instability, 432
of lunotriquetral dissociation, 454, 454*f*
of midcarpal instability, 460
Ciprofloxacin, for anthrax, 69
Circular plate fixation, for scaphotrapeziotrapezoid fusion, 390
Clasped thumb, 1324-1325, 1324*f*, 1325*b*
clinical features of, 1324
treatment of, 1324-1325, 1325*f*
Clavicle
bone loss or nonunion of, vascularized grafting for, 1636
as recipient site, in bone grafting, 1636
Claw-hand deformity
postburn, 1930, 1937-1938, 1939*f*
in ulnar nerve palsy, 1047-1056. *see also* Ulnar nerve palsy
postoperative management of, 1056
surgical correction for, 1048-1056
Burkhalter and strait in, 1054-1055
dynamic tendon transfers in, 1051-1056
extensor carpi radialis longus transfer in
dorsal route of, 1054, 1054*f*
flexor route of, 1055, 1055*f*
extensor indicis proprius and extensor digiti minimi transfers in, 1053-1054
flexor and extensor muscle transfer in, 1054-1056
flexor carpi radialis transfer in, 1055-1056
Fowler's wrist tenodesis in, 1051, 1051*f*
palmar capsulodesis of MP joint (Zancolli) in, 1049-1050, 1049*f*, 1050*b*
palmaris longus four-tail transfer in, 1056
Parkes static tenodesis in, 1050-1051, 1050*f*
Riordan static tenodesis in, 1050
static techniques in, 1048-1051
Stiles-Bunnell procedure in, modified, 1051, 1052*f*
superficialis transfer in, 1051-1053
modifications of, 1051-1053
results of, 1053
Clear cell sarcoma, 2020
Cleft, closure of, first web space release and, 1246-1251, 1246*f*, 1249*f*-1251*f*, 1254*f*
Cleft hand, 1244-1255, 1244*f*, 1255*b*
characteristics of, 1245, 1245*t*
classification of, 1245, 1245*t*
clinical features of, 1245
etiologic findings in, 1244, 1245*t*
surgical treatment for, 1245-1255
in absent thumb deformity, 1251, 1254*f*
Cleft hand *(Continued)*
in cleft deformity, 1246-1251
expected outcomes for, 1255
first web space release and cleft closure in, 1246-1251, 1246*f*, 1249*f*-1251*f*, 1254*f*
indications for surgery, 1245-1246
management of the feet, 1251-1255
Miura and Komada technique in, 1251, 1252*f*
Snow-Littler procedure in, 1248, 1248*f*
surgical management of the progressive deformity in, 1246, 1284*f*
syndactyly release in, 1245*f*, 1246
transverse bone removal in, 1246
in type IIB and III, 1251, 1254*f*
Ueba technique in, 1251, 1253*f*
Clenched fist injury, 48-49, 49*f*
Clinodactyly, 1270-1273, 1271*f*, 1273*b*
classification of, 1271*t*
epidemiologic findings in, 1270-1271, 1272*f*
expected outcomes, 1273
management of, 1272, 1273*f*-1274*f*
preferred technique of, 1272-1273
phalangeal anatomy in, 1271-1272
Clofazimine, for multibacillary Hansen disease, 109
Clonidine, for complex regional pain syndrome, 1814
Closed reduction
cast immobilization with
for lesser-arc injuries, 466-467, 467*f*
for perilunate fracture-dislocations, 470-471
with a cast or splint, of phalangeal shaft fractures, 256-257, 257*f*
of distal radial fracture, 530-531
technique for, 530-531, 531*f*-534*f*
of metacarpal neck fractures, 233-234, 234*f*
percutaneous pin fixation with
for lesser-arc injuries, 467-468, 467*f*
for perilunate fracture-dislocations, 471
percutaneous pinning and
of metacarpal shaft fractures, 237-238, 238*f*
of phalangeal shaft fractures, 257, 258*f*-259*f*
plaster immobilization and, of metacarpal shaft fractures, 237, 237*f*
Closed tendon sheath irrigation, for pyogenic flexor tenosynovitis, 30-31, 30*f*
Clostridial myonecrosis, 56
Cnidarians, venomous, 1791-1792, 1792*f*
Coccidioidomycosis, 85-86
Cold sensitivity, vasospasm and, 2052
Cold-stress testing, for vascular disorders, 2039
Collagenase clostridium histolyticum, enzymatic fasciotomy with, for Dupuytren disease, 140
Collar-button abscess, 37-38, 38*f*
case study, 37-38, 38.*e*1*b*, 38.*e*1*f*
treatment for, 38, 39*f*
preferred method of, 39
Collateral ligament(s). *see also* Radial collateral ligament; Ulnar collateral ligament
anatomy of, 338.*e*1, 338.*e*1*f*
injury to, grading of, 279
lateral (LCL), 830
anatomy of, 813, 832, 832*f*
diagnostic imaging of, 831, 831*f*
instability of
ligament reconstruction for
complications in, 835
contraindications to, 833
indications for, 832-833
outcomes in, 835
postoperative management and expectations of, 835
preoperative evaluation of, 830-831
technique in, 833-835, 834*f*
magnetic resonance image of, 831*f*
physical examination of, 830-831
ulnar, 832
medial (MCL), 830
anatomy of, 813, 836-837, 836*f*
anterior bundle of, 836, 839*f*
diagnostic imaging of, 835-836, 836*f*
instability of
ligament reconstruction for
complications in, 840
contraindications to, 837
indications for, 837
outcomes in, 840
postoperative management and expectations of, 839-840
preoperative evaluation of, 835-836
technique in, 837, 838*f*, 840*f*
magnetic resonance image of, 836*f*
physical examination of, 835
posterior bundle of, 836
transverse bundle of, 836
release of, in metacarpophalangeal joint contracture, 340
Colles' fracture, 524-527, 524*f*, 567
malunited, 579*f*
treatment of, 531*f*
Color, of flap, postoperative, 1582, 1582*f*
Column concept, of distal humeral fractures, 701-703
Columnar classification, of distal radial fracture, 524, 527*f*
"Come-along" flexion splint, for elbow contracture, 857, 858*f*

Comminuted fractures
of capitellum, 703, 704*f*
combined articular and supracondylar, 722, 722.*e1b*, 722.*e1f*-722.*e2f*
minimally, management of, 721-722, 721.*e1b*, 721.*e1f*-721.*e2f*
of radial head, management of, 749, 752*f*-753*f*, 755*f*
supracondylar involvement in, 722
Community-acquired infections (CA-MRSA), methicillin-resistant *S. aureus* (MRSA) and, 18
Compartment pressure, measurement of, 1767*t*
Compartment release, sixth, 511-512
Compartment syndrome, 1763-1772, 1772*b*
acute, 1763
diagnosis of, 1765-1768, 1765*f*, 1766*t*
etiologic findings and incidence of, 1764-1765, 1765*f*

      historical perspective on, 310-311
      postoperative management and expectations in, 311
      preoperative evaluation of, 311
      treatment of, 311
    volar, 300
  of proximal interphalangeal joint, 279-293
    acute dorsal, 279-280
    lateral, 280
    posttraumatic fibrosis and contracture in, 295-296
    volar, 280-281
      treatment of, 280-281
  of radial head, congenital, 1347-1349, 1347*t*, 1348*f*-1349*f*, 1350*b*
  in radial head fractures, 737
  of radioulnar joint, distal, 492
  of scaphoid, 475, 475*f*

Dislocation(s) *(Continued)*
of thumb interphalangeal joint, 296-297
of trapezium, 476
of trapezoid, 476
Displaced fracture(s)
with comminution and/or dislocation of elbow, 781
of radial head, 736
without comminution and proximal to midpoint of olecranon (type IIA), 781
Distal forearm injuries, 179, 179.*e*1*b*, 179.*e*1*f*
Distal interphalangeal (DIP) joint, 42-43, 42*f*
amputation of
with disarticulation, 1717-1718
to metacarpophalangeal joint, 1717-1719, 1718*f*
anatomy of, 338.*e*3, 338.*e*3*f*
arthrodesis of, 346-349
author's preferred method of treatment for, 347-349, 348*f*
complications of, 349
critical points in, 349*b*
expected outcomes for, 349
indications and contraindications of, 346-347
postoperative management and expectations after, 349
preoperative planning for, 347
in rheumatoid arthritis, for swan neck deformity, 1880-1882, 1880*t*
with screw, 1881, 1881*f*
studies of, fixation and outcomes, 347*t*
technique for, 347, 348*f*
dislocation of, 296-297, 297*f*
Elson test in, 156
ganglion of, 333, 333*f*-334*f*, 334*b*
Landsmeer's theory in, 157
stiffness of, after volar plate arthroplasty, 290
Distal intrinsic release, 343.*e*1, 343.*e*1*f*
Distal juncture technique, for tendon graft, 208, 209*f*
Distal oblique bundle (DOB), 482
Distal radioulnar joint (DRUJ)
arthroscopy of wrist, 660-661
reconstruction of, for rheumatoid arthritis, 1860-1863, 1861*f*-1862*f*
Distal radioulnar ligament reconstruction, 496-498, 497*f*
Distal segment, of nerve, 984-985, 985*f*
Distal sleeve anastomosis, for vascular disorders, 2051, 2051*f*
Distal tendon juncture, 206, 207*f*
Distal ulnar excision reconstruction, 1860-1863
Distal ulnar resection, 1862*b*
Distant flaps, 1540, 1563-1568
axial-pattern, 1564-1568
groin, 1564-1568, 1564*f*, 1566*f*-1567*f*, 1568*b*
random-pattern, 1563-1564
Distraction osteogenesis, metacarpal lengthening with, in brachydactyly, 1242-1243
Distraction plate fixation, of distal radial fracture, open reduction with, 557-559, 558*f*, 560*f*
Distraction-compression osteogenesis, treatment of nonunion of forearm bones using, 803
Docking technique, 837, 839
Dog bites, infection from, 46-47
Dome osteotomy, physiolysis and, for Madelung deformity, 1342-1344, 1342*f*-1343*f*
Donor muscle, selection of, for free transfers in brachial plexus injury, 1179, 1202
Donor nerve, in brachial plexus reconstruction, selection of, 1161-1162, 1202
Donor site(s)
for flaps, 1540-1541
for free flaps, 1576*t*
morbidity of, after congenital pseudoarthrosis of ulna surgery, 1357
for skin graft
care of, 1538
in managing injuries, 1511
split-thickness, 1531-1532, 1532*t*
for toe transfer
morbidity of, 1670
rehabilitation of, 1671
for vascularized bone grafts, 1614-1615
Donor tendon, 1036
Doppler flowmetry, laser, for vascular disorders, 2039
Dorsal angulation, as complication of metacarpal fractures, 246, 246*f*-247*f*
Dorsal capsule release, arthroscopic arthrolysis and, 691
Dorsal Dupuytren nodules (DDN), 129
signs of, 129-130, 131*f*
treatment of, 143
Dorsal hand skin, 1528, 1529*f*
Dorsal inlay graft, vascularized, placement of, 1632
Dorsal intercalated segment instability (DISI), 418-419
Dorsal interosseous muscle, 338.*e*3, 338.*e*5*f*. *see also* Interosseous muscle(s)
Dorsal paronychial tissue, assessment, of for digit perfusion, 1490, 1490*f*
Dorsal plate fixation, of distal radial fracture, open reduction with, 547-552, 548*f*
Dorsal radiocarpal ligament (DRCL), 421-422
repair of, 665*f*
tears of, 665
Dorsal radiotriquetral ligament, 421-422
Dorsal radius pedicle grafts, specific, 1630-1632
Dorsal retinacular ganglion, 2009, 2010*f*
Dorsal wrist injuries, 178-179
preferred method of treatment of, 179
Dorsum of the hand, contractures of, postburn, 1940-1941, 1942*f*
Double crush phenomenon, nerve injury and, 1-2
Double free muscle transfer, for brachial plexus injury, 1181-1183
Double-barrel flap, vascularized, in grafting from fibula, 1620
Double-crush mechanism, in compression neuropathies, 922-923
Doxepin, for complex regional pain syndrome, 1812*t*
Doxycycline
for actinomycetoma, 73
for anthrax, 69
for syphilis, 74
Drainage, of nerve abscess, 113
Dressing(s)
bilayer matrix wound, 1711-1712, 1712*f*
for burns, 1934
changes and healing by secondary intention, 1709-1711, 1710*f*
in free flap transfer, 1581-1582
postoperative, after syndactyly treatment, 1226-1227
semiocclusive, 1711
Unna boot, 1538
Drug(s). *see also* Multidrug therapy (MDT); *specific drug or drug therapy*
abuse of, infections caused by, 51-52
for complex regional pain syndrome, 1811
outcome of, 1819
parenteral, 1819
resistance to, in Hansen disease, 109
used in regional anesthesia, 4*t*
Drug-susceptibility tests, for infections, 66
"Drunken face" symptom, of snakebite, 1789
Dry arthroscopy
for arthroscopic arthrolysis, 691
for wrist, 658
Duchenne sign, 1046
Dull nail, 330
Duplication
of ring finger, 1234, 1235*f*. *see also* Polydactyly, central
of thumb, 1304-1315
Dupuytren contracture (DC), 128. *see also* Dupuytren disease (DD)
appearance of, 130
treatment of, historical points in, 138, 139*t*

Dupuytren disease (DD), 128-151
associated conditions with, 128-129
demographics, 128-129, 129*f*
diagnostic imaging of, 134
genetic biomarkers of, 129
heritability and, 128
historical review of, 138, 139*t*
pathology of, 136-138, 136*f*-137*f*
physical examination of, 129-131, 130*f*
preoperative evaluation of, 129-134
prevalence of, 129*f*
skin landmarks of, 132, 133*f*
staging in, 131-134
treatment of, recontracture and, 134*t*
types of operations for, 138-143, 139*t*, 148*b*
dermofasciectomy, 142-143, 143*f*
fasciectomy, 140-142
indications and options for, 140*t*
minimally invasive procedures of, 139-140
open surgical procedures and, 140-143, 141*t*
patient instructions in, 144-145
planning in, 145
postprocedure in, 148
procedures of, 145-148
regional fasciectomy, 141-142, 142*f*
segmental fasciectomy, 141-142
Dynadesis, for scapholunate dissociation, 443, 443*f*
Dynamic splints, for joint stiffness, 340.*e*1, 340.*e*1*f*
Dysesthesia(s)
cutaneous nerve, in thoracic outlet syndrome, 975
definition of, 1799*t*
Dysfunctional postures, in factitious disorders, 1828-1829, 1830*f*-1831*f*
Dysplastic nevus syndrome, 1966, 1967*f*
Dystrophic epidermolysis bullosa, syndactyly in, 1231-1232, 1232*f*

E

Early recontracture, of Dupuytren disease, 133-134, 134*t*
Eccrine poroma, 1964
Ecthyma contagiosum, 123-124, 124*f*
Edema
after posttraumatic interosseous contracture, 343.*e*1
control of, in burn management, 1929
"Eight-pack" tissue culture, 65, 65*t*
Elbow
anterior (transolecranon) fracture-dislocation of, 784.*e*13*b*, 784.*e*13*f*-784.*e*14*f*
arthritis of, posttraumatic, 827
arthroplasty of, total, 905-920. *see also* Arthroplasty, of elbow, total
arthroscopy of, 885-904
Elbow *(Continued)*
advanced procedures of, 903
anesthesia and positioning in, 886, 888*f*
complications of, 903
contributions to, 892*t*
for epicondylitis, 868
historical review of, 891
instrumentation in, 891, 891*f*
pertinent anatomy in, 886-891, 889*f*
portals in, 886-891, 889*f*
preoperative evaluation in, 885-886
diagnostic imaging in, 886, 887*f*-888*f*
physical examination in, 885
types of operations in, 892-903
in brachial plexus birth palsy, 1417-1419, 1418*f*
complex posterior olecranon fracture-dislocation of, 784.*e*1*b*, 784.*e*2*f*-784.*e*3*f*
contracture of. *see* Contracture(s), of elbow
disarticulation of, 1754-1756
dislocation of
complex traumatic, 813-829
classification of, 814-817
clinical assessment of, 813-814
complications of, 826-827
definition of, 813
expected outcomes after, 826
functional anatomy in, 813, 814*f*
historical review of, 817-818
imaging of, 814
olecranon fracture-dislocations in, 816-817, 816*f*
patterns of injury of, 814-817
posterolateral rotational injury in, 814-815
postoperative management after, 825-826
preoperative evaluation of, 813-814
in radial head fracture, 815, 815*f*
reconstruction for, 825, 825*f*
treatment options for, 818-825
in acute injuries, 818-824
in delayed treatment, 824-825, 826*b*
varus posteromedial rotational injury in, 817, 818*f*
posterior, with fracture of olecranon process, 784.*e*11*b*, 784.*e*11*f*-784.*e*12*f*
in radial head fractures, 737
simple, 818-819
displaced fractures with comminution and/or dislocation of, 781
epicondylitis of
lateral, 863-864. *see also* Epicondylitis, lateral
medial, 864-865. *see also* Epicondylitis, medial
Elbow *(Continued)*
extension of, in tetraplegic patient, tendon transfer for, 1127-1129
biceps to triceps, 1127-1129, 1128*f*, 1129*b*

extensor carpi ulnaris transfer to, 1099, 1099*b*, 1100*f*
flexor carpi ulnaris transfer to, 1097-1098, 1098*f*, 1099*b*
pronator teres transfer to, 1101, 1101*f*
transfer of
in restoration of thumb adduction, 1056-1057, 1057*f*, 1057*t*
in tetraplegic patient, to brachioradialis, 1131, 1131*f*, 1132*b*
Extensor carpi radialis intermedius, in wrist extension, 152
Extensor carpi radialis longus, transfer of
in median nerve palsy, 1035-1036
to index profundus, 1044, 1044*f*
operative technique for, 1863
to restore wrist balance, in rheumatoid arthritis, 1863
in tetraplegic patient, to flexor digitorum profundus, 1134
in ulnar nerve palsy
dorsal route of, 1054, 1054*f*
flexor route of, 1055, 1055*f*, 1060
Extensor carpi ulnaris, 152, 154*f*, 1863
lateral collateral ligament and, 832
stabilization of, 511-512, 512*f*
tendinitis of, 1921-1922, 1922*f*
surgical treatment, 1922, 1922*f*
tenodesis of, 1140
tenosynovitis and subluxation of, 511-512, 511*f*
operative technique for, 511-512, 512*f*
outcomes of, 512
transfer of
in median nerve palsy, 1034-1035
to restore wrist balance, in rheumatoid arthritis, 1863
wrist spasticity and, to extensor carpi radialis brevis, 1099, 1099*b*, 1100*f*
Extensor compartment artery
fifth, bone grafting using, 1630, 1630*f*
fourth, bone grafting using, 1629-1630
graft, 5 plus 4, 1632
Extensor compartment(s)
first, ganglion of, 2009, 2010*f*
fourth and fifth, stenosis of, 1921
Extensor digiti minimi (EDM), 152, 153*f*
transfer of
in median nerve palsy, 1036, 1036*f*
in ulnar nerve palsy
combined with extensor indicis proprius, 1053-1054
for little finger abduction, 1060, 1060*f*
for metacarpal arch restoration, 1059-1060
Extensor digitorum brevis manus muscle (EDBM), 152, 153*f*
Extensor digitorum communis (EDC), 153-154, 154*f*
in proximal phalanx, 154
spasticity and, flexor carpi ulnaris transfer to, 1099-1100, 1100*b*
tenodesis of, in tetraplegic patient, House two-stage reconstruction and, 1137, 1138*f*
Extensor indicis proprius (EIP), transfer of
to first dorsal interosseous, 1058-1059
in median nerve palsy, 1031-1032, 1032*f*
in restoration of thumb adduction, 1058
in ulnar nerve palsy, combined with extensor digiti minimi, 1053-1054
Extensor pollicis brevis, imbrication of, for thumb-in-palm deformity, 1112
Extensor pollicis longus
in cerebral palsy
rerouting of, for thumb-in-palm deformity, 1110, 1111*b*, 1111*f*
transfer of, for thumb-in-palm deformity, 1110
entrapment, 1921, 1921*f*
in rheumatoid arthritis, rupture of, treatment of, 1850-1851, 1850*f*
in tetraplegic patient
extensor digitorum communis transfer to, 1141
tenodesis of, House's one-stage reconstruction and, 1135, 1135*f*
transfer of, in median nerve palsy, 1037-1040, 1039*f*-1041*f*
alternative, 1040-1041
Extensor proprius tendons, for tendon graft, 206
Extensor retinaculum, pulley reconstruction using, 222
Extensor tendon(s). *see also specific tendon*
anatomy of, 152-157, 152.e1*b*
juncturae tendinum, 152-154, 153*f*
in muscles, 152
variations of, 153
at the wrist level, 152, 153*f*
centralization of, in total wrist replacement, 413-414, 414*f*

Extensor tendon(s) *(Continued)*
of finger, rupture of, 1852-1853, 1854*f*-1855*f*
diagnosis of, 1849-1850, 1849*f*
multiple-tendon, 1852
with metacarpophalangeal joint disease, 1854
reconstruction for, 1852-1857
options for reconstruction in, 1852-1857
in ring and small finger, 1852, 1853*f*
single-tendon, 1851-1852, 1852*f*
treatment of, 1850-1851, 1850*f*, 1851*t*
ganglions of, 2008, 2010*f*
injury to. *see* Extensor tendon injury
long toe, for tendon graft, 205-206
repair of, 1481
in rheumatoid arthritis, of metacarpophalangeal joint
centralization of, 1875-1876, 1875*f*
rupture of, 1850-1851
preferred method of treatment of, 1851
of wrist, tenosynovitis of, 1843-1845
preferred method of treatment of, 1843-1845, 1843*f*-1844*f*
wrist extensors, 1843-1845
complications, 1845
postoperative management, 1845, 1845*f*
Extensor tendon injury, 152-182
treatment of, 158-162, 162*b*
complications in, 161-162
outcomes in, 161, 161*t*
postoperative management in, 160-161, 161*t*
suture repair techniques in, 158-159
zone(s) of, 158, 158*f*
1, distal interphalangeal joint. *see also* Mallet finger injury; Mallet thumb injury
acute, 162-165, 166*b*, 162.*e*1*b*, 162.*e*1*f*
anatomy of, 162
classification of, 162, 163*t*
incidence of, 162
management of, 163
mechanism of, 162
preferred method of treatment of, 164-165, 165*f*
treatment for, 163-164, 164*f*
chronic, 165-166
treatment of, 166-169
postoperative management of, 160
techniques for, repair, 159
2, middle phalanx, 169
postoperative management of, 160
techniques for, repair, 159, 160*f*
3, proximal interphalangeal joint, 169*f*-170*f*, 169.*e*1*b*,
Extensor tendon injury *(Continued)*
169.*e*1*f*-169.*e*2*f*, 172.*e*1*b*, 172.*e*1*f*. *see also* Boutonnière deformity
closed, 171-172
open, 170, 171*f*
lacerations in, 171
postoperative management of, 160, 169-174
preferred method of treatment of, 170-171
techniques for, repair, 159, 160*f*
4, proximal phalanx, 174
postoperative management of, 160
preferred method of, repairs, 174
techniques for, repair, 159, 160*f*
5, carpometacarpal joint, 174-175
postoperative management of, 160
techniques for, repair, 159, 160*f*
6, metacarpal level, 175-177, 178*f*, 175.*e*1*b*, 175.*e*1*f*
chronic, 177
postoperative management of, 160
preferred method of treatment of, 177
techniques for, repair, 159
7, dorsal wrist, 178-179
injuries and rupture in, chronic, 179, 179*f*
postoperative management of, 160
preferred method of treatment of, 179
techniques for, repair, 159
8, distal forearm, 179, 179.*e*1*b*, 179.*e*1*f*
9, proximal forearm, 179-180
Extensor tendon-splitting approach, to radial head, 745-746, 748*f*
Extensors, repetitive contraction of, microtrauma due to, 863. *see also* Epicondylitis, lateral
External fixation
of distal radial fracture, 532-539, 538*f*
augmented, 535-539, 539*b*, 541*f*-542*f*, 535.*e*1*f*
hybrid, 539.*e*1*f*
technique for, 533-535, 539*f*-541*f*
for mangling injuries, 1500, 1502*f*-1503*f*
of metacarpal shaft fractures, 241, 237.*e*1*t*
of proximal and middle phalangeal fracture, 261
of radial shaft fractures, intramedullary rods and, 793, 793*f*-794*f*, 795*b*
External fixator, for segmental metacarpal loss, 244*f*
External fixator pin clusters, 539
Extraarticular intracapsular fractures, of humerus, 702-703, 702*f*. *see also* Humerus, distal
Extraarticular osteotomy. *see also* Osteotomy
for radial fracture, 577, 578*b*, 578*f*-579*f*
Extraoctave fracture, in children, 1435, 1436*f*
Extraosseous nutrient vessels, in bone grafting, 1629-1630
Extraplexal nerve transfers, for brachial plexus injury, 1177
Extrinsic extensors, anatomy of, 338.*e*4-338.*e*5, 338.*e*6*f*
Extrinsic flexor function, restoration of, 1778-1781, 1781*f*
Extrinsic ligaments, of wrist, 420-422, 421*f*

F

Factitious disorders, 1828-1831
differential diagnosis of, 1829-1830
management of, 1830

extensors, 152
rupture of, 1851-1852
fifth, amputation of, preferred method of treatment of, 1732-1733, 1733*f*-1734*f*
flexor tendons of. *see also* Flexor tendon(s)
tenosynovitis of, 1848-1849
preferred method of treatment of, 1848-1849, 1848*f*
hypoplastic, microvascular toe transfer for, in finger absence, 1263-1270, 1265*f*-1268*f*
index
amputation of, 1721-1723, 1723*f*
preferred method of treatment of, 1722-1723, 1724*f*
independent extension of, 153
mangling injuries and, 1493
resection/transplantation of, in distraction procedures, stump of, pollicization of, 1699-1703, 1702*f*-1704*f*, 1705*b*
injury
dorsal, 1737.*e*1*f*
palmar, 1737.*e*1*f*
joints of. *see* Distal interphalangeal (DIP) joint; Interphalangeal (IP) joint; Metacarpophalangeal (MCP) joint(s); Proximal interphalangeal (PIP) joint
little, abduction of, correction of, 1060
long, amputation of, 1723, 1725*f*
without transposition, 1723-1726, 1725*f*-1726*f*
mangling injuries of, treatment of, 1512-1515, 1512*f*-1517*f*
reconstruction of, microvascular toe transfer in, 1263-1270
rheumatoid arthritis of. *see* Rheumatoid arthritis, of fingers
Finger(s) *(Continued)*
ring
amputation of
preferred method of treatment of, 1731-1732, 1732*f*
with transposition of fifth metacarpal, 1732-1733, 1733*f*-1734*f*
duplication of, 1214*f*
restoration of, 1060-1061
suture to middle finger, 1060-1061, 1061*f*
without transposition, 1730-1733
small, amputation of, 1734-1735
preferred method of treatment, 1734-1735, 1735*f*-1736*f*
stiff, 338-344. *see also* Stiffness, of finger and hand
thumb and, restoration of pinch between, in ulnar nerve palsy, index abduction techniques in, 1059
transposition of, long finger, amputation with, 1726-1730, 1728*f*
trigger, 1322, 1323*f*
Finger extension test, resisted, in scapholunate dissociation, 436
Finger flexion
free functional muscle transfer for, 1782*b*
reconstruction of, 1777
tendon transfer for, 1779*b*
Fingernail(s). *see* Nail(s)
Fingertip(s), amputation of, 1709
cross-finger pedicle flap for, 1714-1716, 1715*f*
free flaps in, 1717
island flaps in, 1717
with skin or pulp loss only, 1709-1711
Smith and Albin thenar H-flap in, 1716, 1716*f*
thenar flap in, 1716

protozoal, 116-118
etiology, diagnosis, and treatment of, 63*t*
scabies and, 118-119
specimen collection and handling of, guidelines for, 64-65, 65*t*
treatment of, 67, 67*t*
viral, 119-125
etiology, diagnosis, and treatment of, 63*t*
as complication
of flexor tendon grafting, 225
of phalangeal fractures, 269
effect of, on wound healing, 1530
of free flaps, 1585
of perionychium
acute, 330-331
chronic, 331-332, 332*f*
to regional anesthesia, 1
secondary, after burns, 1935, 1936*f*
vascularized bone grafting and, 1624
Infiltrative fasciitis, 2014
Informed consent, for brachial plexus surgery, 1154
Infraclavicular block, 7-8, 7*f*
Infraclavicular brachial plexus, 1146
injury to, 1150
decisions and priorities of repair for, 1160
surgical approach to, 1157-1158, 1157*f*
Infraclavicular nerve block, for contracture release, 849
Inspection, in thoracic outlet syndrome, 964-966, 965*f*-967*f*
Instability
after ulnar fractures, 783, 783*f*
posteromedial varus rotational, 784.*e*9*b*, 784.*e*9*f*-784.*e*10*f*
Intercarpal arthrodesis
limited, for midcarpal instability, 461, 462*f*
for wrist arthritis, 690
Intercarpal fusion, for scaphoid nonunion advanced collapse, 623-624
1,2 Intercompartmental supraretinacular artery
bone grafting using, 1629
for scaphoid nonunion, 1630-1632
inlay graft, vascularized bone graft, 1637
for scaphoid nonunion, 617-618, 617*f*-618*f*
2,3 Intercompartmental supraretinacular artery, bone grafting using, 1629
Intercostal nerve
surgical anatomy of, 1169, 1170*f*
transfer of
for brachial plexus injury, 1169-1172, 1170*f*
to musculocutaneous nerve, 1171, 1171*f*, 1172*b*
complications of, 1172
contraindications to, 1171-1172
outcomes of, 1172
postoperative care after, 1171
Interdigital commissure, release of, in syndactyly, 1219-1220, 1219*f*-1222*f*
Interdigital granuloma, 118
Interdigital pilonidal sinus, barber's, 118
Interfragmentary compression screws, for metacarpal shaft fractures, 240, 240*f*, 237.*e*1*t*
Interligamentous sulcus, 420
Intermediate column
single-fragment fractures of, 571-572, 572.*e*1*b*, 572.*e*1*f*-572.*e*2*f*, 572.*e*3*b*, 572.*e*4*f*-572.*e*6*f*
three- and four-part injuries to, 572
Intermediate fibers, 134
Internal fixation
of radial head fractures, "safe zone" for, 738-739, 739*f*
role of, in vascularized bone grafting, 1637
Internal splint, for radial nerve palsy, 1065
International Association for the Study of Pain (ISAP), 1797, 1799*b*
International classification of surgery, for tetraplegia, 1123*t*, 1133*t*
Interosseous ligament, reconstruction of, in longitudinal forearm instability repair, 808-809
Interosseous membrane (IOM), 482
reconstruction of central band of, 807-808, 807*f*-808*f*
Interosseous muscle(s)
anatomy of, 338.*e*3-338.*e*4, 338.*e*4*f*-338.*e*5*f*
contracture of, posttraumatic, 343.*e*1
dorsal, 1770, 1772*f*
slide of, for intrinsic muscle spasticity, 1113-1114
Interosseous nerve
anatomy of, 936
posterior, 886-887
palsy of, 1064, 1064*f*

Interosseous nerve syndrome
anterior, 937
posterior, 949-952
release of, 953*b*
Interosseous wiring, 259, 260*f*, 259.*e*1*t*
for metacarpal shaft fractures, 239, 237.*e*1*t*
Interphalangeal (IP) joint
distal. *see* Distal interphalangeal (DIP) joint
extensor lag, proximal, as complication of phalangeal fractures, 268-269
in mangling injuries, treatment of, 1493
proximal. *see* Proximal interphalangeal (PIP) joint
in rheumatoid arthritis, boutonnière deformity and, 1898
of thumb
arthrodesis of, in ulnar nerve palsy, 1059
dislocation of, 296-297
Interposition graft, for flexor tendon, 219-220, 219*f*
Interscalene block(s), 6, 7*f*
bilateral procedures and, 2
continuous peripheral nerve catheters and, 5
Interscalene triangle, in thoracic outlet syndrome, 963, 963*f*
Interscapulothoracic amputation, 1756, 1757*f*, 1762.*e*2*f*
Intersection syndrome, 1916, 1920-1921, 1920*f*
Intraarticular anesthetic joint injection, for Dupuytren disease, 148
Intraarticular fractures
of humerus, 701-702. *see also* Humerus, distal
in mangling injuries, treatment of, 1499
Intracarpal pronosupination, 424
Intramedullary fixation
for forearm diaphyseal fracture stabilization, in children, 1465, 1467*f*
of metacarpal shaft fractures, 239-240, 239*f*, 237.*e*1*t*
of proximal and middle phalangeal fracture, 259
Intramedullary implants, 559, 561*f*-562*f*, 559.*e*1*b*, 559.*e*1*f*-559.*e*3*f*
radial, for wrist fractures, 1465, 1467*f*
Intramedullary pins
fusion of, for patients with rheumatoid arthritis, 401-404, 402*f*-403*f*
wrist arthrodesis with, critical points in, 404*b*
Intramedullary rods
of distal and midshaft ulnar fractures, 796
of radial shaft fractures, 793, 793*f*-794*f*, 795*b*
Intramuscular transposition, of ulnar nerve, for cubital tunnel syndrome, 945
Intraosseous ganglion, 2009, 2010*f*
Intraplexal nerve transfers, for brachial plexus injury, 1176-1177
Intravenous regional block, 10-11
Intrinsic lateral band release, for intrinsic muscle spasticity, 1114, 1114*f*
Intrinsic ligaments, of wrist, 421*f*-422*f*, 422-423
Intrinsic muscle, spasticity in, 1085
release or slide of origin of, for thumb-in-palm deformity, 1108-1109, 1108*f*
swan neck deformity and, 1113-1117, 1113*f*
Intrinsic tendons, of metacarpophalangeal joint, in rheumatoid arthritis
crossed transfer of, 1869-1870
release of, 1869, 1869*f*
Intrinsic-minus deformities, 1117-1118
Ion channels, voltage-gated, 980-981
Irrigation, closed tendon sheath, for pyogenic flexor tenosynovitis, 30-31, 30*f*
Ischemia
etiology of, 2036-2038, 2037*f*-2038*f*
metabolic changes after, 1488
Island flap(s)
neurovascular, for soft tissue defects of thumb, 1684-1686, 1686*f*
pedicle, 1540
in reconstruction of amputated fingertip, 1717
Isolated displaced fractures, of radial head fractures, management of, 741-742, 742*f*
Isoniazid
dosage of, 101*t*
for tuberculosis, 100
cutaneous, 92
Itraconazole
for aspergillosis, 84-85
for blastomycosis, 85
for coccidioidomycosis, 86
for cryptococcosis, 86
for deep sporotrichosis, 88
for eumycetoma, 73
for fungal infections, 79, 90

for shoulder reconstruction, in brachial plexus injury, 1188
Latissimus dorsi muscle flap, 1561-1562, 1562*f*, 1563*b*
free, 1597-1602, 1598*f*-1601*f*, 1602*b*
tailored, 1599*f*, 1602-1603
for mangling injuries, 1515, 1520*f*
operative technique, 1601-1602
"Law of diminishing returns," in metacarpophalangeal joint extension contracture, 340
Leather-Mills valvulotome, for vascular disorders, 2050, 2050*f*
Leeches
animal bite and, 48
for free flap failure, 1582*f*, 1583-1584
Leiomyosarcoma, 2020
Leishmaniasis infection, 116-117
Lentigo maligna, 1978, 1980*f*
Lentigo simplex, 1965
Lepra reaction, in Hansen disease, 110
classification of, 111*t*
treatment of, 111*t*
Lepromin skin test, for Hansen disease, 107-108
Leprosy. *see* Hansen disease (HD)
Leri-Weill dyschondrosteosis, 1213-1214, 1214*f*
Lesser-arc injuries, in dorsal perilunate dislocations, 465-470, 465*f*-466*f*
Levofloxacin, dosage of, 101*t*
Lichtman classification, of Kienbock disease, 641*t*
Lidocaine
in Bier block, 10-11
characteristics of, 4*t*
for complex regional pain syndrome, 1814*t*
Ligament(s)
definition of, 838
of elbow, 739, 740*f*
reconstruction, for carpometacarpal joint osteoarthritis
operative techniques, 362-363
treatment, 361
of scaphoid, 589-590, 589*f*
Ligamentoplasty, using tendon graft, in scapholunate dissociation, 443-446
Ligamentotaxis, 516.*e*1
Ligamentum subcruetum, 481, 481*f*
Light moving touch, in compression neuropathy evaluation, 928
Limb, threatened at birth, treatment of, 1255-1256

Limb amputation, major, 1753-1756
case study of, 1762.e1b, 1762.e1f-1762.e3f, 1762.e3b
indications for, 1753, 1754f
Limb bud, 1208, 1209f
formation of, 1212b
Limb development
anteroposterior, 1210-1211, 1212f, 1213t
dorsoventral, 1211
during embryogenesis, 1208
key milestones in, 1209t
proximodistal, 1209-1210, 1210f-1211f
spatial axes of, 1209-1211
Limb function, poor, free flap contraindicated in, 1575
Limited open reduction, of distal radial fractures, 536
Lipofibromatosis, macrodactyly associated with, 1276-1277
Lipofibromatous hamartomas, 2011-2012
Lipomas, 2011
Liposarcoma, 2017-2018, 2018f
Liquefaction necrosis, 1948-1949
Little finger
restoration of, 1060-1061
suture to middle finger, 1060-1061, 1061f
Littler flap. *see* Neurovascular island flap
LMB spring finger extension splint, 340.e1f
Local fasciectomy, for Dupuytren disease, 139t
Local flaps, 1540-1542
transposition flaps, 1542
axial-pattern, 1543-1545
flag, 1545, 1545f
random-pattern, 1542
rhomboid, 1543, 1544f
"Z"-plasty, 1542, 1542f, 1543b
four-flap, 1543, 1543f
Localized compartment syndrome, 1767f
Long bone reconstruction, vascularized bone grafting for, 1617-1624
Long toe extensor tendon, for tendon graft, 205-206
Loose body, arthroscopic removal of, 892-893
indications and contraindications of, 892
outcomes of, 893
postoperative management of, 893
preoperative planning of, 892
technique of, 892-893
Lucio reaction, in Hansen disease, 110-111, 111t
Luck classification, of staging, in Dupuytren disease, 131
Lumbrical canal, palmar space infection through, 36
Lumbrical muscles, anatomy of, 338.e4, 338.e6f
Lumbrical-plus finger deformity
after amputation, 1718
as complication of flexor tendon grafting, 225
Lunate, 660f
blood supply to, 638, 640f
bone grafting to, 1632
deformity of, carpal misalignment secondary to, 464
dislocation of, 427-428
fractures of, 636-637, 637b
incidence of, 625t
in Kienbock disease, 639
mechanism of injury in, 637-638, 638f
radiographic presentation of, 637-638
treatment of, 638, 639f
Lunate triquetrum arthrodesis, 457b
Lunate triquetrum dissociation, pathomechanics of, 427
Lunocapitate angle, measurement of, in wrist instability, 430
Lunocapitate dislocation, pathomechanics of, 427-428
Lunotriquetral arthrodesis, 387-389
author's preferred method of treatment for, 388
indications and contraindications for, 387-388
patients and, 389
pearls on, 389f
pitfalls of, 389
postoperative management for, 388
Lunotriquetral dissociation, 450-457
diagnosis of, 451-454
arthrography in, 454
arthroscopy in, 454
cineradiography in, 454
physical examination in, 451-452, 452f
radiographic examination in, 452-454, 452f-453f
pathomechanics of, 450-451, 451f
treatment of, 454-457, 455f-456f
preferred method of, 457
Lunotriquetral ligament, 422, 422f
interosseous, 660f
carpal instability and, 661
tears of, associated with distal radial fracture, 542
Lunotriquetral synchondrosis, 451-452
Lymphangiosarcoma, 1981-1983
Lymphangitis, nodular, differential diagnosis and treatment for, 83, 84t
Lymphatic basins, evaluation of, 1981, 1982f-1983f
Lymphatics, of nail bed, 318
Lymphedema, factitious, 1828, 1829f

postoperative management and expectations in, 306
treatment of, 303, 304*f*-305*f*, 306*b*
ulnar collateral ligament injuries in
acute, 302-306
chronic, 306-308
volar instability of, chronic, 311-312
Metallic arthroplasty, of radial head, 764
Metaphyseal fracture, bicortical, of distal radius, in children, 1448-1453, 1450*f*-1452*f*, 1454*f*
preferred method of treatment for, 1453-1454
Metaphyseal posterior Monteggia fracture, 784.*e*23*b*, 784.*e*23*f*-784.*e*24*f*
Metaphysis, bending fractures of, 524-527
Metastases, of musculoskeletal tumors, 1989
Metastatic tumors, 1983, 1985*f*
of bone, 2031-2032, 2031*f*
Metatarsal artery, first dorsal
anatomy of, 1606, 1606*f*
in sensory flap from first web space of foot, 1606-1608, 1607*f*
Methicillin-resistant *Staphylococcus aureus* (MRSA), 18, 18*f*
antibiotic recommendations for, 21*t*
Methylprednisolone, for stiff finger, postoperative management of, 341
Mexiletine, for complex regional pain syndrome, 1814*t*
Michigan Hand Outcomes Questionnaire (MHQ), 924
Microbial nucleotide sequences, detection of, 66
Microvascular flow, regulation of, in complex regional pain syndrome, 1807-1808, 1807*f*-1810*f*
Microvascular surgery, regional anesthesia for, 2
Midanterolateral portal, in elbow arthroscopy, 889-890
Midcarpal fusion, scaphoidectomy and, 449-450
Midcarpal joint
instability of, nondissociative, 459
diagnosis of, 459-461
differential diagnosis of, 460-461
pathomechanics of, 459, 459*f*
physical examination in, 460
proximal row, volar, 459-461
radiographic examination in, 460
treatment of, 460-461, 461*f*-462*f*
preferred, 462-463
osseous anatomy of, 420
portals of
for arthroscopic arthrolysis, 691
for arthroscopy of wrist, 656-657, 653.*e*1*t*
Midcarpal ligaments, 422
Midpalmar space
infections of, 34*f*
characteristics of, 35*t*
clinical presentation and preoperative evaluation of, 34-35
treatment for, 36, 37*f*
preferred method of, 39
pertinent anatomy of, 35
Midposterolateral portal, in elbow arthroscopy, 890-891
Milker's interdigital granuloma, 118
Milker's nodule, 123-124, 124*f*
Miller criteria, for extensor tendon function, 161, 161*t*
Mirror hand(s), 1237-1238, 1237*f*, 1238*b*
classification of, 1212*f*, 1213*t*, 1238*t*
etiologic findings, 1237-1238
treatment of, 1238, 1238*f*-1239*f*
Mitsuda reaction, in Hansen disease, 107-108
Miura and Komada technique, in cleft hand surgery, 1251, 1252*f*
Moberg's techniques, in tetraplegia, of passive key pinch reconstruction, 1132, 1132*f*
Mohs micrographic surgery, 1962, 1965*f*
Moles, 1966
Monteggia fracture-dislocation, in children, 1468-1470, 1469*f*-1470*f*, 1469*t*
Monteggia fractures
classification of, 773, 773*f*
metaphyseal posterior, 784.*e*23*b*, 784.*e*23*f*-784.*e*24*f*
posterior (Bado type 2), 773, 773*f*
plate loosening after operative treatment of, 784.*e*28*b*, 784.*e*28*f*-784.*e*29*f*
ulnohumeral instability after, 784.*e*30*b*, 784.*e*30*f*
preoperative evaluation of, 770
treatment of, 780, 780*f*, 781*b*
plate fixation in, 778, 779*f*
Monteggia fractures *(Continued)*
type A posterior, 784.*e*1*b*, 784.*e*2*f*-784.*e*3*f*, 784.*e*15*b*, 784.*e*15*f*-784.*e*17*f*
Monteggia lesion, posterior, 817, 817*f*
classification of, 817
Moray eel, nonvenomous, injury caused by, 1795*f*
Morbidity, donor site, in toe transfer, 1670
Morpheaform (sclerosing) BCC, 1974
Motion
amplitude of, in tendon transfers, 1023-1025
improved, after elbow contracture release, 860
loss of
assessment of, in stiff elbow, 845-847
as complication of phalangeal fractures, 268
Motion protocol, after biceps rupture repair, 878
Motor conduction velocity, for cubital tunnel syndrome, 942
Motor evoked potentials (MEPs), in brachial plexus surgery, 1158
Motor rehabilitation, after toe transfer, 1670-1671
Motor-sensory neuropathy, hereditary, 923
Moxifloxacin, dosage of, 101*t*
Mucormycosis, 87-88, 89*b*
Mucous cyst, 2005-2006
clinical characteristics of, 2005-2006, 2005*f*
complications in, 2006
operative technique for, 2006, 2006*f*
preferred method of treatment for, 2006
Multidisciplinary approach, to complex regional pain syndrome, 1811
Multidisciplinary team approach, for complex regional pain syndrome, 1818
Multidrug therapy (MDT)
for Hansen disease, 109
for mycobacterial tenosynovitis, 95-96
for tuberculosis, 100-103, 101*t*
Multiple enchondromatosis, 2021, 2022*f*
Multiple joints, involvement in rheumatoid arthritis, 905
Multiple warts, 121
Muscle(s). *see also named muscle*
fibula with, in vascularized grafting, 1620
free transfer of
for brachial plexus injury, 1152-1153, 1178-1185
donor muscle selection in, 1179
grasp reconstruction with, 1180-1184
complications of, 1184
donor muscle selection in, 1181-1182

Muscle(s) *(Continued)*
operative technique of, 1181-1183, 1181*f*-1182*f*, 1184*b*
outcome of, 1184, 1184*f*
postoperative protocol for, 1183
prerequisites for, 1181
subsequent surgery for, 1183-1184
operative procedures for, 1179-1185, 1180*f*
for elbow flexion, in delayed cases, 1202, 1202*f*, 1203*b*
prerequisites for, 1178-1179
single-stage, for prehension, 1185, 1185*f*
work capacity of, 1023, 1024*t*
Muscle flaps. *see also specific muscle flap e.g.*, Latissimus dorsi muscle flap
free, 1576
Muscle grading system, Medical Research Council, in tetraplegia, 1122, 1123*t*
Muscle strengthening, for thoracic outlet syndrome, 969-970
Muscle tightness
excessive, elbow contracture with, 856
in spasticity, 1085
Muscle transfer, flexor and extensor, in ulnar nerve palsy, 1054-1056
Muscular neurotization, direct, for nerve injury, 1001, 1001*f*
Muscular release, in spasticity, evaluation of, 1085
Musculocutaneous flap(s), 1561-1562, 1576. *see also* Skin flap(s); *specific muscle flap*
free, 1576, 1597-1602. *see also* Free flap(s)
Musculocutaneous nerve transfer, for brachial plexus injury, 1165-1166, 1165*f*
intercostal nerve to, 1171, 1171*f*, 1172*b*
complications of, 1172
contraindications to, 1171-1172
outcomes of, 1172
postoperative care after, 1171
median nerve transfer to brachialis motor branch in, 1167-1169, 1168*f*, 1169*b*
operative procedure for, 1165
outcomes of, 1166
triceps transfer to axillary nerve in, 1172-1173, 1173*f*-1174*f*
outcomes of, 1174*b*, 1174*f*
ulnar nerve transfer to biceps in, 1166-1167, 1166*f*-1167*f*
outcomes of, 1167, 1167*f*
Musculocutaneous neurectomy, for spasticity, 1090-1091
Musculoskeletal tumors
benign, excision for, 1992
biopsy for, 1990-1992
excisional, 1991-1992
incisional, 1991
needle, 1990-1991
open, 1991, 1991*f*, 1992*b*
definitive treatment for, 1992-1996
diagnosis and management of, 1987-1988
evaluation protocol for, 1989-1992, 1989*f*
excision of, 1993-1996
from finger metacarpals, 1994-1996, 1995*f*
from first metacarpal, 1994, 1995*f*
from phalanx
distal, 1993, 1993*f*
middle, 1993-1994, 1993*f*-1994*f*
from wrist and distal forearm, 1996, 1996*f*-2000*f*
histologic grade and surgical staging of, 1988-1989, 1988*t*-1989*t*
laboratory studies for, 1990
location (site) of, 1989
malignant, excision for, 1992-1993
metastases of, 1989
Musculotendinous components, of radiocapitellar joint, 813
Mycetoma, 70-73
clinical findings on, 71
diagnosis of, 72, 72*b*
differential diagnosis of, 72
etiology and epidemiology of, 70
microbiology of, 70-71
staging of, 71-72, 71*f*
treatment of, 72-73
Mycobacterial infections, 90-103
antituberculous drugs for, multidrug therapy regimens and, 100-103, 101*t*
cutaneous tuberculosis and, 91-92
deep infections and, 93-100, 94*f*-95*f*
eight-pack tissue culture for, 65*t*
etiology, diagnosis, and treatment of, 63*t*
growth rates of, 91*t*
nontuberculous, 90-103
diagnosis and treatment of, 102*t*
subcutaneous tuberculosis and, 92-93, 93*f*
tuberculous, 90-103
Mycobacterial tenosynovitis, 93-96, 94*f*-95*f*
Mycobacterium avium, 91, 93
Mycobacterium haemophilum, 91
Mycobacterium leprae, 92, 103
Mycobacterium marinum, 93, 94*f*
Mycobacterium scrofulaceum, 93, 95*f*
Mycobacterium tuberculosis, 91-93
Mycobacterium ulcerans, 65, 92-93, 93*f*
Myelography
in brachial plexus birth palsy, 1395-1396
of brachial plexus injury, 1152, 1152*f*
Myoblastomas, granular cell, 2013-2014, 2013*f*
Myocutaneous flaps, 1576
Myoelectric devices, in prosthetics, 1759
Myoelectric hands, types of, 1742*f*
Myofascial manipulation, for thoracic outlet syndrome, 969
Myofibroblast, Dupuytren disease and, 131
extracellular matrix, cycle of, remodeling, 136*f*
gene expression of, 136
Myonecrosis, 56, 56*f*

N

Nager syndrome, radial longitudinal deficiency associated with, 1329*t*
Nail(s)
absence of, 326-328, 328*f*
anatomy of, 20-21
dull, 330
germinal matrix of, 318
hooking of, 329, 329*f*
infections of
bacterial, 331, 331*f*
fungal, 330-331
nonadherence of, 326, 327*f*
pincer, 330, 330*f*, 331*b*
split, 326, 326*f*-327*f*
Nail bed
acute injuries of, delayed treatment in, 324
amputation in, 323-324, 324*f*-325*f*
anatomy of, 319*f*
avulsion of, 321, 321*f*
cornified, 328, 328*f*
defect of, 321-322, 322*f*
graft for, harvest of, 322, 322*f*
postburn deformities of, 1937, 1939*f*
repair of, 319-321, 320*f*
scarring of, 325
stellate lacerations of, 320, 320*f*
Nail cysts, 328, 328*f*
Nail fold
infection of
acute, 20-22, 22*b*, 22*f*-23*f*
chronic, 23-25, 24*f*-25*f*, 25*b*
Keyser-Eaton marsupialization of, 331-332
paronychia and, 81
syphilis and, 73-74
treatment of, 81.*e*1
Nail graft, vascularized, in toe transfer flap design and elevation in, 1661-1663
flap designs and elevation, 1661-1663, 1663*f*
indications, 1661, 1662*f*
Nail horns, 1711
Nail ridges, 325-326
Nail spikes, 328, 328*f*
Necrosis
avascular
after radial head fractures, 761, 761*f*
of capitate, 649
vascularized bone grafting for, 1613

Necrosis *(Continued)*
wound, after elbow contracture release, 859, 860*f*
Necrotizing fasciitis, 17, 54-55, 54*f*
animal bites and, 48
antibiotic recommendations for, 21*t*
case study, 55.*e*1*b*, 55.*e*1*f*
diabetic hand infections and, 54
fungal, 55, 55*f*
shooter's abscesses and, 51
Needle biopsy, for musculoskeletal tumors, 1990-1991
Needle depth penetration, 146*f*
Needle fasciotomy, for Dupuytren disease, 139*t*
percutaneous, 140
Needle maneuvers, in procedure, for Dupuytren disease, 146, 146*f*
Needle problems, in procedure, for Dupuytren disease, 147
Needle size, in procedure, for Dupuytren disease, 146
Negative pressure wound therapy
for mangling injuries, 1509, 1510*f*
for skin grafting, 1536
Nerve(s)
anatomy of, 980, 980*f*
conduction studies of, in compression neuropathies, 929
exploration of, in radial nerve palsy with humeral fractures
at 6 to 8 weeks, 1074-1075, 1075*f*
early, 1074
if no return at longer waiting period, 1075, 1075*f*
preferred method of, 1075
gap of, 1007-1008
iatrogenic injuries to, operations for, 1013*t*
issues, in procedure, for Dupuytren disease, 147
longitudinal mobility of, in compression neuropathies, 923
into muscle
implantation of, 1018*f*
translocation of, 1017-1019
preparation of, in toe transfer, 1645, 1666
reconstruction of, in brachial plexus injury
primary, 1154, 1160-1177
secondary, 1154, 1186-1202
reimplantation of, 1185
repair of
in mangling injuries, 1508, 1508*b*
in microvascular toe transfer, for hypoplastic digits, 1269
in radial nerve palsy, 1065
in toe transfer, 1668
Nerve abscess, in Hansen disease, 112-113, 113*f*-114*f*
drainage technique for, 113
treatment of, 112-113
Nerve action potentials (NAPs), in brachial plexus surgery, 1158, 1158*f*
Nerve bed, preparation of, 993
Nerve biopsy, for Hansen disease, 108-109
fine-needle nerve aspiration technique and, 108-109
open, 109
Nerve block(s)
axillary, 8, 8*f*
for complex regional pain syndrome, continuous autonomic, 1817
infraclavicular, 7-8, 7*f*
interscalene, 6, 7*f*
supplementary, 8-11
at digit, 9-10, 10*f*-11*f*
at elbow, 8
at wrist, 8-9, 9*f*
supraclavicular, 6-7, 7*f*
Nerve compression
chronic, pathophysiology of, 921-924, 922*f*
electrodiagnostic studies and, 929-930
Nerve conduction studies, 12
in brachial plexus injury, 1153
Nerve conduction velocity (NCV), 1396
Nerve gliding exercises, for carpal tunnel syndrome, 933
Nerve graft/grafting, 996-999, 999*b*
in brachial plexus birth palsy, 1397, 1398*f*-1399*f*, 1400-1404, 1401*f*-1404*f*
in brachial plexus reconstruction, 1160-1163
allografts in, 1163
coaptation and, 1162-1163, 1162*f*
conduits in, 1163
conventional, 1161-1162, 1161*f*
donor nerve for, 1161-1162
indications for, 1160
operative procedure for, 1160-1161, 1161*f*
other options for, 1162
postoperative care for, 1177
choice of, 996-999, 997*f*-998*f*
for mangling injuries, 1522, 1523*f*
other methods of, 999-1000
postoperative care after, 999
suturing of, 998*f*
tendon transfer *versus*, nerve repair and, for radial nerve palsy, 1065
vascularized, 999
Nerve injury
after radial head fractures, 761
aggravating, 1-2
cause of, 1003
classification of, 982, 982*t*, 984*b*
clinical diagnosis of, 985-991, 986*f*, 990*b*
depth of, 986*t*
digital, repair of, 1008-1009, 1009*t*
preferred method of treatment of, 1009
electrodiagnosis of, 988-989, 988*t*
Nerve injury *(Continued)*
imaging of, 989, 990*f*
lesions in
continuity in, 989-990
distribution and diagnosis of, 1010.*e*1
level of the lesion in, 1002-1003
mangling
evaluation of, 1492
repair/reconstruction of, 1508*b*
restoration of sensation in, 1495
nature of, 1003
level and, 1007
neurologic examination of, 987-988
physical examination of, 986-988, 987*f*
repair of, 979-1022
alternative methods of, 999-1000
closure in, 996
delay in, 1003
effects of, 1005*t*
denervation and reinnervation of, electromyographic findings in, 989*t*
epineurial, 994
exposure in, 991
grafting in, 996-999, 997*f*-998*f*, 999*b*
indications for, 979-982, 980*f*
neurolysis in, 992-993
outcomes of, 1010.*e*2*t*
postoperative care after, 996
recovery after, 1001-1009
factors in prognosis of, 1002-1003, 1003*b*
measurement of, grading and, 1001-1003, 1002*t*
results of, 1003-1009, 1003*t*-1004*t*
grading, 1002*t*
rehabilitation after, 1009-1010, 1010*b*
resection of a damaged nerve of, 991-992
surgical interventions for
considerations before, 990-991
consultation and operative record in, 991
outcomes of, 1010.*e*3-1010.*e*5
techniques of, 991-1001
suturing in, methods of, 993-996
delayed, 994-996, 995*f*-996*f*
direct, 993-994, 994*f*
end-to-end, 993
fibrin clot glue in, 996
responses to, 982-985, 983*f*
conduction block in, 983-984
stretch injury as, 985
Wallerian degeneration in, 984-985
severity of, in war wounds, 1010.*e*1, 1010.*e*1*t*
Tinel sign in, 986, 987*b*
war wounds and, 1010.*e*1-1010.*e*5
Nerve palsy
after elbow contracture release, 859
peripheral, constriction ring associated with, treatment of, 1256

Nerve percussion test, 924
Nerve reconstruction, 1777, 1777*f*
  in brachial plexus birth palsy, 1397-1398
Nerve status
  postoperative, assessment of, 1
  in rheumatoid arthritis, 905
Nerve surgery, for brachial plexus birth palsy, 1397-1407, 1401*b*
  postoperative management for, 1407, 1408*t*
  preferred treatment, 1406-1407
  results of, 1399
  technique of, 1400-1404
    nerve grafting in, 1397, 1398*f*, 1400-1404, 1401*f*-1404*f*

Nonadherence
hyponychial, 329-330
of nails, 326, 327*f*
Nonarticular bone loss, associated with humeral fractures, 726
Nonarticular fractures, of phalanges, 255-256
at neck, 255-256, 256*f*-257*f*
at shaft, 256
expected outcomes of, 264-265
preferred method of treatment of, 261
Nondisplaced fractures, of distal radius, treatment of, 567
Nonmetacarpal hand, multiple-digit amputation, 1648
Nonmicrosurgical coverage, of upper extremity, 1528-1573
flap coverage, local and regional, 1539-1571
skin grafting. *see* Skin graft/grafting
Nonoperative management, of radial head fractures, 741-742, 742*f*
outcome of, 756-758
Nonsteroidal antiinflammatory drugs (NSAIDs), infections and, 19
Nontuberculous mycobacterial infections, 90-103
diagnosis and treatment of, 101, 102*t*
special features of, 101-103
Nonunion
of distal humeral fracture, 728
associated with elbow contracture, 854
of distal radial fracture, 576
of forearm fractures, 799-803
postoperative management and expectations after, 803
preferred method of treatment of, 800-801
preoperative evaluation of, 799-800, 799*f*-801*f*
of metacarpal fractures, 247-248
of olecranon osteotomy, 728-729, 729*f*
of phalangeal fractures, 267-268, 268*f*-269*f*
of radial head fractures, 762
of scaphoid fractures, 588-624
biologic stimulation of, 607
bone graft for, nonvascularized, 610, 610*f*
in children, 1445, 1446*f*
case study for, 1445.*e*1*b*, 1445.*e*1*f*-1445.*e*3*f*
of distal pole, 622
dysvascular, 616-619, 616*f*
evaluation of, 608-609
activity level in, 609
age in, 609
amount of deformity and malalignment in, 608
arthritis in, presence and location of, 609
bone loss in, 608
Nonunion *(Continued)*
comorbidities in, 609
fracture site in, 608
length of time in, 609
pain or dysfunction in, 609
previous treatment in, 608
salvageability of fragment in, 609
vascularity of fragments in, 608
implications of, 590-591, 591*f*
management of, 608-624
preferred method for, 621
open dorsal technique for, 614-615
operative treatment for, 609-619, 609*t*
prognosis for healing in, 620-621
proximal pole, 614-616
treatment for, preferred, 621*t*
unsalvageable proximal pole, 621
vascularized bone grafting for, results of, 1637-1638
without arthritis, 609-611
without substantial bone loss, 609
of ulnar fractures, 783, 784*f*, 784.*e*31*b*, 784.*e*31*f*
No-reflow phenomenon, in mangling injuries, 1488
Nortriptyline, for complex regional pain syndrome, 1812*t*
Nosocomial infections, 18
Notta nodule, in trigger thumb, 1321, 1321*f*, 1915*f*
Nubbin, residual, after suture ligation of ulnar polydactyly, 1233, 1233*f*
Nucleic acid amplification, for infections, 66

decisions and priorities of repair for, 1159-1160
Panton-Valentine leukocidin (PVL), methicillin-resistant *S. aureus* (MRSA) and, 18
Pantrapezial degenerative disease, as contraindication for thumb arthroscopy, 693
Paprika sign, 1578
Para-aminosalicylic acid, dosage of, 101*t*
Parasitic infections, chronic, 116-118
etiology, diagnosis, and treatment of, 63*t*
worm, 117-118
Paratricipital approach, to distal humeral fractures, 711, 712*f*, 711.*e*1*b*, 711.*e*1*f*-711.*e*2*f*
Paratricipital exposure, for total elbow arthroplasty, 711.*e*1*b*, 711.*e*1*f*-711.*e*2*f*
Parenteral medications, for complex regional pain syndrome, 1815*t*, 1816
authors' preferred method of, 1819
Paresthesia
definition of, 1799*t*
with needle movement, for Dupuytren disease, 147-148, 147*f*
Parkes static tenodesis, in ulnar nerve palsy, 1050-1051, 1050*f*
Parona space infections, 32-34
clinical presentation and preoperative evaluation of, 33
pertinent anatomy in, 33
postoperative management of, 34
treatment of, 33-34
open, 33-34
preferred method of, 34
Paronychia
acute, 20-22, 22*b*, 22*f*-23*f*
antibiotic recommendations for, 21*t*
chronic, 23-25, 24*f*-25*f*, 25*b*, 81, 81*f*, 81.*e*1*f*
Paronychial fold, formation of, in management of syndactyly, 1221-1222

Parosteal osteochondromatous proliferation, bizarre, 2022
Paroxetine, for complex regional pain syndrome, 1813*t*
Parsonage-Turner neuritis, 936
Partial articular loss, 726.*e*1*b*, 726.*e*1*f*-726.*e*3*f*
Partial hand silicone prosthesis, 1737.*e*3*f*
Partial wrist fusion, for arthritic wrist, 690
Passive key pinch reconstruction, in tetraplegia, 1131-1133, 1132*f*
Passive motion rehabilitation, postoperative, of zone 2 tendon lacerations, 189
Passive stability, of proximal interphalangeal joint, 279
Patient refusal, to regional anesthesia, 1
Patient surveillance, 1960
Patient-Specific Functional Scale (PSFS), 924
Peau d'orange skin, 54
Pectoral nerve transfer, for brachial plexus injury, 1176-1177
Pectoralis minor space, in thoracic outlet syndrome, 964
Pectoralis muscle, transfer of
  for elbow reconstruction, in brachial plexus injury, 1198-1202, 1200*f*-1201*f*, 1201*b*
  for shoulder reconstruction, in brachial plexus injury, 1188
Pediatric Outcomes Data Collection Instrument (PODCI), 1394-1395
Penetrating trauma, to brachial plexus, 1149
Penicillin, for actinomycosis, 68
Penicillin G, for syphilis, 74
Percutaneous needle fasciotomy (PNF), for Dupuytren disease, 140, 143-144
Percutaneous pin fixation, of distal radial fracture, 531-532, 535*f*-537*f*
Percutaneous trigger digit release, 1913-1914, 1913*b*-1914*b*, 1913*t*, 1914*f*
Perforator flaps, 1576-1577
Periarterial sympathectomy, of vasospastic disease, 2053*f*-2054*f*, 2054
Perilunate fracture-dislocations, 427
  dorsal, 470-472
    in complex carpal instability
      greater-arc injuries and, 470
      lesser-arc injuries and, 465-470, 465*f*-466*f*
    transscaphoid, 470-471
    transscaphoid-transcapitate, 471-472, 472*f*
    transtriquetrum, 472, 473*f*
    treatment of, 465-470, 472, 473*f*
      preferred method of, 470
  palmar, 472, 474*f*
  transscaphoid, arthroscopic treatment of, 604-605, 606*f*-607*f*
Perilunate instability
  acute, treatment of, 456
  chronic, treatment of, 456-457, 457*f*
Perionychium, 318-337. *see also* Nail bed
  anatomy of, 318, 319*f*
  complications to, postoperative, 325-330
    absence as, of nails, 326-328, 328*f*
    dull nail as, 330
    eponychial deformities as, 329
    hyponychial deformities as, 329-330, 329*f*
    nail ridges as, 325-326
    nail spikes, cysts, and cornified nail bed as, 328, 328*f*
    nonadherence as, 326, 327*f*
    split nail as, 326, 326*f*-327*f*
  infections of
    acute, 330-331
    chronic, 331-332, 332*f*
  postoperative management of, 324-325
  preoperative evaluation for, 318, 319*f*
  tumors of, 332-336
    benign, 332-334
    malignant, 334-336, 335*f*
  types of operation for, 318-324
    in amputation, 323-324, 324*f*-325*f*
    in avulsion, 321, 321*f*
    in delayed treatment of acute injuries, 324
    in fracture, 322-323, 322*f*-323*f*
    in nail bed defect, 321-322, 322*f*
    in nail bed graft, harvest of, 322, 322*f*
    in nail bed repair, 319-321, 320*f*
    in subungual hematoma, 318-319, 320*f*
Periosteal chondroma, 2021-2022, 2022*f*
Periosteal graft, vascularized, 1624-1634
Peripheral nerve implant, for complex regional pain syndrome, 1817
Peripheral neuroma, 1010-1019
Peripheral ulnar-sided tears
  knotless technique for, 680, 680*f*-683*f*
  Tuohy needle technique for, 678-679
Perivascular blocks, regional anesthesia and, 12
Phaeomycotic cysts, 84
Phalangeal line test, 1427, 1427*f*
Phalanx (phalanges)
  amputation through
    middle, 1718-1719, 1719*f*-1720*f*
    proximal, 1719, 1721*f*-1722*f*
  delta, 1271
  distal
    fracture of, 248-249, 322-323
      in children, 1428-1431, 1431*b*
      classification of, 248.*e*1*t*
      complications of, 249
      epiphyseal, 248-249, 248*f*
      preferred method of treatment for, 1429
      shaft, 248
        in children, 1428-1429
Phalanx (phalanges) *(Continued)*
    tuft, 248
      in children, 1428-1429
  musculoskeletal tumors of, excision of, 1993, 1993*f*
  fracture of, 248-270
    antibiotics in the management of, 270
    articular, 249-251
      at base, 249-251, 251*f*-253*f*
        in children, 1436-1437
        preferred method of treatment for, 1437
      at condyle, 249, 250*f*-251*f*
      at head, 249
        in children, 1431
        preferred method of treatment for, 1431, 1432*f*
      preferred method of treatment of, 251-255, 254*f*-256*f*
      at shaft, 251
    biomechanical testing in, 261.*e*1
    closed reduction and percutaneous pinning in, 257, 258*f*-259*f*
    closed reduction with a cast or splint in, 256-257, 257*f*
    complications of, 266-269
      apex volar angulation as, 266, 266*f*
      entrapment as, 269
      flexor tendon rupture as, 269
      infection as, 269
      lateral angulation as, 266-267, 266*f*
      loss of motion as, 268
      malrotation as, 266
      malunion as, 266, 266.*e*1*b*
        articular, 267
        osteotomy for, 267*b*
      nonunion as, 267-268, 268*f*-269*f*
      proximal interphalangeal joint extensor lag as, 268-269
      shortening as, 267
    displaced
      stable after closed reduction, 261
      unstable after closed reduction, 261-263
        spiral and oblique, 261-262
        transverse, 262-263, 263*f*-265*f*
      unstable and comminuted, 263-264
    external fixation in, 261
    healing time for, 256
    indications for fixation of, 232*b*
    infected, treatment of, 270
    intramedullary fixation in, 259
    at neck, in children, 1431-1434, 1433*f*
      preferred method of treatment for, 1434, 1435*f*
    nonarticular, 255-256
      at neck, 255-256, 256*f*-257*f*
      at shaft, 256
        expected outcomes of, 264-265
        preferred method of treatment of, 261

Phalanx (phalanges) *(Continued)*
nondisplaced and stable, 261
open reduction and internal fixation in, 257
open reduction with pin fixation in, 258-259, 260*f*
plate fixation in, 260-261
screw fixation in, 259-260
at shaft, in children, 1434-1435
preferred method of treatment for, 1435, 1436*f*
surgical approaches in, 257-258, 259*f*-260*f*
of thumb, 270
extraarticular thumb fractures, 270, 270*f*
free transfer of, in absent finger, 1261-1262, 1262*f*
complications of, 1262
in mangling injuries, treatment of, 1499
middle
anatomy of, 154, 156*f*
angulation of, after proximal interphalangeal joint arthroplasty, for fracture-dislocation, 290
fracture of, 249-265
in children, 1431-1437, 1437*b*
musculoskeletal tumors of, excision of, 1993-1994, 1993*f*-1994*f*
proximal
anatomy of, 154, 155*f*
fracture of, 249-265
at base, 265-266
in children, 1431-1437, 1437*b*
unicondylar, operative management of, 250*b*
injuries of, 174
preferred method of, repairs, 174
Phalen test, for nerve compression, 924-927
Phenol burns, treatment of, 1951, 1952*t*
Phenoxybenzamine, for complex regional pain syndrome, 1814, 1814*t*
Phentolamine, for complex regional pain syndrome, 1814
Phenytoin, for complex regional pain syndrome, 1813*t*
Phosphorus burns, white, treatment of, 1951, 1952*t*
Phrenic nerve transfer, for brachial plexus injury, 1177
Physical examination, in rheumatoid arthritis, 905
Physical therapy, after elbow contracture release, 857-858
Physiolysis, for Madelung deformity, 1339-1342
dome osteotomy and, 1342-1344, 1342*f*-1343*f*
fat grafting and, 1339-1342, 1341*f*
Physis(es)
arrest of, 1457
case study for, 1457.*e*1*b*, 1457.*e*1*f*-1457.*e*5*f*
surgical intervention for, 1455, 1457*f*
vascularized bone grafting for, 1613
fibula with, vascularized bone grafting for, 1619-1620
fracture of
in distal phalanges, of children, 1429, 1429*f*-1430*f*
preferred method of treatment for, 1430-1431
in distal radius, of children, 1454, 1455*b*
postoperative expectations and management of, 1455-1457
preferred method of treatment for, 1454-1455, 1456*f*-1460*f*
in middle and proximal phalanges, of children, 1435-1436, 1436*f*
preferred method of treatment for, 1436
Pigmented epidermal lesions, 1965-1966
Pigmented macules, 1965
Pigmented villonodular tenosynovitis, 2012, 2012*b*
Pilomatricoma, 1968, 1969*f*
Pilon fracture, of PIP joint, 282, 283*f*
Pin clusters, external fixator, 539
Pin fixation
of distal radial fracture, 531-532, 535*f*-537*f*
in metacarpophalangeal joint extension contracture, 340
Pin plate, in fragment-specific fixation, 554, 556*f*
Pincer nail, 330, 330*f*, 331*b*
Pinning, extension block, for proximal interphalangeal joint fracture-dislocation, 283
"Pins-and-plaster" technique, for distal radius fractures, 516.*e*1
Pisiform
anatomy of, 419
fracture of, 634-636, 635*b*, 636*f*
in children, 1448, 1449*f*
incidence of, 625*t*
"Pisiform boost splint," for volar instability of the proximal row, 460, 461*f*
Pivot shift test, 830
Plantaris tendon, for tendon grafts, 204-205
Plastic deformation, of forearm, 1460-1461, 1461*f*
operations for, 1464
Plate fixation
of both-bone forearm fractures, 798*b*
circular, for scaphotrapeziotrapezoid fusion, 390
of distal and midshaft ulnar fractures, 796
Plate fixation *(Continued)*
of humeral fractures, 717
of metacarpal shaft fractures, 240-241, 237.*e*1*t*
of Monteggia fractures, 778, 779*f*
of nonunion or malunion of radius or ulna, 803*b*
of proximal and middle phalangeal fracture, 260-261
for proximal interphalangeal joint arthrodesis, 350
of radial shaft, 795*b*
for scaphoid fractures, 597
of ulnar fractures, 778-779, 779*f*, 780*b*, 784.*e*22*b*, 784.*e*22*f*
for wrist arthrodesis, critical points in, 400*b*
Plating systems, locked, 796
Platysma motor branch transfer, for brachial plexus injury, 1177
Poikilothermia, 1766
Poland syndrome, syndactyly in, 1231, 1231*f*
Pollicization, 1295-1299, 1295.*e*1*b*, 1295.*e*1*f*-1295.*e*3*f*
complications of, 1303*t*
of index finger, and removal of hypoplastic triphalangeal thumb, 1320, 1320*f*
of index finger stump, 1699-1703, 1702*f*-1704*f*, 1705*b*
of long finger stump, 1699-1703, 1702*f*-1704*f*
pitfalls of, 1303*t*
procedure of, 1295-1299, 1295*b*, 1296*f*-1301*f*
results of, 1301-1303, 1302*f*
Polydactyly, 1232-1236
central, 1234-1236, 1237*b*
epidemiologic findings, 1234, 1234*f*-1235*f*
treatment of, 1235-1236, 1235*f*-1236*f*
ulnar, 1232-1234, 1232*f*-1233*f*, 1234*b*
classification and treatment of, 1233, 1233*f*
epidemiologic findings, 1232
surgical technique for, 1233-1234, 1233*f*
Polymethyl methacrylate beads, antibiotic-impregnated, 1500, 1504*f*
Polymorphonuclear neutrophils (PMNs), in mangling injuries, 1488, 1488*f*
Polytrauma, distal humeral fractures in, management of, 707
Porokeratosis, 1970, 1971*f*
Poroma, eccrine, 1964
Portal sequence, in procedure, for Dupuytren disease, 146
Portals, for arthroscopy of wrist, 653-656, 653.*e*1*t*
1-2, 654
3-4, 653-654, 654*f*-656*f*, 653.*e*1*t*
4-5, 653-654, 653.*e*1*t*

accessory thumb carpometacarpal, 657-658
distal radioulnar, 657-658, 653.*e*1*t*
midcarpal, 656-657, 653.*e*1*t*
radiocarpal, 653-656, 654*f*-656*f*
scaphotrapeziotrapezoidal, 657
trapeziometacarpal, 657, 658*f*
volar, 655-656, 653.*e*1*t*
Portuguese man o' war, venomous, 1792*f*
Position of function, 1930-1931
Position of safety, 1930-1931, 1931*f*
Positioning
for complex traumatic elbow dislocation, 824-825
in elbow arthroscopy, 886, 888*f*
Posterior central portal, in elbow arthroscopy, 890
Posterior compartment portals, in elbow arthroscopy, 890-891, 890*f*
Posterior dislocation, of elbow, associated with fracture of olecranon process, 784.*e*11*b*, 784.*e*11*f*-784.*e*12*f*
Posterior drawer test, in midcarpal instability, 461
Posterior interosseous artery flap, reversed, 1558-1561, 1560*f*
Posterior Monteggia fracture
metaphyseal, 784.*e*23*b*, 784.*e*23*f*-784.*e*24*f*
plate loosening after operative treatment of, 784.*e*28*b*, 784.*e*28*f*-784.*e*29*f*
type A, 784.*e*1*b*, 784.*e*2*f*-784.*e*3*f*
ulnohumeral instability after, 784.*e*30*b*, 784.*e*30*f*
Posterior Monteggia lesion, 817, 817*f*
Posterior olecranon fracture-dislocation, 784.*e*4*b*, 784.*e*4*f*-784.*e*5*f*, 784.*e*6*b*, 784.*e*7*f*-784.*e*8*f*, 784.*e*15*b*, 784.*e*15*f*-784.*e*17*f*
failed operative fixation of, 784.*e*25*b*, 784.*e*25*f*-784.*e*27*f*
Posteroanterior (palm down) projection, carpal injury and, 428, 428*f*-429*f*
Posterolateral compartment portals, in elbow arthroscopy, 891
Posterolateral portal, in elbow arthroscopy
distal, 891
proximal, 890
Posterolateral rotatory drawer test, 830
Posterolateral rotatory instability (PLRI), 830
Posteromedial varus rotational instability pattern, 784.*e*9*b*, 784.*e*9*f*-784.*e*10*f*
Postoperative swelling, intravenous dexamethasone for, 857
Posttraumatic arthritis
of elbow, 827
preoperative assessment of, 906
Posttraumatic arthritis *(Continued)*
preoperative planning for, 906
total elbow arthroplasty for, 906, 907*f*
Posttraumatic neuralgia, nerve injury and, 1010.*e*4-1010.*e*5
Postures
abnormal, 923-924, 923*f*
dysfunctional, 1828-1829, 1830*f*-1831*f*
Potassium iodide, for sporotrichosis, 83
Pox, farm yard, 123-124, 124*f*
Prazosin, for complex regional pain syndrome, 1814, 1814*t*
Prednisone
for chronic bacterial infections, 67
in Hansen disease
for lepra reaction, 111*t*
for Lucio reaction, 111-112
for pyoderma gangrenosum, 77
Pregabalin (Lyrica), 969
Pregnancy
de Quervain disease of, 1917
regional anesthesia for, 2-3
Prehension, free muscle transfer for, single-stage, 1185, 1185*f*
Preiser disease, 648-649
Pressure therapy, postburn, 1953, 1954*f*
Pressure thresholds, cutaneous, in compression neuropathies, 928
Prestyloid recess (PSR), 659*f*
Primary arterial coaptation, 1482
Procaine, characteristics of, 4*t*
Profundus tendon, superficialis transfer to, in spasticity, 1104-1105, 1106*f*, 1107*b*
Progressive macrodactyly, 1276-1277, 1284*f*
Progressive recontracture, of Dupuytren disease, 133-134, 134*t*
Pronator, insertion of, release of, 1095
Pronator syndrome, 936-937
Pronator teres
rerouting of, for spasticity, 1095, 1096*b*
transfer of, to extensor carpi radialis brevis, for spasticity, 1101, 1101*f*
Prone positioning, in elbow arthroscopy, 886
Proprioception, wrist, reeducation of, 439
Prosthesis
customized, for mangled hand, 1492, 1493*f*
hand, after amputation, 1738-1745, 1743*f*, 1743*t*-1744*t*, 1745*f*, 1746*b*
types of, 1740-1745, 1740*f*
infections of, 50-51
longevity of, in total elbow arthroplasty, 914
passive, 1758
Prosthetic control, improved, 1760-1761, 1760*f*
Prosthetic designs, 1758-1759, 1759*f*
improved, 1761
Prosthetic rehabilitation
current, 1756-1758
frontiers in, 1759-1761
Prosthetic replacement, of elbow, 905
Prothionamide, dosage of, 101*t*
Prototheca wickerhamii, 116
Protothecosis, 116
etiology, diagnosis, and treatment of, 63*t*
Protozoal infections, chronic, 116-118

indications and contraindications for, 349
postoperative management and expectations on, 350-352
preferred method of treatment for, 350, 351*f*
preoperative planning for, 349
technique for, 349-350, 350*f*
arthroplasty of, 353-358
complications of, 358, 358*f*
critical points in, 356*b*
expected outcomes on, 356-357
indications and contraindications for, 353
postoperative management and expectations on, 356-358
preferred method of treatment for, 354-356, 354*f*-356*f*
preoperative planning of, 353
technique for, 353-354, 354*f*
arthroscopy of, 694.*e*1
biomechanics of, 346
central slip deficiency of, in tetraplegic patient, 1143
intrinsic tenodesis for, 1143, 1143*f*
central slip of, anatomic integrity of, 155
contractures of
extension, release of, 341-343, 343*f*
flexion, release of, 341
expectations and outcomes in, 341.*e*2
preferred approach for, 341, 342*f*
late posttraumatic
interosseous, 343.*e*1-343.*e*2, 343.*e*2*f*
intrinsic, 343.*e*1

Proximal interphalangeal (PIP) joint *(Continued)*
nonoperative treatment of, 340.*e*1-340.*e*2
treatment for, Dupuytren disease and
needling, 148, 148*f*
severe, 143, 144*f*
deformity, in systemic lupus erythematosus, 1838
dislocations of, 279-293
acute dorsal, 279-280
lateral, 280
posttraumatic fibrosis and contracture in, 295-296, 296*b*, 296*f*
volar, 280-281
treatment of, 280-281
Elson test in, 156
extensor mechanism in, 156*f*
fracture-dislocations of, 281-282, 281*f*
chronic, 293-294
stable, 281-282
tenuously stable, 282
treatment of, 281*f*
preferred method of, 284-294, 284*f*
unstable, 282, 282*f*
treatment of, 282-293
volar, 280
ganglion of, 2007-2008, 2008*f*-2009*f*
hyperextension of, as complication of flexor tendon grafting, 225
injury to, 169-174, 169.*e*1*b*, 169.*e*1*f*-169.*e*2*f*
clinical evaluation of, 279
open, 170
preferred method of treatment of, 170-171
preoperative evaluation of, 278-279
radiographic evaluation of, 278-279, 279*f*
in intrinsic muscle spasticity, 1114
little finger, of Dupuytren disease, 138
rheumatoid arthritis of, 1878-1879, 1879*f*
swan neck deformity in, 1879-1890, 1880*t*
type I, 1879-1883, 1881*f*
type III, 1883-1885
type IV, 1886-1890
synovectomy for, 1878-1879
stiffness of. *see also* Stiffness, of finger and hand
articular surface of, 338-339
examination of, 339
subluxations of, 294-295, 295*f*
Proximal row, wrist
dorsal instability of, 461-462
volar instability of, 459-461
Proximal tendon juncture, 208, 210*f*
Pseudoarthrosis, congenital, of ulna, 1354-1357, 1357*b*
Pseudogout, 57-58
tendinopathy in, 1906
Pseudosarcomatous fasciitis, 2014
Psoriatic arthritis, 1834-1836
digital deformity in, 1836, 1836*f*
thumb deformity in, 1836
wrist deformity in, 1836
Psychological impairment, in tetraplegia, 1126-1127
Psychological problems, mimicking complex regional pain syndrome, 1802
Pterygium, 329
Pulley system
design of, for opponensplasty, 1027
disruption of, as complication of flexor tendon grafting, 224
of flexor tendon, 186, 186*f*
reconstruction of, 221-223, 223*b*
indications of, 221
postoperative care of, 223
preferred technique of, 222-223, 223*f*
using a flexor digitorum superficialis tendon, 222, 222*f*
using a free tendon graft, 221-222, 222*f*
using artificial materials, 222
using the extensor retinaculum, 222
using the volar plate, 222
in toe preparation, 1666
Pull-out sutures, for tendon graft, 207-208, 208*f*-209*f*
Pulmonary function tests, in brachial plexus injury, 1153
Pulp flaps, transfer of, from toes to fingers, 1659-1660
Pulp loss, fingertip amputation with, 1709-1711
Pulsed electromagnetic field (PEMF) therapy, for scaphoid fractures, 607
Pulvertaft end-weave technique, modified, for tendon graft, 210-211, 210*f*
Punch biopsy, 1961, 1963*f*
Pustular dermatitis, contagious, 123-124, 124*f*
Putti sign, 1408
Pyarthrosis, antibiotic recommendations for, 21*t*
Pyoderma gangrenosum, 57-58, 75-77
clinical findings on, 76-77, 76*f*
diagnosis of, 77
etiology and epidemiology of, 75-76
treatment of, 77
Pyogenic flexor tenosynovitis, 28-32, 32*b*
clinical presentation and preoperative evaluation of, 28-29
pertinent anatomy in, 29
treatment for, 29-31
operative, 30-31, 30*f*
preferred methods of, 31, 31*f*
Pyogenic granuloma, 57-58, 58*f*, 1970, 1971*f*
of nails, 332, 332*f*
Pyrazinamide (PZA)
dosage of, 101*t*
for tuberculosis, 100
Pyridoxine, for tuberculosis, 100, 103
Pyrocarbon implant
for metacarpophalangeal joint arthroplasty, 358
for proximal interphalangeal joint arthroplasty, 357

Q

Quadriga syndrome, as complication of flexor tendon grafting, 224-225
Quantitative sudomotor axon reflex test (QSART), 1802-1803

R

Radial artery
anatomy of, 787, 1588-1589
in forearm flap, 1555-1558, 1556*f*-1559*f*, 1559*b*
puncture, 2036
Radial bow, assessment of, 787, 788*f*
Radial bursal infections, 32-34
clinical presentation and preoperative evaluation of, 33
pertinent anatomy in, 32-33
postoperative management of, 34
treatment for
open, 33-34
preferred method of, 34
Radial collateral ligament
anatomy of, 739, 740*f*
injury of, 308-310
anatomy in, 308-309
in metacarpophalangeal joint dislocation, 300-301
postoperative management and expectations in, 310
preoperative evaluation of, 309
treatment of, 309
preferred method of, 309-310, 310*b*, 310*f*
types of operations for, 309-310
Radial deficiency, syndromes associated with, 1289, 1290*t*
Radial forearm flap, 1588-1591, 1589*f*, 1591*b*
composite, for reconstruction of amputated thumb, 1697-1699, 1700*f*, 1701*b*, 1699.*e*1*f*
for mangling injuries, 1513, 1514*f*-1515*f*
operative technique for, 1589-1591, 1590*f*, 1592*f*
Radial head excision
in hereditary multiple exostoses of forearm, 1360
in proximal radioulnar synostosis, 1353

Radial longitudinal deficiency, 1328-1334, 1334*b*
  Bayne classification of, 1328, 1329*t*
  pertinent anatomy in, 1328
  preoperative evaluation of, 1328, 1330*f*
  surgical treatment of, 1329-1334, 1331*f*
    expected outcomes of, 1334, 1335*f*
    postoperative management and expectations after, 1334
    preferred method of, 1333-1334, 1334*f*
    preliminary soft tissue distraction in, 1329-1330, 1331*f*-1332*f*
    ulnar lengthening in, 1329, 1333, 1333*f*
  syndromes associated with, 1328, 1329*t*
Radial lunate ligament, 658-659, 658*f*
Radial midcarpal portal, 660*f*
Radial nerve
  anatomy of, 786-787, 788*f*, 950-951, 951*f*
  compression of, 947-949. *see also* Radial tunnel syndrome
    postoperative care of, 949
    proximal, 953
      operative technique of, 953
      postoperative care of, 953
    superficial, 947-949, 948*f*
  in cross-finger flap, for thumb reconstruction, 1682-1684, 1683*f*, 1684*b*, 1684.*e1f*
  excessive deviation of, after tendon transfer, 1069-1070
  innervation of, 1064*t*
  intermediate zone injuries of, repair of, outcomes of, 1004*t*
  repair of
    effects of delay in, 1005*t*
    recovery after, 1005*t*
    results of, 1003-1005
      grading of, 1003*t*
  restoration of, 1076
    outcome of, 1076
    technique of, 1076
  sensory branch of
    anatomy of, 948, 948*f*
    decompression of, 949, 949*f*
    release of, 950*b*
  superficial, in complex regional pain syndrome, surgical management of, 1821-1822, 1821*f*
Radial nerve block
  at elbow, 8
  at wrist, 9, 9*f*
Radial nerve palsy, 1064-1076, 1064*f*
  associated with fractures of humerus, 1074-1076
    early, 1074
    if no return at longer waiting period, 1075, 1075*f*
    nerve exploration in, at 6 to 8 weeks, 1074-1075, 1075*f*
    preferred method of treatment of, 1075
Radial nerve palsy *(Continued)*
  associated with Holstein-Lewis spiral fracture, 1074
  nerve transfer in, 1075-1076
  nonoperative treatment of, 1064-1065, 1065*f*
  operative treatment of, 1065-1074
    tendon transfers in, 1066-1074, 1067*t*, 1070*b*
      flexor carpi radialis, 1071, 1071*b*, 1071*f*
      flexor carpi ulnaris, 1067-1070, 1067*f*-1069*f*
        postoperative management of, 1069
        potential problems of, 1069-1070
      historical review of, 1066, 1066*f*, 1066*t*
      nerve repair and graft *versus*, 1065
      outcome of, 1072
      preferred method of, 1072-1074, 1073*f*-1074*f*
      superficialis in, 1070-1071, 1071*b*
        postoperative management of, 1071
      timing of, 1065-1066
  patient requirements for, 1064
  secondary, 1074
Radial osteotomy
  articular, 580-581, 582*f*, 581.*e1b*, 581.*e1f*-581.*e6f*
  closing wedge, for Kienbock disease, 646, 647*f*
  dorsal approach to, 577-578, 579*f*
  extraarticular, 577, 578*b*, 578*f*
  malunited Smith, 580, 580.*e4f*
  ulnar-shortening, 580
  volar approach to, 578-580, 581*f*, 580.*e1b*, 580.*e1f*-580.*e2f*
  Watson's trapezoidal, 580.*e3*, 580.*e3f*
  with and without ulnar osteotomy, 1378-1380, 1380*b*
    complications of, 1380
    contraindications to, 1379
    indications for, 1378-1379
    postoperative management and expectation after, 1379-1380
    preferred method of, 1379
    preoperative planning in, 1379
    technique of, 1379, 1380*f*
Radial styloidectomy
  for scaphoid nonunion advanced collapse, 622
  for scapholunate dissociation, 449
Radial translation, 561-563
Radial tunnel syndrome, 949-952
  nerve anatomy in, 950-951, 951*f*
  operative techniques for, 951-952
    anterior (modified Henry) approach to, 952
    posterior (Henry or Thompson) approach to, 951-952, 951*f*
Radial tunnel syndrome *(Continued)*
    postoperative care after, 952
    preferred method of, 952, 952*f*
    transmuscular brachioradialis-splitting approach to, 951, 951*f*
  release of, 953*b*
Radial-to-axillary transfer, 1404, 1407*f*
Radiocapitellar joint, 813
  capsuloligamentous components of, 813
  musculotendinous components of, 813
Radiocarpal joint
  fracture-dislocation of, management of, 572-573, 573*f*, 573.*e1f*-573.*e3f*, 573.*e2b*
  instability of, nondissociative, 458-459, 458*f*
  osseous anatomy of, 419-420
  rheumatoid arthritis of, 1858-1863
    reconstruction of, 1863-1866
      partial, 1864-1866, 1864*f*
    synovectomy for, 1858-1859, 1859*f*
Radiocarpal ligaments
  dorsal, 421-422
  palmar, 420, 421*f*
Radiography
  of capitate fracture, 630
  in complex regional pain syndrome, 1805
  of distal humeral fracture, 697-698, 698*f*-699*f*, 906-907
  of distal radial fracture, 520-523, 521*f*-523*f*, 520.*e1f*
  of distal radioulnar joint, 484-485, 485*f*
  for free flaps, 1577
  of Galeazzi-type fracture-dislocations, 792, 792*f*
  of hamate fracture, hook of, 631-632, 632*f*
  of Kienbock disease, 641, 641*f*
  of lunate fracture, 637-638
  of mangled extremity, 1490, 1491*f*
  plain, for musculoskeletal tumors, 1990
  of proximal interphalangeal joint injury, 278-279, 279*f*
  of radial head fractures, 734-736, 735*f*
  of radioulnar synostosis, 803-804, 804*f*
  of trapezium fracture, 628
  of triquetrum fracture, 626
Radiological examination
  of carpal injury, 428-430
    additional views, 429-430, 429*f*
    distraction views, 431
    routine views, 428-429, 428*f*-429*f*
    stress views, 431, 432*f*
  of lunotriquetral dissociation, 452-454, 452*f*-453*f*
  of midcarpal instability, 460
  of scapholunate dissociation, 436, 437*f*
Radiolunate angle, measurement of, in wrist instability, 430

Radiolunate fusion, 377-380
author's preferred method of treatment for, 378-380, 381*f*-382*f*
critical points in, 381*b*
indications for, 377, 379*f*
net analysis of literature in, 380
pitfalls of, 380
postoperative management for, 380
technique for, 377, 379*f*-380*f*
Radioscaphocapitate (RSC) ligament, 589-590, 589*f*
Radioscaphoid-lunate fusion, and distal scaphoidectomy, 448-449, 449*f*
Radioscapholunate fusion, 385-386
complications of, 375*f*, 386
critical points in, 388*b*
indications and contraindications in, 385, 385*f*
patients and, 386, 388*f*
postoperative care for, 386
preferred method of treatment for, 385-386, 386*f*-387*f*
Radioulnar inclination, kinematics in, 423*f*, 424
Radioulnar joint
distal, 479-515, 480*f*
anatomy of, 479-483, 480*f*-483*f*
arthritis of, 503-507
distal ulnar resection (Darrach procedure) for, 505-506, 506*f*
hemiresection-interposition arthroplasty for, 503-504, 504*f*
Sauvé-Kapandji procedure for, 504-505, 505*f*
stabilization of resected distal ulna in, 506-507, 507*f*
arthrography of, 486
arthroscopy of, 487
biomechanics of, 479-483
computed tomography of, 486, 486*f*
contracture of, 510-511
after radial fracture, 582-584
operative technique for, 510-511
extensor carpi ulnaris in, tenosynovitis and subluxation of, 511-512, 511*f*
operative technique for, 511-512, 512*f*
outcomes of, 512
failed ulnar resection in, 507-508, 507*f*
fracture of, injuries associated with
classification of, 527, 528*f*-529*f*
treatment of, 563, 564*f*-565*f*
instability of
acute, 491-493, 491*f*-492*f*
evaluation of, 492
simple dislocations in, 492
triangular fibrocartilage complex repair (class 1B injury) in, 492-493
ulnar styloid fractures in, 493, 493*f*
Radioulnar joint *(Continued)*
chronic, 494-498, 495*f*
author's preferred treatment for, 496-498, 497*f*
evaluation of, 494
osteoplasty of sigmoid notch and ulna in, 498, 498*f*
outcomes in, 498
treatment for, 494-498, 496*f*
magnetic resonance imaging of, 486-487, 487*f*
physical examination for, 483-484, 484*f*
radiography of, 484-485, 485*f*
radius and forearm malunions in, 498-500, 499*f*
residual disability of, procedures for, 581-582, 583*f*, 584*t*
scintigraphy of, 487
ulnar head implant arthroplasty in, 508-510
operative technique for, 509-510, 509*f*
outcomes of, 510, 510*f*
ulnar impaction syndrome in, 500-503, 500*f*
author's preferred treatment for, 502, 502*f*
evaluation of, 500-501
treatment of, 501-503
partial distal ulnar resection (wafer procedure), 497*f*, 501, 501*f*
ulnar-shortening osteotomy, diaphyseal and metaphyseal, 501-503
ultrasonography of, 485
portals of, for arthroscopy of wrist, 657-658, 653.*e*1*t*
rheumatoid arthritis of, 1858-1863
distal ulnar excision and reconstruction for, 1860-1863
complications of, 1862-1863
synovectomy for, 1858-1859, 1859*f*
Radioulnar ligaments
anatomy of, 481, 481*f*
distal, reconstruction of, 496-498, 497*f*
role of, 482
Radioulnar synostosis, 803-804, 803*f*-804*f*, 804*t*
postoperative management and expectations of, 804
posttraumatic, 1457
preferred method of, 804, 805*f*
proximal, 1349-1354, 1354*b*
classification of, 1351*t*
pertinent anatomy in, 1350
preoperative evaluation of, 1349-1350, 1350*f*-1351*f*
surgical treatment of, 1351-1353
derotation osteotomy in, 1351-1352, 1352*f*-1353*f*
expected outcomes in, 1354
Radioulnar synostosis *(Continued)*
postoperative management and expectations after, 1354
preferred method of, 1353
radial head excision in, 1353
resection in, 1351
Radius
congenital pseudoarthrosis of, 1354-1357, 1357*b*
deformity of, carpal misalignment secondary to, 463-464
distal
anatomy of, 516-520, 518*f*-519*f*
fracture of, 516-587, 671-672
articular, management of, 568-573
bending, 527, 567-568, 568.*e*1*b*, 568.*e*1*f*-568.*e*13*f*, 568.*e*3*b*, 568.*e*7*b*, 568.*e*9*b*, 568.*e*11*b*
carpal ligament injuries associated with, 575
in children, 1448-1455, 1458*b*
preferred method of treatment for, 1448
classifications of, 523-527
AO, 524, 526*f*
associated radioulnar joint injuries in, 527, 528*f*-529*f*
columnar, 524, 527*f*
Fernandez, 524-527, 528*f*-529*f*
fragment-specific, 524, 526*f*

emergency management in, 1476
epidemiology in, 1476
patient selection in, 1476-1478
indication for, 1477*f*
intraoperative technique for, 1478-1482
amputated part, preparation of, 1478-1479, 1479*f*
arterial repairs, 1482
digital nerve repairs, 1481
digital vein repairs, 1481
extensor tendon repairs, 1481
flexor tendon repairs, 1481
osseous fixation in, 1481
preparation of the hand, 1479, 1479*f*
reperfusion in, 1482
replantation, 1479-1481
skin closure in, 1482
locating distal veins for, 1481*b*
major, 1480-1481, 1480*f*, 1484*b*
postoperative protocol for, 1482-1483
preparing for, technical considerations in, 1478
Resection
primary, of radial head, outcome of, 759
of pseudoarthrosis of ulna, 1356
of radial head, for congenital dislocation, 1348, 1349*f*
of radial head, outcome of, 759
of synostosis, radioulnar, 1351
Resection arthroplasty, for carpometacarpal joint osteoarthritis
expected outcomes on, 366-368, 367*t*
as operative technique, 363-364, 363*f*
as treatment, 361
Reserpine, for complex regional pain syndrome, 1815*t*
Resisted finger extension test, in scapholunate dissociation, 436
Resisted isometric elbow flexion, 740
Resource materials, for Hansen disease, 115-116
Resting extension splint, for elbow contracture, 857
Restorative wrist, in rheumatoid arthritis, 376, 378*f*
Reticular ligament, reconstruction of, for swan neck deformity, in rheumatoid arthritis, 1883
Retinacular ligament, oblique, 156-157
spiral, reconstruction, technique of, 168, 168*f*
Retroclavicular brachial plexus, 1146
injury to, 1150
Revascularization, of mangled extremity, 1505, 1506*f*-1507*f*
Reversal reaction (leprae type 1), in Hansen disease, 110, 111*t*
Reversed cross-finger flap, 1552
Reversed dart-thrower's motion, 424
Rhabdomyosarcoma, 2020
Rheumatoid arthritis, 1842-1857
arthrodesis, of wrist, complications of, 1867
crossed intrinsic transfer for, 1869-1870
extensor tendon relocation for, 1870, 1870*f*
of fingers, 1876-1877
boutonnière deformity in, 1890-1894
stage I, 1891-1892
extensor tenotomy for, 1891-1892, 1891*f*
stage II, 1892-1893, 1892*f*
treatment options for, 1891*t*
hand deformities, 1835*f*
intrinsic release for, 1869, 1869*f*
medical considerations of, 1833
of metacarpophalangeal joints, 1867-1878
arthroplasty for, 1870-1878
contraindications to, 1871-1872, 1871*f*
extensor tendon centralization in, 1875-1876, 1875*f*
flexible implant, 1872-1875, 1872*f*-1875*f*
indications for, 1871, 1871*f*
options in, 1872
outcome of, 1878
rehabilitation after, 1876-1877, 1876*f*-1877*f*
technical points in, 1876
etiology of, 1867
surgical treatment of
contraindications to, 1868
indications for, 1868, 1868*f*
nodulosis in, 1841-1842
patients with, intramedullary pin fusion for, 401-404, 402*f*-403*f*
physical examination of, 905
preoperative evaluation of, 905-906
preoperative planning of, 905-906
of proximal interphalangeal joint, swan neck deformity in, 1879-1890, 1880*t*

distal radius and, fractures of, 603-604
examination of, 591-592
imaging of, 592, 593*f*
incidence of, 588, 589*f*, 625*t*
management of, 594-596, 666
algorithm for, 594*t*
in athletes, 603
at distal pole, 594
Geissler technique in, 666-668, 666*f*-668*f*
Herbert-Whipple technique in, 669-670, 669*f*-670*f*
incomplete, through waist, 594
mechanics of fracture fixation in, 595-596
at proximal pole, 595
Slade technique in, 668-669, 668*f*
at waist, 595
nonsurgical treatment for, cost of, 605-607
physical examination of, 591, 591*f*
rigid fixation for, 596-597
surgical treatment for, 597-603
arthroscopy-assisted percutaneous fixation in, 603
complications of, 605
cost of, 605-607
dorsal percutaneous Slade technique in, 598
fixation in, palmar percutaneous method of, 601-603, 602*f*
mini-open screw in, palmar approach to, 600-601, 600*f*
open reduction and internal fixation in, 597-598
palmar percutaneous method in, 600
pitfalls for, 601*b*, 601*f*-602*f*
postoperative care, 602-603
preferred, 597-598, 597*f*
waist fracture, displaced, 598-599, 599*f*
vascularized bone grafting for, 1624
nonunion of, results of, 1637-1638
malunion of, treatment of, 621-622
nonunion of, 588-624
arthroscopic reduction of, 670
biologic stimulation of, 607
bone graft for, nonvascularized, 610, 610*f*
classifications of, 670*t*
of distal pole, 622
dysvascular, 616-619, 616*f*
evaluation of, 608-609
Scaphoid *(Continued)*
activity level in, 609
age in, 609
amount of deformity and malalignment in, 608
arthritis in, presence and location of, 609
bone loss in, 608
comorbidities in, 609
fracture site in, 608
length of time in, 609
pain or dysfunction in, 609
previous treatment in, 608
salvageability of fragment in, 609
vascularity of fragments in, 608
implications of, 590-591, 591*f*
management of, 608-624
preferred method for, 621
open dorsal technique for, 614-615
operative treatment for, 609-619, 609*t*
prognosis for healing in, 620-621
proximal pole, 614-616
treatment for, preferred, 621*t*
unsalvageable proximal pole, 621
without arthritis, 609-611
without substantial bone loss, 609
osteitis of, 648
preparation, for bone grafting, 1631
projection, carpal injury and, 429
Scaphoid nonunion advanced collapse (SNAC), 435, 591
salvage procedures for, 622-624
Scaphoid ring sign, in scapholunate dissociation, 436, 437*f*
Scaphoid shift test, in scapholunate dissociation, 436, 436*f*
Scaphoid-capitate arthrodesis, in scapholunate dissociation, 448
Scaphoidectomy
midcarpal fusion and, 449-450
radioscaphoid-lunate fusion and, 448-449, 449*f*
Scaphoid-lunate-capitate arthrodesis, in scapholunate dissociation, 448
Scaphoid-trapezium-trapezoid arthrodesis, in scapholunate dissociation, 447
Scapholunate advanced collapse (SLAC) wrist, 435
arthroscopy for, 665
Scapholunate angle
increased, in scapholunate dissociation, 436-437, 437*f*
measurement of, in wrist instability, 430
Scapholunate arthrodesis, 387, 447
Scapholunate ballottement test, 436-437
Scapholunate dissociation, 434-450
diagnosis of, 435-436
ballottement test in, 436-437
physical examination in, 435-436
radiological examination in, 436, 437*f*

Scapholunate dissociation *(Continued)*
resisted finger extension test in, 436
scaphoid shift test in, 436
pathomechanics of, 426, 434-435, 435*f*
treatment of, 437-447, 438*b*
preferred method of, 449*f*, 450
Scapholunate interosseous ligament, 658-659, 659*f*
carpal instability and, 661
grade I injury to, 662*f*
grade II injury to, 662*f*
grade III injury to, 662*f*
grade IV injury to, 663*f*
Scapholunate joint
increased space in, 436, 437*f*
Kirschner wire fixation of, 439
reduction-association of, 446-447, 446*f*
Scapholunate ligament, 422, 422*f*
injury to
stage I: partial, treatment in, 438-447, 438*t*
stage II: complete, repairable, treatment in, 438*t*, 440, 440*f*-441*f*
stage III: complete, nonrepairable, normally aligned scaphoid, treatment in, 438*t*, 441-442, 442*f*
stage IV: complete, nonrepairable, reducible flexion deformity of scaphoid, treatment in, 438*t*, 443, 444*f*-445*f*
stage V: reducible carpal collapse, plus instability of radiolunate joint and normal joint cartilage, treatment in, 438*t*, 447, 447*f*-448*f*
stage VI: irreducible carpal collapse, with normal joint cartilage, treatment in, 438*t*, 447
stage VII: with irreducible malalignment and cartilage degeneration, treatment in, 438*t*, 449
interosseous, 589-590, 589*f*
tears of, associated with distal radial fracture, 542
Scapholunate-intercarpal-carpal (SLIC) screw, 663, 663*f*
Scapholunotriquetral tenodesis, 445*f*
Scaphotrapeziotrapezoid arthritis, carpal misalignment secondary to, 464
Scaphotrapeziotrapezoidal fusion, 389-390
alternative techniques for, 390-391
author's preferred method of treatment for, 390, 391*f*
contraindications for, 389
indications for, 389
patients on, 390-391, 392*f*
Scaphotrapeziotrapezoidal joint
portal of, for arthroscopy of wrist, 657
resection arthroplasty of, 693-694
Scaphotrapezoid portal, for arthroscopy of wrist, 657
Scapula
evaluation of, in compression neuropathies, 927
vascularized bone graft from, 1634
Scapular flap, 1554
free, 1591-1593, 1593*b*
anatomy in, 1591, 1593*f*
for mangling injuries, 1515, 1518*f*
operative technique for, 1591-1593, 1594*f*
Scarring
after skin grafting, control of, 1538
of eponychium, 329
of nail bed, 325
postburn, 1953
Schwannomas, 2012, 2013*f*
malignant, 2019
Scintigraphy
in complex regional pain syndrome, 1806-1807, 1806*f*
of distal radioulnar joint, 487
in Kienbock disease, 640
for musculoskeletal tumors, 1990
Sclerodactyly, 1839
Scleroderma, 1839-1840
authors' method of, 1840
calcinosis, 1839
digital deformity in, 1839-1840, 1839*f*
first web contracture in, 1841
proximal interphalangeal joint deformity in, 1838
vascular insufficiency and, 1841
Scratch collapse test, for nerve compression, 927
Screw(s)
bioresorbable, for scaphoid fractures, 596
malposition of, fluoroscopy and surgical navigation to reduce, 605
Screw fixation
in capitate-lunate-hamate-triquetrum fusion, 393-394
of distal humeral fractures, 719
of proximal and middle phalangeal fracture, 259-260
of radial shaft fractures, 793-794, 795*f*
of scaphoid fractures, 596-597, 596*f*
guidewire placement in, 600
length of screw in, 600-601
in scaphotrapeziotrapezoid fusion, 390
sequence of, 724
of ulnar fractures, 778-779, 779*f*, 780*b*
Sea urchins, venomous, 1792, 1792*f*
Seborrheic keratosis, 1964, 1966*f*
Second-degree burns
deep partial-thickness, 1928, 1929*f*
superficial partial-thickness, 1928, 1929*f*
Secretan disorder, 177
Segmental fasciectomy, for Dupuytren disease, 141
Segmental metacarpal loss, 243-244, 244*f*
Selective serotonin reuptake inhibitors, for complex regional pain syndrome, 1812, 1813*t*
Self-report questionnaires, 924
Semipronated (oblique) projection, carpal injury and, 429
Semmes-Weinstein monofilaments, 928
Senile lentigo. *see* Solar lentigo
Sensation
defects in, free flaps for, 1609
preservation of, in Hansen disease, 113-114
Sensibility, restoration of
in Hansen disease, 114
in ulnar nerve palsy, 1061
Sensory evaluation, in compression neuropathies, 927-928
Sensory flaps, from first web of foot, 1605-1608, 1606*f*, 1608*b*
Sensory nerve action potential (SNAP), 929
in thoracic outlet syndrome, 968
Sensory rehabilitation, after toe transfer, 1671
Sentinel lesion, of neonatal compartment syndrome, 1763-1764
Sepsis, regional anesthesia and, 12-14
Septic arthritis, 40-41
clinical presentation and patient evaluation of, 40-41
postoperative management of, 43
treatment for, 41
Septic boutonnière deformity, 43
Septic flexor tenosynovitis, 31.*e*1*b*, 31.*e*1*f*
Septic tenosynovitis, 1907
Septic thrombophlebitis, 52
Serial casting, for proximal interphalangeal joint contractures, 340.*e*2
Serial static splints, for joint stiffness, 340.*e*1, 340.*e*1*f*
Serratus anterior free muscle flap, 1603, 1603*f*
Sertraline, for complex regional pain syndrome, 1813*t*
Seymour fractures, in children, 1429, 1429*f*
Shaft fractures
of metacarpal, 236-243
closed reduction and percutaneous pinning in, 237-238, 238*f*
closed reduction and plaster immobilization of, 237, 237*f*
expected outcomes of, 243
open reduction for, 238-241
cerclage and interosseous wiring in, 239
composite (tension band) wiring in, 238*f*, 239
external fixation in, 241
fracture stabilization techniques in, 237.*e*1*t*

Shaft fractures *(Continued)*
interfragmentary compression screws in, 240, 240*f*
intramedullary fixation in, 239-240, 239*f*
Kirschner wires in, 238-239, 238*f*
plate fixation in, 240-241
preferred method of treatment of, 241-243, 242*f*
of phalanx
distal, 248
nonarticular, 256
expected outcomes of, 264-265
preferred method of treatment of, 261
of thumb, 271-272, 271*f*
SHAFT (sad, hostile, anxious, frustrating, and tenacious) syndrome, 1802
Shave biopsy, 1961, 1962*f*
Shear test, for lunotriquetral dissociation, 451, 452*f*
Shearer's disease, 118
Shearing fracture
of capitellum, 703, 703*f*, 737, 738*f*
of radius, 527
dorsal, isolated, 568, 569*f*-570*f*
management of, 568-573, 569*f*, 568.*e*14*b*, 568.*e*14*f*-568.*e*19*f*, 568.*e*17*b*
Shooter's abscess, 51-52
Shortening, as complication of phalangeal fractures, 267
Shoulder
anatomy of, 1186
arthrodesis of, for brachial plexus injury, 1190-1192
preferred method of, 1192, 1194*b*, 1194*f*
biomechanics of, 1186
contractures of, in arthrogryposis, 1365
examination of, in compression neuropathies, 927
free muscle transfers in, 1178-1179
as recipient site, in vascularized bone grafting, 1636
reconstruction of, in brachial plexus injury, 1186
tendon transfer in, 1187
preferred procedure for, 1189-1190, 1193*f*
spasticity in
examination of, 1084, 1084*f*
operative management of, 1088-1090
treatment of, preferred method of, 1090
stiffness of, after bending fractures, 567-568
weakness and deformity in, in brachial plexus birth palsy, 1408
historical review of, 1411-1412, 1412*b*
Shoulder *(Continued)*
operations for, 1412-1416, 1413*f*-1416*f*
expected outcome of, 1417*b*
postoperative management of, 1416-1417
preferred treatment of, 1416, 1417*f*
preoperative evaluation of, 1409-1411, 1410*f*-1412*f*
Shoulder internal rotation deformity, soft tissue release of, 1088-1089
contraindications to, 1088-1089
indications for, 1088
preoperative planning for, 1089
technique for, 1089
SHOX gene, mutation of, 1339
Shriners Burn Institute, 1529
Shunts, in major replantation, 1480-1481, 1480*f*
Sigmoid notch, 479, 480*f*, 516, 522*f*
osteoplasty of, and ulna, in chronic radioulnar joint instability, 498, 498*f*
Silastic implant
for metacarpophalangeal joint arthroplasty, 358
for proximal interphalangeal joint arthroplasty, 357
Sildenafil, for Raynaud disease, 2053
Silent neuritis, in Hansen disease, 114
"Silhouette" capsulotomy, 584
Silicone sheeting
for burns, 1954
for skin grafting, postoperative care of, 1538
Silver sulfadiazine, glove filled with, for burns, 1931, 1932*f*
Single-column fractures, 701, 701*f*
Single-stage flexor tendon grafting
flexor digitorum profundus and flexor digitorum superficialis tendons disrupted, 202-211, 203*f*, 207*b*
biology of, 203
Boyes' preoperative classification, 202*t*
distal juncture technique of, 209*f*-210*f*, 210
donor for, 203-206
incorporation of, 211
indications for, 202
initial exploration of, 202
placement of, 210
postoperative care of, 211
preferred technique of, 209-210
proximal juncture technique of, 210-211, 210*f*-211*f*
flexor digitorum profundus tendon disrupted, flexor digitorum superficialis tendon intact, 211-212, 212*b*, 214*b*
expectations of, 212
indications for, 211-212, 212*f*-213*f*
postoperative care of, 212
Single-tendon transfer, for radial nerve palsy, 1071-1072
"Six-pack" exercises, for distal radial fractures, 531, 534*f*
Sixth dorsal compartment release, 511-512
Skeletal system, in mangling injuries
evaluation of, 1490
reconstruction of, 1499-1500, 1501*f*-1504*f*, 1502*b*
Skier's thumb, 302-306
Skin, 1528
anthrax in, 68-69, 69*f*
treatment of, 69
chronic paronychia in, 81
treatment of, 81.*e*1, 81.*e*1*f*
closure of
in replantation, 1482
in toe transfer, 1668
on contractures, 340.*e*2
dorsal hand, 1528, 1529*f*
fungal infections of, 80
grafts. *see* Skin graft/grafting
histologic finding of, 1528, 1529*f*
injury of, response to, 1529, 1529*f*
mycetoma in, 71
treatment of, 73
palmar hand, 1528, 1529*f*
pattern of, in free flap transfer, 1579, 1590*f*
preparation of, in toe transfer, 1645
sporotrichosis in, 82, 83*f*
tuberculosis infection of, 91-92
tularemia in, 74
yaws in, 74-75
Skin biopsy, for Hansen disease, 108, 108*t*
Skin flap(s). *see also* Flap(s)
fibula with, 1619
free. *see* Free flap(s)
for paronychial fold formation, in syndactyly, 1221-1222
Skin graft/grafting, 1528-1538
for burns, 1932-1935, 1933*f*-1934*f*
composite, 1709
for digital resurfacing, in syndactyly, 1221, 1225*f*-1226*f*
donor sites for
care of, 1538
in mangling injuries, 1511
filling the defect with, 1536-1537, 1536*f*-1537*f*
full-thickness, 1534-1535, 1535*b*, 1535*f*
choice of graft for, 1535-1536, 1536*f*
technique of obtaining, 1534-1535
general considerations in, 1528-1531
loss of, after burns, 1935
for mangling injuries
donor sites of, 1511
postoperative management of, 1519-1521
type of, 1510
negative pressure wound therapy in, 1536

Skin graft/grafting *(Continued)*
in outpatient surgery, 1538
postoperative care for, 1537-1538
primary closure
in reconstruction of amputated fingertip, 1711
semiocclusive dressings, 1711
skin substitutes for, 1531
skin thickness in, 1531
guidelines for, 1532*t*
split-thickness, 1531-1534, 1533*b*
choice of donor sites for, 1531-1532, 1532*t*
dermatomes for, 1532-1533
Padgett, 1532-1533, 1532*f*
Zimmer air, 1533
harvesting, 1532
meshed. *see* Meshed grafting
split-thickness, in reconstruction of amputated fingertip, 1711
substitution by, 1528-1529
temporary storage of, 1528-1538
timing of, 1530
types of, 1530
Skin lesions, for Hansen disease, 107, 107*f*
Skin loss, fingertip amputation with, 1709-1711
Skin necrosis, after phalangeal transfer, for digital augmentation, 1262
Skin patch, anesthetic, for Hansen disease, 106
Skin protuberances, in constriction ring syndrome, 1257, 1257*f*
Skin release, for swan neck deformity, in rheumatoid arthritis, 1883-1884, 1884*f*
Skin repair, in microvascular toe transfer, 1269
Skin test, lepromin, for Hansen disease, 107-108
Skin tumors, of hand and upper extremity, 1958-1986
anatomy and clinical examination of, 1958-1960, 1959*f*
basal cell carcinoma and, 1973-1975, 1976*f*
classification of, 1974, 1974*t*, 1976*f*
treatment of, 1974-1975, 1977*f*-1978*f*
dermal lesions in, 1966-1968
diagnostic procedures and nonsurgical treatment for, 1960-1961, 1960*f*-1963*f*
epidermal lesions in, 1962-1964
pigmented, 1965-1966
seborrheic keratosis as, 1964, 1966*f*
sweat glands and, 1964
warts as, 1962-1964
malignant, less common, 1981-1983
dermatofibrosarcoma protuberans as, 1983, 1985*f*
human immunodeficiency virus (HIV) and, 1983, 1984*f*
Skin tumors, of hand and upper extremity *(Continued)*
lymphangiosarcoma (Stewart-Treves syndrome) as, 1981-1983
Merkel cell (neuroendocrine) carcinoma as, 1981, 1984*f*
metastatic tumors as, 1983, 1985*f*
sweat gland tumors as, 1983
melanoma, 1977-1981, 1980*f*
local surgical excisional treatment for, 1980-1981
lymphatic basins in, evaluation of, 1981, 1982*f*-1983*f*
prognosis and staging of, 1980, 1981*t*
nonhemangiomatous vascular lesions in, 1968-1970
premalignant, indeterminate behavior lesions and, 1970-1972
actinic keratosis as, 1972, 1972*f*
arsenical keratosis as, 1972
Bowen disease as, 1972, 1973*f*
cutaneous horns as, 1970, 1971*f*
distal digital keratoacanthoma as, 1971-1972
keratoacanthoma as, 1971, 1972*f*
porokeratosis as, 1970, 1971*f*
squamous cell carcinoma, 1975-1977, 1979*f*-1980*f*
surgical lesion excision for, 1962, 1964*f*-1965*f*
syndromal conditions in, 1972-1973
Gorlin syndrome in, 1972-1973, 1974*f*
xeroderma pigmentosum in, 1973, 1975*f*
Skipping lesions, 1946
Slade technique
percutaneous, dorsal, for scaphoid fracture, 598
for scaphoid fractures, 668-669, 668*f*
Slaughterman's interdigital granuloma, 118
Slit-skin smears, for Hansen disease, 108, 108*t*
Slow intermittent passive positioning device, for elbow contracture, 857-858
Smaller-gauge needles, 146
Smith and Albin thenar H-flap, in reconstruction of amputated fingertip, 1716, 1716*f*
Smith fractures, 524-527, 525*f*
malunited, 580, 580.*e*4*f*
Snakes, venomous, 1789-1791, 1790*f*-1791*f*
preferred method of treatment of, 1791
Snow-Littler procedure, in cleft hand surgery, 1248, 1248*f*
"Snuffbox tenderness", 591
Sockets system, 1759
Soft tissue
contractures, 340.*e*2
at elbow, poor-quality, as contraindication to elbow arthroplasty, 909
Soft tissue coverage
in mangling injuries, 1495, 1521*b*
technique of, 1508-1519, 1509*f*-1517*f*
poor, acceptable length and, thumb reconstruction for, 1676, 1676*f*
Soft tissue defects
examination of, prior to free flap transfer, 1577
free flap selection influenced by, 1608-1609
of thumb
heterodigital flaps in, 1679-1681, 1680*f*
palmar advancement flaps in, 1676-1677, 1677*b*
reconstruction of, 1687-1688
Soft tissue deficiencies, after elbow contracture release, 859
Soft tissue distraction, preliminary, in management of radial longitudinal deficiency, 1329-1330, 1331*f*-1332*f*
Soft tissue envelope, in posttraumatic arthritis, 906
Soft tissue flaps, for split thumbs, types III and IV, 1307-1309, 1308*f*

and balancing, in management of radial longitudinal deficiency, 1331-1333, 1333*f*
of shoulder internal rotation deformity, 1088-1089
contraindications to, 1088-1089
indications for, 1088
preoperative planning for, 1089
technique for, 1089
Soft tissue tumors, 1987-2035
benign, 1997-2014
fibromatoses as, 2014
foreign body lesions as, 2010
ganglions and mucous cysts, 1997-2010, 1999*t*. *see also* Cyst(s); Ganglion(s)
giant cell tumors as, of tendon sheath, 2012, 2012*b*
granular cell tumors as, 2013-2014, 2013*f*
lipofibromatous hamartomas as, 2011-2012

Soft tissue tumors *(Continued)*
lipomas as, 2011
neurofibromas as, 2012
schwannomas (neurilemomas) as, 2012, 2013*f*
malignant, 2015-2020
soft tissue sarcomas as, 2015-2020, 2017*b*
SoftHand prosthetic component (SoftHand Pro), 1740-1741
Solar lentigo, 1965
Solid (nodular) BCC, 1974
Somatosensory evoked potentials (SSEPs)
in brachial plexus surgery, 1158
in thoracic outlet syndrome, 968
Sonography, for musculoskeletal tumors, 1990
Spacer wires, for segmental metacarpal loss, 244*f*
Spastic thumb adductor, insertion of, release of, 1109-1110, 1109*f*, 1110*b*
Spastic thumb intrinsic muscles, release or slide of origin of, 1108-1109, 1108*f*
Spasticity, 1080-1121
botulinum toxin for, 1088
diagnostic testing of, 1085-1086
dynamic electromyography of, 1086, 1087*f*
evaluation of, 1081-1082
imaging of, 1085
of intrinsic muscle, 1085
release or slide of, for thumb-in-palm deformity, 1108-1109, 1108*f*
operative management of, 1088-1118
elbow in, 1090-1093
preferred method of, 1091*f*, 1092-1093
types of, 1090
forearm in, 1093-1095
preferred method of, 1095, 1096*f*
intrinsic muscle spasticity and digital swan neck deformity in, 1113-1117, 1113*f*
preferred method of, 1116-1117
shoulder in, 1088-1090
preferred method of, 1090
types of, 1088
thumb-in-palm deformity in, 1106-1113, 1107*t*
preferred method of, 1112-1113
wrist and digital extension in, 1095-1102, 1097*f*, 1097*t*
preferred method of, 1101-1102, 1102*f*-1103*f*
wrist and digital flexor tightness in, 1102-1106, 1104*f*
preferred method of, 1105-1106
outcome studies of, 1118
physical examination of, 1082-1085, 1082*f*, 1083*t*
in tetraplegia, 1126-1127
Spasticity *(Continued)*
therapy for, 1086-1088, 1088*f*
treatment considerations of, 1081-1086, 1081*f*
Specimen, collection and handling, guidelines for, 64-65, 65*t*
Spiders, venomous, 1788-1789, 1789*f*
Spinal accessory nerve transfer
for brachial plexus injury, 1163-1166, 1163*f*, 1164*b*
to suprascapular, 1404, 1405*f*
Spinal cord stimulation implant, for complex regional pain syndrome, 1817
Spine, cervical, in thoracic outlet syndrome, 960*f*
Spiral bundle, of Dupuytren disease, 145
neurovascular, 138
Spitz nevus. *see* Benign juvenile melanoma
Splenomegaly, 1833
Splint/splinting
for burns, 1930-1931, 1931*f*, 1953, 1953*f*-1954*f*
in camptodactyly release, 1388
for clasped thumb, 1325
dynamic, for joint stiffness, 340.*e*1, 340.*e*1*f*
extension block, for proximal interphalangeal joint fracture-dislocation, 282-283
flexor hinge, wrist-driven, 1130-1131, 1131*f*
for Kirner deformity, 1274-1275
night
for arthrogryposis, 1380
for cubital tunnel syndrome, 942
for epicondylitis, 865
for trigger thumb, 1321
"playing," for ulnar collateral ligament injury, 303
postoperative, for mangling injuries, 1519, 1521*f*
for radial nerve palsy, 1065, 1065*f*
internal, 1065
static
after elbow contracture release, 857
for joint stiffness, 340.*e*1, 340.*e*1*f*
progressive, for joint stiffness, 340.*e*1, 340.*e*1*f*
serial, for joint stiffness, 340.*e*1, 340.*e*1*f*
sugar tong, for distal radial fracture, 531, 532*f*
in thumb reorientation osteotomy, 1383
for trigger finger, 1910
wrist, for carpal tunnel syndrome, 932
Split flexor pollicis longus (FPL) tenodesis, 1059
Split nail, 326, 326*f*-327*f*
Split thumb, 1305
Split-hand/split-foot (SHSF) syndrome, 1244
Split-thickness grafts, 1528-1530. *see also* Skin graft/grafting, split-thickness
Sporotrichosis, 82-83, 83*b*
clinical findings on, 82, 82*f*
deep (extracutaneous), 88
diagnosis of, 82-83, 83*f*, 84*t*
etiology and epidemiology of, 82
treatment of, 83
Spurling test, for cervical nerve root impingement, 927
Spurt test, 1482
Squamous cell carcinoma, 1975-1977, 1979*f*-1980*f*
of perionychium, 334-335, 335*f*
SSEPs. *see* Somatosensory evoked potentials (SSEPs)
"S"-shaped incision, in transmuscular brachioradialis-splitting approach, for radial tunnel syndrome, 951, 951*f*
Stable fractures (type II), nondisplaced, preferred method of, 781
Staphylococcal scalded skin syndrome, 17
Staphylococcus aureus, 17, 1834-1835
methicillin-resistant, 18, 18*f*
Staple fixation
in capitate-lunate-hamate-triquetrum fusion, 393, 394*f*
for scaphoid fractures, 596
in scaphotrapeziotrapezoid fusion, 390
Stapling, hemiepiphyseal, of distal radius, 1359-1360, 1360*f*
Static macrodactyly, 1276-1277
Static splints
for elbow contracture, 857
for joint stiffness, 340.*e*1, 340.*e*1*f*
Static techniques, in ulnar nerve palsy, 1048-1051
Steindler flexorplasty, 1418, 1418*f*
Steindler procedure, modified, for elbow reconstruction, in brachial plexus injury, 1195-1196, 1195*f*, 1196*b*
Stener lesion, 302-303, 303*f*
historical review of, 303
postoperative management and expectations in, 306
treatment of, 303, 304*f*-305*f*, 306*b*
Stewart-Treves syndrome, 1981-1983
Stick-up test, 966-967
Stiffness
after bending fractures, minimization of, 567-568
after humeral fracture, 730-731, 730*f*
after radial head fractures, 764, 764*f*
after ulnar fracture, 784
of finger and hand, 338-344
case study on, 343.*e*3*b*, 343.*e*3*f*-343.*e*7*f*
pathophysiologic findings in, 338, 339*f*
treatment of, 338-343

Stiffness *(Continued)*
evaluation and planning of, 338-340
nonoperative intervention for, 340
operative intervention for, 340-343
recurrent, after elbow contracture release, 859
of thumb, after pollicization, 1303
Stiles-Bunnell procedure, in ulnar nerve palsy, modified, 1051, 1052*f*
Stiletto flap, 1383
Stingrays, venomous, 1793
Straight line of pull, in tendon transfers, 1025
Streptobacillus moniliformis, 47
Streptokinase, for free flap failure, 1585
Streptomycin
for actinomycetoma, 70-73
dosage of, 101*t*
for tuberculosis, 92-93, 100, 101*t*
Stress fractures, after bone grafting, 1616-1617, 1616*f*
Stretch injury, in responses to nerve injury, 985
Styloid
radial, shear fractures of, 569-570, 570*f*-571*f*
of ulna, fracture of, 493, 493*f*
Styloidectomy, radial
for scaphoid nonunion advanced collapse, 622
for scapholunate dissociation, 449
Subaponeurotic space abscess, 37
treatment of, 38-39
Subclavian artery, in thoracic outlet syndrome, 972
Subcoracoid space, in thoracic outlet syndrome, 964
Subcutaneous anterior transposition, of ulnar nerve, for cubital tunnel syndrome, 944, 944*f*-945*f*
Subcutaneous digital nerve block, 9-10, 11*f*
Subcutaneous flap, 1593
Subcutaneous fungal infections, 80-84
classification of, 80-81
paronychia and, chronic, 81, 81*f*, 81.*e*1, 81.*e*1*f*
phaeomycotic cysts and, 84
sporotrichosis and, 82-83, 82*f*-83*f*, 83*b*, 84*t*
Subcutaneous nodules, 1836
Subcutaneous pseudosarcomatous fibromatosis, 2014
Subcutaneous space abscess, 37
treatment of, 38-39
Subfascial space infections, deep, 36-40, 38*f*
clinical presentation and evaluation of, 37-38
pertinent anatomy in, 38
Subfascial space infections, deep *(Continued)*
postoperative management of, 39-40
treatment for, 38-39
preferred method of, 39
Subluxating nerve, 885
Subluxation
of extensor carpi ulnaris, 511-512, 511*f*
of metacarpophalangeal joint, simple, 299
of proximal interphalangeal joint, 294-295, 295*f*
of scaphoid, 435
Submuscular transposition, of ulnar nerve, for cubital tunnel syndrome, 945, 945*f*
Subungual hematoma, 318-319, 320*f*
Subungual melanoma, 1978
Subungual nevi, 332-333, 332*f*-333*f*
Subungual osteochondroma, 2022
Suction drainage, closed, after open release of elbow contracture, 853
Sudeck atrophy, classic, 1805
Sudomotor activity, assessment of, in complex regional pain syndrome, 1808
Sugar tong splint, for distal radial fracture, 531, 532*f*
Superficial basal cell carcinoma, 1974
Superficial displacement, of Dupuytren disease, 138
Superficial fibers, 134
Superficial finger flexor tendons, in rheumatoid arthritis, rupture of, 1857
Superficial head, of interosseous muscles, 338.*e*3, 338.*e*5*f*
Superficial intradermal anesthetic injection, 145
Superficial palmar fascia, anatomy of, in Dupuytren disease (DD), 134
Superficial radial nerve, grafting of, 997
Superficial spreading melanoma, 1978, 1980*f*
Superficialis
harvest of, 1029-1030
opponensplasties, in median nerve palsy, 1029-1031
transfer of
to profundus tendon, in cerebral palsy, 1104-1105, 1106*f*, 1107*b*
in radial nerve palsy, 1070-1071, 1071*b*
postoperative management of, 1071
in ulnar nerve palsy, 1051-1053
modifications of, 1051-1053
results of, 1053
Supine position, in elbow arthroscopy, 886
Supraclavicular brachial plexus, 1146
surgical approach to, 1156-1157, 1156*f*
Supraclavicular nerve block, 6-7
bilateral procedures and, 2
ultrasound-guided, 7*f*
Supracondylar fractures, of distal humerus. *see also* Humerus, distal
management of, 721
Suprascapular nerve transfer, for brachial plexus injury, 1164-1165, 1164*b*, 1164*f*
outcomes of, 1165, 1165*f*
Sural nerve, grafting of, 997, 997*f*
in brachial plexus reconstruction, 1161-1162, 1161*f*
Surface replacement arthroplasty, 356-357
Surgical excision
for burns, 1932-1935, 1933*f*
lesion, 1962, 1964*f*-1965*f*
primary wide, for musculoskeletal tumors, 1992
of radial head, 744-745
delayed, 743-744, 744*f*
outcome of, 759
as preferred treatment, 750-752, 753*f*, 754*b*
of radial head fragments, 743
outcome of, 758-759
as preferred treatment, 746, 748*b*, 749*f*
of ulnar anlage, in management of ulnar deficiency, 1336-1338, 1339*f*
of warts, 123
Suspension system, 1759
Suture
in biceps rupture repair, 877, 878*f*
for extensor tendon laceration repair, 158-159
in triceps avulsion repair, 880, 880*f*-881*f*
Swan neck deformity, 294
classification of, 1880*t*
intrinsic muscle spasticity and, 1113-1117, 1113*f*
treatment of, preferred method of, 1116-1117
in rheumatoid arthritis, of fingers, 1879-1890, 1880*t*
type I, 1879-1883, 1881*f*, 1899*f*
type II, 1883
type III, 1883-1885
type IV, 1886-1890
of thumb, 1896-1897, 1896*f*
operative treatment
indications for, 1896-1897, 1896*t*, 1897*f*
options for, 1896*t*
treatment of, 295*f*
options for, 1880*t*
Sweat gland tumors, 1983
Symbrachydactyly, 1231, 1258-1260, 1261*b*
classification of, 1258-1259, 1258*t*
clinical features of, 1258-1259

Symbrachydactyly *(Continued)*
management of, 1260
in monodactylic type, 1260
in oligodactylic type, 1260
in peromelic type, 1260, 1261*f*
in short finger types, 1260
types of, 1258, 1258*f*
anatomy in, 1259-1260, 1259*f*
Sympathectomy
for complex regional pain syndrome
chemical, 1819-1820
surgical, 1820
summary of role of, 1820
Sympathetic blockade, in complex regional pain syndrome, 1808-1809
Sympathetic nervous system, in complex regional pain syndrome, function of, 1803
Syndactyly, 1217-1227, 1232*b*
in acrosyndactyly, 1227, 1227*f*-1228*f*
in Apert syndrome, 1227-1232, 1228*t*, 1229*f*
classification of, 1217
cleft hand and, 1244, 1245*f*
release of, 1246-1251, 1249*f*-1251*f*
complete, 1217, 1218*f*
complex, 1217, 1218*f*-1219*f*
in dystrophic epidermolysis bullosa, 1231-1232, 1232*f*
epidemiologic findings of, 1217, 1218*f*
expected outcomes for, 1232
incomplete, 1217
management considerations for, 1217-1227, 1218*f*
commissure reconstruction in, 1219-1220, 1219*f*-1220*f*
complications of, 1223
outcome of, 1222-1223
paronychial fold formation in, 1221-1222
preferred method of, 1219*f*, 1223*f*, 1224-1227, 1226*f*-1227*f*
separation and resurfacing of digits in, 1220-1221, 1223*f*-1225*f*
pathologic findings in, 1217
in Poland syndrome, 1231, 1231*f*
preoperative evaluation of, 1217
simple, 1217, 1218*f*
special cases of, 1227-1232
surgery for, 1218
timing of, 1219, 1219*f*
in symbrachydactyly, 1231
web space, postburn, 1938, 1940*f*
Synergism, in tendon transfers, 1025
Synostosis
radioulnar, 803-804, 803*f*-804*f*, 804*t*. *see also* Radioulnar synostosis
tibiofibular, 1356, 1356*f*
Synovectomy
in mycobacterial tenosynovitis, 95
of proximal interphalangeal joint, 1878-1879
for rheumatoid arthritis, 897
Synovectomy *(Continued)*
of metacarpophalangeal joints and, 1868
soft tissue reconstruction
postoperative management after, 1870
techniques of, 1868-1870
of thumb, with reconstruction of extensor mechanism, 1898
of wrist, 1859
for wrist arthritis, arthroscopic, 689-690
Synovial sarcoma, 2017
Synovitis, as complication of flexor tendon grafting, 225, 225.*e1f*
Synpolydactyly, 1213-1214, 1213*f*-1214*f*, 1218, 1234, 1235*f*
treatment of, 1235-1236
Syphilis, 73-74, 73*f*
Systemic lupus erythematosus, 1837-1839, 1837*f*
authors' preferred method of treatment for, 1838
digital deformity in, 1838
proximal interphalangeal joint deformity in, 1838
thumb deformity in, 1838-1839
wrist deformity in, 1837-1838
Systemic sclerosis, 1839

Thermography, in complex regional pain syndrome, 1809
Thigh
anterolateral, free flap from, 1513-1515, 1516*f*, 1597, 1598*f*
anterolateral, free flap from, for burn deformities, 1945
Third-degree burns, 1928-1929, 1929*f*
Thomine coefficient, 133
Thompson APL sling, 363*f*
Thompson approach, to radial tunnel syndrome, 951-952, 951*f*
Thoracic intercostal nerves, transfer of, for brachial plexus birth palsy, 1405-1406
Thoracic outlet, anatomy of, 962, 962*f*
Thoracic outlet syndrome, 959-978
arterial, 959-960, 960*f*
case study in, 977.*e*1*b*
classification of, 959-961
Roos, 961
Wilbourn, 959
clinical findings in, 964
diagnostic studies of, 968, 970*b*
electrodiagnostic evaluation of, 968
epidemiology of, 962, 962*f*
history of, 959
neurogenic, 960
electrically negative, 960-961
true, 960, 961*f*
physical examination of, 964-967, 970*b*
inspection and palpation, 964-966, 965*f*-967*f*
provocative tests for, 966-967
radiologic evaluation of, 968, 970*f*
recurrent, after surgical treatment, 975-976
treatment of, 968-976
Thoracic outlet syndrome *(Continued)*
complications of, 974-975
nonoperative, 968-970, 970*b*
operative, 970-971
recurrent symptoms after, 975-976
preferred method of, 971-976, 971*f*-974*f*
results of, 975-976, 976*f*
venous, 960, 960*f*
Thoracodorsal artery perforator flap, 1602-1603
Thoracodorsal nerve transfer, for brachial plexus injury, 1177
Thoracoepigastric flap, for soft tissue defects of thumb, 1680*f*
Thoracoscopic sympathectomy, for vasospastic disease, 2053
Thrombocytopenia-absent radius (TAR) syndrome, radial deficiency associated with, 1289, 1290*t*
longitudinal, 1329*t*
Thrombolytic agents, for free flaps failing, saving of, 1584-1585
Thrombosis
after toe transfer, 1669
in ulnar artery, 2042, 2045*f*, 2053
venous, 2054-2055
Through-and-through incision, for felon, 27*f*, 27*t*
Thumb
absent, 1255-1270
in cleft hand, management of, 1251, 1254*f*
with acceptable length and poor soft tissue coverage, 1676-1677, 1676*f*, 1677*b*
heterodigital flap in, 1679-1681, 1680*f*
dual innervated, 1684, 1685*f*
first dorsal metacarpal artery, 1684-1686, 1686*f*
innervated, 1681-1684, 1681*b*
radial-innervated, 1682-1684, 1683*f*, 1684*b*, 1684.*e*1*f*
with proximal releasing incision, 1677-1679, 1679*b*, 1679*f*
without proximal releasing incision, 1677, 1678*f*
adduction of, restoration of, 1056-1058
after total amputation with preservation of basal joint, pollicization for, injured digit in, 1699-1703
arthritis mutilans of, 1897
arthrodesis for, 1899-1900
arthrodesis of, in ulnar nerve palsy, 1059
basal joint of
amputation with preservation of, 1696-1699
composite radial forearm flap for, 1697-1699, 1700*f*, 1701*b*, 1699.*e*1*f*
Thumb *(Continued)*
osteoplastic reconstruction for, 1696-1697, 1697.*e*1*f*
pollicization for, index/long finger stump in, 1699-1703, 1702*f*-1704*f*, 1705*b*
carpometacarpal joint of, 312-315
clasped, 1324-1325
contractures of, postburn, 1938-1939, 1941*f*
deformity of, 1289-1292, 1894-1901
pathophysiology of, 1894, 1894*t*
preferred method of treatment of, 1839
psoriatic arthritis in, 1836
secondary to joint destruction, 1897-1901
in systemic lupus erythematosus, 1838-1839
type I, 1894-1896, 1895*f*
type II, 1896
type III, 1896-1897
type IV, 1897
type V, 1897
duplication of, 1304-1315, 1315*b*
classification of, 1304, 1304*t*
clinical features of, 1304-1305, 1306*f*
complications of, 1313-1315
epidemiologic findings in, 1304
general considerations in, 1304-1305
treatment of, 1305-1315
outcomes of, 1310-1313, 1316*f*
in type I or II split thumb, 1305-1307, 1306*f*-1307*f*
in type III or IV split thumbs, 1307-1310, 1308*f*-1313*f*
in type V or VI split thumbs, 1310
in type VII split thumb, 1310, 1313*f*-1316*f*
and first web, classification of ulnar deficiency based on, 1338*t*
flexion, reconstruction of, 1779*b*
flexor tendon reconstruction of, 217-219, 220*b*
free tendon graft in, 218-219
technique in, 218-219
indication of, 217-218
staged tendon reconstruction in, 219
floating, 1291, 1291*f*
fractures of, 270-275
articular, avulsions of, 271
in children, 1439-1442
diaphyseal, in children, 1440
at metacarpal base, 272-273
in children, 1440-1441, 1441*f*
preferred method of treatment for, 1441-1442, 1442*f*
complications of, 273
expected outcomes of, 273
operative management of, 274*b*
preferred method of treatment of, 272, 272*f*-273*f*
at metacarpal head, 271

Thumb *(Continued)*
phalangeal, 270
in children, 1439
preferred method of treatment for, 1439-1440, 1440*f*
extraarticular, 270, 270*f*
Rolando, 273-275, 274*f*-275*f*
preferred method of treatment of, 274-275
at shaft, 271-272, 271*f*
function of, reconstruction of, 1777
heterodigital flap in, neurovascular island flap, 1686-1687, 1688*f*, 1689*b*
hypoplasia of, 1289-1303, 1290*f*, 1304*b*
classification of, 1290-1292, 1290*t*
diagnosis of, 1289
treatment for, 1292-1303
complications of, 1303, 1303*t*, 1304*f*-1305*f*
results of, 1301-1303, 1302*f*
type I, 1290
type II, 1290, 1291*f*, 1290.*e*1*b*, 1290.*e*1*f*-1290.*e*3*f*
type III, 1290, 1291*f*
type IV, 1291, 1291*f*
type V, 1291
interphalangeal joints of, 296-297
mangling injuries of, treatment of, 1493
opposition of
absence of, 1320
biomechanics of, 1026
deficit and deformity in, 1026
in median nerve palsy, tendon transfers for, 1026-1036. *see also* Opponensplasty, for median nerve palsy
history of, 1026
opponensplasty insertions in, 1027-1029, 1028*f*
patient counseling in, 1026-1027
prevention and preoperative treatment of contractures prior to, 1027
principles of, 1027
pulley design in, 1027
results of, 1027-1029, 1028*t*, 1029*f*
selection of motor for transfer in, 1027
osteoarthritic, treatment of, 345-372
with questionable remaining length, 1688-1691
regional and distant flaps for, 1694-1696
"Z"-plasty procedures, 1689-1691
four-flap, 1690-1691, 1690*b*, 1691*f*-1692*f*
simple, 1689, 1690*f*, 1689.*e*1*f*
reconstruction of, 1292-1295, 1293*b*, 1674-1707
after partial or complete traumatic loss, 1675-1704
Thumb *(Continued)*
after total amputation with destruction of basal joint, 1703-1704

preferred method of treatment of, 1654-1656
postburn, 1943
skin incisions for, 1665-1666
wraparound flap in, 1657-1658, 1659*f*
flap design in, 1658
indications for, 1657-1658
toe fixation in, 1666-1668
venous preparation for, 1666
Tophi, gouty, 57-58, 58*f*
Topical medications, 1960, 1960*f*
Toronto Test Score, 1394, 1396*t*
Torus fracture, in children, 1448
recommended treatment of, 1448, 1450*f*
Total elbow arthroplasty (TEA), 905-920, 919*b*
complications of, 914-915, 914*f*
contraindications to, 909
for fractures of distal humerus, 906-907, 908*f*
geriatric, 710.*e*1*b*, 710.*e*1*f*
for hemophilic arthropathy, 909
Total elbow arthroplasty (TEA) *(Continued)*
historical review of, 909, 910*t*
mortality rates and, 918
paratricipital exposure for, 711.*e*1*b*, 711.*e*1*f*-711.*e*2*f*
postoperative management and expectations after, 913-918
of posttraumatic arthritis, 906, 907*f*
for primary osteoarthritis, 907-909
for rheumatoid arthritis, 905-906, 906*f*
Total wrist arthrodesis, 395-401
author's preferred method of treatment for, 396-399, 396*f*-400*f*
closure in, 399, 401*f*
complications of, 400, 401*f*-402*f*
postoperative management of, 399
Total wrist replacement, 404-414, 406*f*
centralization of extensor tendons in, 413-414, 414*f*
patients on, 414
preoperative evaluation for, 407
Toxicity
prevention of, 4*b*
systemic, prevention of, 4*b*
Traction, dynamic skeletal, for proximal interphalangeal joint fracture-dislocation, 283
outcomes of, 287
postoperative protocol for, 286-287
preferred method for, 285-287, 285*f*-287*f*, 286*b*
Traction injury, to brachial plexus, 1148-1149, 1148*f*
Transcondylar fractures, of distal humerus. *see also* Humerus, distal
management of, 721
Transfixation pins, for segmental metacarpal loss, 244*f*
Transhumeral amputation, 1755-1756, 1756*f*
with elbow disarticulation, 1754-1756, 1759*f*
Transmetacarpal digital nerve block, 9, 11*f*
Transmuscular brachioradialis-splitting approach, to radial tunnel syndrome, 951, 951*f*
Transolecranon (anterior) fracture-dislocation, of elbow, 784.*e*13*b*, 784.*e*13*f*-784.*e*14*f*
Transolecranon fracture-dislocations, 816-817, 816*f*
Transplantation, toe-to-hand, 1643-1673. *see also* Toe transfer
Transposition flaps, 1542
axial-pattern, 1543-1545
flag, 1545, 1545*f*
random-pattern, 1542
rhomboid, 1543, 1544*f*
"Z"-plasty, 1542, 1542*f*, 1543*b*
four-flap, 1543, 1543*f*

Transradial amputation, 1737, 1754, 1755*f*
with wrist disarticulation, 1753-1754, 1754*f*
Transscaphoid perilunate fracture-dislocations, 470-471
arthroscopy for, 670-671, 671*f*-672*f*
Transscaphoid-transcapitate-perilunate fracture-dislocations, 471-472, 472*f*
Transthecal digital nerve block, 9, 10*f*
Transtriquetrum-perilunate fracture-dislocations, 472, 473*f*
Transverse deficiency, 1345-1346, 1346*b*
evaluation of, 1345-1346, 1346*f*
pertinent anatomy in, 1346
surgical treatment of, 1346
expected outcomes for, 1346
preferred technique for, 1346, 1347*f*
Transverse fibers, of interosseous muscles, 338.*e*3, 338.*e*5*f*
Transverse intercarpal ligaments, 422
Transverse retinacular ligament, 338.*e*5
Trapeziometacarpal joint
degenerative disease of, arthroscopy for, 693
portals of, for arthroscopy of wrist, 657, 658*f*
Trapezium
dislocation of, 476
fractures of, 626-629, 627*b*, 627*f*
imaging of, 628
incidence of, 625*t*
mechanism of injury in, 626-628, 628*f*
treatment of, 628-629, 628*f*-629*f*
Trapezius tendon, transfer of, for shoulder reconstruction, in brachial plexus injury
contralateral lower, 1189, 1191*f*-1192*f*
lower, 1188-1189, 1189*f*-1191*f*
upper, 1187-1188
Trapezoid
dislocation of, 476
fractures of, 636, 636*b*
incidence of, 625*t*
Trapezoidal osteotomy, Watson's, for radial fracture, 580.*e*3, 580.*e*3*f*
Trauma
associated with distal radial fracture, 573
in elbow instability, 830
elbow stiffness caused by, 902-903
Traumatic brain injury, 1080-1081
Traumatic left midcarpal amputation, 1738*f*
Traumatic loss of digits in pediatric hand, 1650-1651
Trazodone, for complex regional pain syndrome, 1812*t*
Triad repair, terrible, 822*b*
Triangular fibrocartilage complex (TFCC), 480-481, 1444-1445
injuries to
class IA, 677*f*
class IB, 678, 678*f*-679*f*
class II, 687-688
Triangular fibrocartilage complex (TFCC) *(Continued)*
radial-sided, knotless repair of, 685, 686*f*-687*f*
treatment of, 676-677
lesions in, 487-491
author's preferred method of treatment for, 490-491, 490*f*
outcomes in, 491
Palmer's classification of, 487*t*, 488*f*
class 1A tear in, 489
class 1B tear in, 489
class 1C tear in, 489, 489*f*
class 1D tear in, 489-490, 490*f*
neurovascular supply to, 483, 483*f*
repair of (class 1B injury), 492-493
Triangular ligament, 156*f*, 338.*e*5
function of, 154
Triceps
advancement and excision of, in ulnar fracture management, 777, 777*b*
avulsions and rupture of, 878-881, 879*f*, 881*b*
preferred method of treatment of, 880-881, 880*f*-881*f*
partial tears of, 880
in tetraplegic patient, biceps transfer to, 1127-1129, 1128*f*, 1129*b*
transfer of
to axillary nerve, in musculocutaneous nerve transfer, for brachial plexus injury, 1172-1173, 1173*f*-1174*f*
outcomes of, 1174*b*, 1174*f*
to biceps, for elbow reconstruction, in brachial plexus injury, 1196-1197, 1197*b*, 1197*f*
Triceps-reflecting anconeus pedicle (TRAP) approach, to distal humeral fractures, 714, 715*f*
Triceps-splitting approach, to distal humeral fracture, 712-713, 713.*e*1*b*, 713.*e*1*f*-713.*e*4*f*
Triceps-splitting open reduction and internal fixation, 713.*e*1*b*, 713.*e*1*f*-713.*e*4*f*
Trigger digits, 1908-1915
in childhood, 1916
classification of, 1908
demographics of, 1908
outcomes of steroid injection for, 1909*t*
pathologic findings of, 1908
Trigger finger, 1322, 1323*f*, 1908
classification of, 1908
demographics of, 1908
splinting in, 1910
surgical treatment of, 1910-1914, 1911*f*
treatment of, 1909-1914
complications, 1914-1915
preferred method of, 1914
surgical, 1917-1919, 1918*f*
open trigger digit release in, 1912-1913, 1912*f*
Trigger finger *(Continued)*
percutaneous trigger digit release in, 1913-1914, 1913*b*-1914*b*, 1913*t*, 1914*f*
skin incisions, 1911-1912, 1911*f*-1912*f*
topographic anatomy, 1911-1912, 1911*f*-1912*f*
technique of injection of, 1917, 1917*f*
Trigger thumb, 1320-1322, 1322*b*
congenital, 1915-1916
treatment, 1915-1916
surgical technique, 1915-1916
incidence and etiologic findings of, 1320-1321, 1321*f*
treatment of, 1321-1322
natural history in, 1321
nonoperative, 1321
surgical, 1321-1322, 1322*f*
Trimethoprim-sulfamethoxazole
for actinomycetoma, 72-73
for tuberculosis arthritis, 97
Triphalangeal thumb, 1315-1320, 1317*f*-1319*f*, 1320*b*
management of, 1318-1319
treatment of, 1319-1320
absence of thumb opposition in, 1320
concomitant anomalies, 1320
extra interphalangeal joint in, 1319-1320
length and angulation in, 1319
thumb/index finger web space, 1320, 1320*f*
Triquetral-hamate portal, for arthroscopy of wrist, 657
Triquetrocapitate ligaments, 423
Triquetrohamate fusion, 389
Triquetrohamate ligaments, 423
Triquetrum, 660*f*
fracture of, 427, 624-626, 625*b*
body, 625-626
in children, 1447, 1447*f*
clinical and radiographic features of, 626
dorsal cortical, 624-625, 626*f*
incidence of, 625*t*
patterns of, 624-626
treatment of, 626, 627*f*
volar avulsion, 626
Triquetrum-ulnar lunate ligaments, plication of, 665
Triscaphe arthrodesis, 389. *see also* Scaphotrapeziotrapezoidal fusion
Trochlear fractures. *see also* Humerus, distal
classification of, 703-704

classification and treatment of, 1233, 1233*f*
epidemiologic findings, 1232
surgical technique for, 1233-1234, 1233*f*
Ulnar portal, distal, in elbow arthroscopy, 891
Ulnar styloid fixation, 559-561
Ulnar translocation, in radiocarpal instability, 458-459, 458*f*
Ulnar translocation ratio, measurement of, in wrist instability, 430, 431*f*
Ulnar variance, 480
measurement of, in wrist instability, 430
method of perpendiculars for, 485, 485*f*
negative, in stages I, II or IIIA Kienbock disease, 641-646
positive or neutral, in stages I, II or IIIA Kienbock disease, 646
Ulnar-humeral joint, functional anatomy of, 813, 814*f*
Ulnar-shortening osteotomy
for class 1B tear, 490-491, 490*f*
for ulnar impaction syndrome, 501-503, 502*f*
Ulnocapitate ligament, 420-421, 481-482
Ulnocarpal ligaments, 481-482
palmar, 420-421, 421*f*
Ulnocarpal stress testing, 484, 484*f*
Ulnohumeral instability, after posterior Monteggia fracture, 784.*e*30*b*, 784.*e*30*f*
Ulnohumeral joint, surface of, assessment of, in stiff elbow, 847
Ulnotriquetral (UT) ligament, 659*f*
Ultrasonic probes, in monitoring of vascularized bone grafts, 1615

Ultrasonography
axillary block and, 8
for brachial plexus birth palsy, 1411, 1411*f*
of carpal instability, 432
of distal radioulnar joint, 485
infraclavicular nerve block and, 7*f*
regional anesthesia and, 5
supraclavicular nerve block and, 6-7, 7*f*
Undisplaced fractures, of radial head fractures, management of, 741-742, 742*f*
Unicameral bone cysts, 2024, 2024*f*
Unicolumnar fractures, of distal humerus. *see also* Humerus, distal
management of, 724-725, 725.*e*1*b*, 725.*e*1*f*-725.*e*2*f*
Unicolumnar injury, 725.*e*1*b*, 725.*e*1*f*-725.*e*2*f*
Unilateral longitudinal incision, for felon, 27*f*, 27*t*
Universal II implant, 406
surgical technique for, 407-410, 408*f*-411*f*
Unna boot dressing, 1538
Unstable fractures, external fixation for, 535
Upper extremity
amputation, rehabilitation after, 1757-1758
bone defects of, vascularized bone grafting for, 1614
compartments of, 1768*t*, 1771.*e*1*b*
embryology of, 1208-1216, 1209*t*
fibular and iliac crest grafts in, 1622-1623, 1623*f*
loss of, 1756-1757
mangling injuries to, 1486-1527, 1487*f*
nonmicrosurgical coverage of, 1528-1573
Upper limb tension test, for thoracic outlet syndrome, 967, 969*f*
Urokinase, for free flap failure, 1585

V

VACTERL syndrome, radial deficiency associated with, 1289, 1290*t*, 1329*t*
Vacuum-assisted wound closure (VAC), 51
Valacyclovir, for herpes simplex virus, 120
Valgus instability, after radial head fractures, 764
Valgus stress test, 743-744, 744*f*
Valproic acid, for complex regional pain syndrome, 1813*t*
Varus posteromedial rotational injury, in elbow dislocation, 817, 818*f*
Varus rotational instability pattern, posteromedial, 784.*e*9*b*, 784.*e*9*f*-784.*e*10*f*
Varus stress test, 743-744, 744*f*
Vascular anastomoses, in toe transfer, 1668
Vascular lesions, nonhemangiomatous, 1968-1970
Vascular pedicle, 1574
Vascular system
anatomy of, 2036, 2037*f*
disorders of, 2036-2059
arterial
closed, 2042-2047, 2044*f*-2046*f*
complications of, 2046-2047, 2047*f*-2048*f*
preferred method of treatment of, 2046-2047, 2047*f*
open, 2040-2042, 2040*f*
complications of, 2042
postoperative care after, 2042
preferred method of treatment of, 2040-2042, 2041*f*-2042*f*
vein grafting of, 2041, 2041*f*, 2042*b*, 2043*f*
evaluation of, 2038-2039, 2039*f*, 2040*b*
management of, 2040-2056
distal sleeve anastomosis of, 2051, 2051*f*
end-to-end anastomosis of, 2051, 2051*f*
preoperative evaluation in, 2048-2049, 2049*f*
in situ bypass of, 2049-2052, 2050*f*
complications of, 2051-2052, 2052*f*
insufficiency of, in scleroderma, 1840
malformations of, 2055-2056
in mangling injury, repair/reconstruction of, 1505-1508, 1506*f*-1507*f*, 1508*b*
case study of, 1505.*e*1*b*, 1505.*e*1*f*-1505.*e*3*f*
Vascular territory, 1539
Vascularity, of wound, 1530
Vascularized bone grafts. *see* Bone graft(s)
Vascularized composite tissue allotransplantation, 1483-1484
Vascularized medial femoral trochlea osteocartilaginous flap reconstruction, in scaphoid nonunion, 619, 619.*e*4*b*, 619.*e*4*f*-619.*e*5*f*
Vascularized nail graft, in toe transfer flap design and elevation in, 1661-1663, 1662*f*
flap designs and elevation in, 1661-1663, 1663*f*
indications for, 1661, 1662*f*
Vascularized nerve graft, 999
Vasospasm, after toe transfer, 1669
Vasospastic disorders, management of, 2052-2054
nonsurgical, 2053
operative, 2053-2054, 2053*f*-2054*f*
postoperative, anticoagulation and, 2054
Vectors, infections and, 46-58
Vein grafting
for ischemia, 2037-2038
for open arterial trauma, 2041, 2041*f*, 2042*b*, 2043*f*
postoperative care after, 2042
reversed, for aneurysm, 2054, 2055*f*
Vein(s)
dissection of, 1479, 1479*f*
distal, location of, for replantation, 1481*b*
preparation of, in toe transfer, 1666
Venograph, in thoracic outlet syndrome, 968, 970*f*
Venomous injuries
of hand, 1794*b*
management of, 1788-1796, 1795*b*
case study of, 1793.*e*1*b*, 1793.*e*1*f*
Venous flaps, free, 1577
Venous malformations, 2055-2056, 2056*f*
Venous thrombosis, 1482, 2054-2055
Verruca plana, 1962
Verruca vulgaris, 121, 1962. *see also* Warts
of perionychium, 333
Vesicles, anthrax, 68-69, 69*f*
Vessels
preparation of, in toe transfer, 1645
resection of, 1478-1479, 1479*f*
Vibration thresholds, in compression neuropathies, 928
Vibrio infections, 48
Vibrometers, fixed-frequency and variable-frequency, 928
Vickers ligament, in Madelung deformity, 1339
release of, 1339, 1340*f*
Villonodular tenosynovitis, pigmented, 2012, 2012*b*
Viral infections, chronic, 119-125
acquired immunodeficiency syndrome (AIDS) and, 119-121, 119.*e*1*t*
etiology, diagnosis, and treatment of, 63*t*
human orf and, 123-124, 124*f*
Milker's nodule and, 124-125
warts and, 121-123, 122*f*
Viral warts. *see* Verruca vulgaris
Vitamin C, for complex regional pain syndrome, 1811, 1816*t*
Volar advancement V-Y flap, in reconstruction of amputated fingertip, 1714, 1715*f*
Volar approach
for thenar space, 35-36, 36*f*
transverse, 39, 39*f*
zigzag, 38-39, 39*f*
Volar capsulectomy, arthroscopic arthrolysis and, 691
Volar incision, for felon, 27*f*, 27*t*
Volar instability, of thumb metacarpophalangeal joint, chronic, 311-312
Volar intercalated segment instability (VISI), 418-419

Volar interossei, 338.*e*3-338.*e*4
Volar ligament reconstruction, of thumb carpometacarpal joint, technique of, 313-314, 314*f*
Volar plate
  of metacarpophalangeal (MP) joint, 338.*e*1, 338.*e*2*f*
  of proximal interphalangeal joint, 338.*e*2*f*, 340.*e*1, 338.*e*1-338.*e*3
  pulley reconstruction using, 222
Volar plate arthroplasty, for proximal interphalangeal joint fracture-dislocation, 284
  complications of, 290
  postoperative management of, 290
  preferred method for, 288-290, 289*f*, 290*b*
Volar plate fixation, of distal radial fracture, open reduction with, 548-552, 549*f*-553*f*, 554*b*
Volar portals, for arthroscopy of wrist, 655-656, 653.*e*1*t*
Volar proximal interphalangeal dislocations, 280-281
  treatment of, 280-281
    closed, 280-281
    open reduction in, 281
    outcomes of, 281
    preferred method of, 280-281
Volar radial (VR) portal, for arthroscopy of wrist, 655-656
Volar release, 1770
Volar retinacular (flexor tendon sheath) ganglion, 2005, 2005*f*
Volar skin, 1528
Volar surgical approach, for contractures, 341.*e*1, 341.*e*1*f*
Volar ulna (VU) portal, for arthroscopy of wrist, 656
Volar wrist ganglions, arthroscopic excision of, surgical technique for, 688-689, 689*f*
Volar wrist synovectomy, for rheumatoid arthritis, 1847*b*, 1859
Volkmann contracture, 1772-1786, 1773*f*
  classification of, 1773-1774, 1774*f*-1775*f*
  complications of, 1785-1786
  flexor pronator slide for, 1779*b*
  of hand, 1783-1785
  ischemic, 1764
    surgical options for management of, 1776*t*
  late management of, 1785*b*
  moderate, 1778.*e*1*b*, 1778.*e*1*f*
  neonatal, 1763-1764, 1764*f*
  operative treatment of
    bone procedures in, 1775-1776
    soft tissue procedures in, 1776
  outcomes of, 1781-1783
  preferred methods of treatment, 1776-1781
Volkmann contracture *(Continued)*
  severe, 1782.*e*1*b*
  treatment of, 1774-1786
    operative, 1775-1776
Volkmann test, for digital flexor tendon, 1084-1085, 1085*f*
Voltage-gated ion channels, 980-981
von Recklinghausen disease, 2012
"V-Y" advancement flap, 1548-1550, 1549*f*-1551*f*

W
Wafer procedure, for ulnar impaction syndrome, 497*f*, 501, 501*f*
Wafer resection, of ulnar head, arthroscopic, 687-688, 687*f*
Waist fracture, in scaphoid, delayed presentation of, 603
Wallerian degeneration, in responses to nerve injury, 984-985, 984*f*
War Nerve Injuries Clinic (WNIC), 1010.*e*1
Wartenberg syndrome, 948
Warts, 121-123, 1962-1964
  classification of, 121
  common verrucated, 121
  diagnosis, 121
  flat (plane), 121
  multiple, 121
  treatment of, 121-123, 122*f*
  viral, of perionychium, 333
Wasted intermetacarpal spaces, 1061
Watershed, 1540
Watson's trapezoidal osteotomy, for radial fracture, 580.*e*3, 580.*e*3*f*
Web creep, after separation of syndactyly, 1223, 1226*f*
Web space
  abscess of, 37-38, 38*f*
    treatment for, 38, 39*f*
      preferred method of, 39
  Dupuytren disease in, 134
  first
    contracture of
      postburn, 1938, 1940*f*
      in scleroderma, 1841
    cross-arm flap coverage of, 1695-1696, 1695*f*
    of foot
      neurosensory flap, from indication, 1658-1661
      sensory flaps from, 1605-1608, 1606*f*, 1608*b*
    scarring of, after pollicization, 1303
  normal, 1217
  pertinent anatomy in, 38
  in syndactyly, 1217, 1218*f*
  thumb/index
    classification of ulnar deficiency based on, 1338*t*
    narrowing of, 1292, 1293*f*
  in triphalangeal thumb, 1320, 1320*f*
Weck-Goulian knife set, 1532, 1532*f*
Wedge graft, for scaphoid nonunion, 612-614
  anterior, technique of, 614, 614*f*
  arguments against, 614
  Fernandez-Fisk, 612-614, 613*f*
Wedge osteotomy
  for clinodactyly, 1272, 1273*f*
  for Kirner deformity, 1274-1275, 1275*f*
  for Madelung deformity
    dorsal closing, of distal radius and ulnar shortening, 1344
    radial opening, 1344
  for malunited radial fracture, 577
Wedge resection arthrodesis, of wrist, in cerebral palsy, 1102
Weilby sling, 363, 363*f*
Weinstein Enhanced Sensory Test, 928
Weiss-Hastings classification, of unicondylar fractures, 250*f*
White phosphorus burns, treatment of, 1951, 1952*t*
Whitlow, herpetic, 52-53, 52*f*
Wire fixation, double intrafocal, of distal radial fracture, 532, 537*f*
Worm (nematode) infection, parasitic, 117-118
Wound(s)
  bacterial content determination of, 1530
  gunshot, to brachial plexus, 1149
  human bite, zone 5 injuries, of extensor tendon, 174-175
  in mangling injuries, excision of, 1496-1499, 1499*b*
    case study for, 1499.*e*1*b*, 1499.*e*2*f*-1499.*e*3*f*
  preparation of, for flap transfer, 1540-1541
  tissue defects of
    examination of, prior to free flap transfer, 1577
    free flap selection influenced by, 1608-1609
  vascularity of, 1530
Wound care, local, for burns, 1931-1932, 1932*f*
Wound closure, negative pressure therapy for, in mangling injuries, 1509, 1510*f*
Wound healing
  infection on, effect of, 1530
  moist, for burns, 1931
Wound necrosis, after elbow contracture release, 859, 860*f*
W-plasty, in constriction ring surgery, 1256-1257
Wraparound flap procedure, in toe transfer, for finger/thumb replacement, 1658
Wrist, 418-478
  amputation through
    with disarticulation, 1737-1738, 1739*f*, 1753-1754, 1754*f*

Wrist *(Continued)*
preferred method of treatment of, 1737-1738
anatomy of, 419-423, 419*t*
ligamentous, 420-423, 421*f*
osseous, 419-420, 420*f*
arthrodesis of, 373-417. *see also* Arthrodesis, of wrist
combined, 1866-1867, 1867*f*
operative technique for, 1865, 1865*f*
partial, 1864-1865
arthroplasty of, 373-417. *see also* Arthroplasty, of wrist
arthroscopy of. *see* Arthroscopy, of wrist
biomechanics of, 423-426, 423*f*, 425*f*-426*f*
in brachial plexus birth palsy, 1419-1421
deformity of, 1328-1364
in psoriatic arthritis, 1836
in systemic lupus erythematosus, 1837-1838
dislocation of, 465-476
definition of, 465
disorders of, 426-476
diagnosis of, 428-432
pathomechanics of, 426-428
flexion-extension of, kinematics in, 423-424
fracture of, in children, 1442-1457
epidemiology of, 1442-1443, 1443*f*
pertinent anatomy in, 1444-1445
preoperative evaluation of, 1443-1444, 1444*f*
types of operations for, 1445-1457
ganglions of
dorsal, 2001-2003
author's preferred method of treatment for, 2001-2003
clinical characteristics of, 2001, 2001*f*
complications in, 2003
operative technique for, 2001-2003, 2001*f*-2003*f*
postoperative care for, 2003
volar, 2004-2005
author's preferred method of treatment for, 2004-2005
clinical characteristics of, 2004, 2004*f*
complications in, 2005
Wrist *(Continued)*
operative technique in, 2004-2005, 2004*f*
postoperative care for, 2005
hemiarthroplasty of, 414-416
mangling injuries of, treatment of, 1512-1515, 1512*f*-1517*f*
musculoskeletal tumors of, excision of, 1996, 1996*f*-2000*f*
physical examination of, 374
proprioception reeducation of, 439
radioulnar inclination of, kinematics in, 423*f*, 424
range of motion of, 373-374
as recipient site, in vascularized bone grafting, 1637
reconstruction of, with scapholunate/scaphoid nonunion advanced collapse, 391-393
alternative methods of fixation for, 393-394
author's preferred method of treatment for, 392-393, 393*f*-394*f*
contraindications for, 392
critical points on, 395*b*
indications for, 391-392, 392*f*
patients on, 394
postoperative management for, 393
spasticity in
examination of, 1084-1085, 1085*f*
extension of, operative management of, 1095-1102, 1097*f*, 1097*t*
preferred method of, 1101-1102, 1102*f*-1103*f*
flexor tendon tightness in, operative management of, 1102-1106, 1104*f*
preferred method of, 1105-1106
stability, definition of, 433
stabilization of, 425, 425*f*-426*f*
supplementary blocks at, 8-9, 9*f*
tendon entrapment, 1920-1923
total replacement of, 404-414, 406*f*
centralization of extensor tendons in, 413-414, 414*f*
patients on, 414
preoperative evaluation for, 407
Wrist joint, infections of, 41-43
postoperative management of, 43, 44*f*
Wrist splinting, for carpal tunnel syndrome, 932

X
Xenograft. *see also* Allograft(s); Autograft(s)
